Combining and integrating cross-institutional data remains a challenge for both researchers and those involved in patient care. Patient-generated data can contribute precious information to healthcare professionals by enabling monitoring under normal life conditions and also helping patients play a more active role in their own care.

This book presents the proceedings of MEDINFO 2019, the 17th World Congress on Medical and Health Informatics, held in Lyon, France, from 25 to 30 August 2019. The theme of this year's conference was 'Health and Wellbeing: E-Networks for All', stressing the increasing importance of networks in healthcare on the one hand, and the patient-centered perspective on the other. Over 1100 manuscripts were submitted to the conference and, after a thorough review process by at least three reviewers and assessment by a scientific program committee member, 285 papers and 296 posters were accepted, together with 47 podium abstracts, 7 demonstrations, 45 panels, 21 workshops and 9 tutorials. All accepted paper and poster contributions are included in these proceedings. The papers are grouped under four thematic tracks: interpreting health and biomedical data, supporting care delivery, enabling precision medicine and public health, and the human element in medical informatics. The posters are divided into the same four groups. The book presents an overview of state-of-the-art informatics projects from multiple regions of the world; it will be of interest to anyone working in the field of medical informatics.

MEDINFO 2019: HEALTH AND WELLBEING E-NETWORKS FOR ALL

Studies in Health Technology and Informatics

International health informatics is driven by developments in biomedical technologies and medical informatics research that are advancing in parallel and form one integrated world of information and communication media and result in massive amounts of health data. These components include genomics and precision medicine, machine learning, translational informatics, intelligent systems for clinicians and patients, mobile health applications, data-driven telecommunication and rehabilitative technology, sensors, intelligent home technology, EHR and patient-controlled data, and Internet of Things.

Studies in Health Technology and Informatics (HTI) series was started in 1990 in collaboration with EU programmes that preceded the Horizon 2020 to promote biomedical and health informatics research. It has developed into a highly visible global platform for the dissemination of original research in this field, containing more than 250 volumes of high-quality works from all over the world.

The international Editorial Board selects publications with relevance and quality for the field. All contributions to the volumes in the series are peer reviewed.

The HTI series is indexed by MEDLINE/PubMed; Web of Science: Conference Proceedings Citation Index – Science (CPCI-S) and Book Citation Index – Science (BKCI-S); Google Scholar; Scopus; EMCare.

The Proceedings of MEDINFO 2019 (the 17th World Congress of Medical and Health Informatics located in Lyon, France) illustrate how informatics scholars from all over the world are pursuing projects related to the theme of *Health and Wellbeing e-Networks for All*. Throughout this publication, readers will find innovative approaches to the collection, organization, analysis, and sharing of data and knowledge related to health and wellbeing. The articles in these proceedings not only document the state-of-the-art in our field worldwide, but also remind readers of how they can build on past discoveries and get motivated to pursue new paths in the future.

Every two years the medical and health informatics community assembles to discuss the latest findings in informatics, to meet old friends, and to make new ones. New generations come together to showcase their research, hear from their peers as well as from those who contribute to their training, and start to pave their way to be our future leaders. Those of us who have been attending these meetings for a long time continue to be amazed by the energy of newcomers, the wisdom and determination of informatics pioneers, the drive of foundational and practice-oriented informaticians, and the incredible amount of work that it takes to organize this conference.

These Proceedings are a small but critical part of what MEDINFO is all about. They feature articles and abstracts describing research, training, and service functions that informaticians all over the world are designing, implementing, and evaluating. They represent the wide range of informatics development in different regions. The way these Proceedings are edited is emblematic of our field: the collaboration needed to produce a top-quality publication, even in the absence of a dedicated staff or a large budget, is only possible because reaching our destination is more important than the few barriers that present themselves along the way. The Proceedings are the output of a large group of volunteers who receive a small token of appreciation and are rewarded by knowing that, because of their contributions, authors disseminate their work beyond regional boundaries and readers within and outside our field can learn and reuse tools, data, and knowledge.

It was our great pleasure and honor to work with Associate Editors Todd Lingren and Scott McGrath to produce these Proceedings. They coordinated a large group of informatics trainees from multiple institutions (Table 1) in order to ensure that the contents were easy to read and formatted uniformly. We thank the whole editorial team as well as the Scientific Program team for making the editing role a fun and enjoyable one. And we thank our readers for understanding the difficulties in editing a large number of accepted papers for clarity, grammar, and style in such a short amount of time.

These Proceedings feature state-of-the-art informatics projects from multiple regions of the world. Enjoy learning how informatics is changing the way we approach health and wellbeing for all.

[b]Peter L. Reichertz Institute for Medical Informatics, TU Braunschweig and Hannover Medical School, Hannover, Germany

The 17th World Congress of Medical and Health Informatics, MedInfo2019, was held in Lyon, France, from August 25th to 30th, 2019. The conference was hosted by the International Medical Informatics Association (IMIA) and the French Association of Medical Informatics (AIM).

MedInfo2019

The overarching theme of MedInfo2019 was *Health and Wellbeing: E-Networks for all*, stressing the increasing importance of networks in healthcare on the one hand, and the patient-centered perspective on the other hand. Combining and integrating cross-institutional data remains a challenge for both patient care and research. Patient-generated data, e.g. originating from mobile apps, sensor-based wearables, and smart home environments, contribute precious information to health care professionals. Not only do these data enable rigorous patient monitoring under normal life conditions, but they also help patients play a more active role in the care process.

The MedInfo2019 Scientific Program Committee (SPC) called for submissions in four thematic tracks:

1. *Interpreting health and biomedical data*,
2. *Supporting care delivery*,
3. *Enabling precision medicine and public health*, and
4. *The human element in medical informatics*.

We received over 1100 submissions from 62 countries across all IMIA regions – the largest number of submissions in the more recent history of MedInfo conferences. With support from four track chairs, 51 track members, and 990 active reviewers, we have conducted a thorough review process. Virtually all submissions were reviewed by at least three reviewers and assessed by one SPC track member. Based on these recommendations, final decisions were made by the SPC track chairs and the SPC co-chairs during a three-day face-to-face meeting in Paris, France. Finally, 285 full papers/student papers, 47 podium abstracts, 296 posters, seven demonstrations, 45 panels, 21 workshops and nine tutorials were accepted. All IMIA regions were well represented in the final program. All accepted paper and poster contributions are included in these proceedings.

MedInfo2019 included five keynotes by internationally recognized experts in medical informatics:

- *Artificial Intelligence in Medicine* by Tze-Yun Leong from Singapore,
- *Capacity Building in Developing Countries* by Binyam Tilahun from Ethiopia,
- *Drawing Reproducible Conclusions from Observational Clinical Data with OHDSI* by George Hripcsak from the United States,
- *From Biological Genotype to Digital Phenotype* by Jacques Demongeot from France, and
- *European Vision of Medical Informatics: The Role of the European Institute of Innovation and Technology* by Jean-Marc Bourez from France.

We thank the SPC track chairs, the SPC track members, and the reviewers for their invaluable contribution to MedInfo2019.

International Medical Informatics Association

IMIA plays a major global role in the application of information science and technology in the fields of healthcare and research in medical, health, and bio-informatics. Established in 1967, it continues to advance and nurture international cooperation in these fields, to stimulate education, research and applications in close collaboration with the World Health Organization (WHO).

Sincerely,

Olivier Bodenreider and Michael Marschollek,

The MeSH-Gram Neural Network Model: Extending Word Embedding Vectors with MeSH Concepts for Semantic Similarity

Saïd Abdeddaïm[a], Sylvestre Vimard[a], Lina F. Soualmia[a,b]

Abstract

Eliciting semantic similarity between concepts remains a challenging task. Recent approaches founded on embedding vectors have gained in popularity as they have risen to efficiently capture semantic relationships. The underlying idea is that two words that have close meaning gather similar contexts. In this study, we propose a new neural network model, named MeSH-gram, which relies on a straightforward approach that extends the skip-gram neural network model by considering MeSH (Medical Subject Headings) descriptors instead of words. Trained on publicly available PubMed/MEDLINE corpus, MeSH-gram is evaluated on reference standards manually annotated for semantic similarity. MeSH-gram is first compared to skip-gram with vectors of size 300 and at several windows' contexts. A deeper comparison is performed with twenty existing models. All the obtained results with Spearman's rank correlations between human scores and computed similarities show that MeSH-gram (i) outperforms the skip-gram model and (ii) is comparable to the best methods that need more computation and external resources.

Keywords:

Medical subject headings, Neural network models, Unified medical language system.

Introduction

Eliciting semantic similarity and relatedness between concepts is a major issue in the biomedical domain. Different measures have been proposed the last decades [1]. Those measures quantify the degree to which two concepts are similar. They rely either on knowledge-based approaches using ontologies and terminologies, or on corpus-based approaches, which are founded on distributional statistics (e.g. literature-based drug discovery) [2-5]. Several clinical applications of importance rely on semantic similarity and relatedness [6], such as biomedical information extraction and retrieval, clinical decision support, or disease prediction. For instance, biomedical information extraction and retrieval are improved by including semantically related terms and concepts [7-10].

The recent approaches that have given better results in semantic similarity and relatedness measures are founded on word embedding vectors computed by neural networks. Indeed, such architectures implemented initially by word2vec [11], have gained in popularity in the biomedical domain as they risen to efficiently capture semantic similarity and relatedness relationships between words and concepts [12-17]. Word embeddings is based on neural network language modeling where words are mapped to fixed-dimension vectors of real numbers. The similarity between words can thus be measured by the (cosine) similarity between vectors that are constructed over a training corpus. All co-occurrences of a word and its neighbors (*i.e.* contexts) within a predefined window size are considered. The idea behind those representation learning approaches is that two words that have close meaning generally have similar contexts [18]. For example, the words *epilepsy* and *convulsion* will both have *brain* and *mind* as neighbors.

The word2vec developed by Mikolov et al. [11] is a neural network language model that learns word vectors that either maximizes the probability of a word given the surrounding context, referred to as the CBOW (Continuous Bag Of Words) approach, or to maximize the probability of the context given a word, referred to as the skip-gram approach.

In this study we propose a new method, named MeSH-gram, which relies on a straightforward approach: it computes the word vectors by only using the MeSH (Medical Subject Headings) descriptors that are already included in the PubMed/MEDLINE corpus. The MeSH-gram model extends the skip-gram neural network model used in word2vec [11] and fastText tools [19]. The fastText is a successful re-implementation of word2vec which is designed to compute the vector of each word using its neighbors. The extension we propose in the MeSH-gram model replaces the neighbors by the MeSH descriptors of the abstract where each word occurs.

Related Works

Several semantic similarity and relatedness measures have been proposed the last decades [17]. Many of them have been implemented in the UMLS::Similarity package [20] available in the UMLS (Unified Medical Language System). They differ on the method used: path-based, content-based, UMLS-based, corpus-based, and more recently, methods based on word vectors and concepts vectors. Path-based measures [7] use the hierarchical structure of a taxonomy to measure similarity: concepts close to each other are more similar. For instance, Sajadi et al. [21, 22] developed a ranking algorithm based on Wikipedia graph metrics and used it to compare biomedical concepts. Content-based information measures [23, 24] quantify the amount of information a concept provides: the more specific concepts have a greater amount of information content. Other approaches [25, 26] use the entire UMLS Metathesaurus® [27] in order to compare the context in the definition of the concept to quantify its relatedness.

Several methods are vector-based: the concepts are represented by vectors, and the relatedness is usually estimated using the cosine similarity between them. In [26], the authors proposed to compute gloss vectors based on second order co–occurrences trained on WordNet. In [28], the authors computed the cosine

of two Latent Semantic Indexing concept vectors based on Pointwise Mutual Information association measure matrix. Recent vector-based methods use neural networks in order to compute concept vectors. The word2vec tool [11] was trained on different corpora: OSHUMED by Sajadi et al. [22]; PubMed/MEDLINE by Chui et al. [13]; PubMed Central by Muneeb et al. [12], Chiu et al. [13], and Pakhomov et al. [14]; and CLINICAL-ALL by [14]. Following the approach used by De Vine et al. [29] on OSHUMED, Yu et al. [15] trained word2vec on PubMed/MEDLINE transformed into UMLS concepts using the MetaMap indexing tool [30].

Other recent methods rely on word vectors. In their previous work, Yu et al. [31] retrofitted word vectors obtained by word2vec with hierarchical information from the MeSH thesaurus. Recently, Henry et al. [16] compared different ways to combine word vectors in order to compute multi-word term vectors. The compared multi-word term aggregation method consists in the summation (averaging) of component word vectors, creating concept vectors using the MetaMap indexing tool [30], and creating multi-word term vectors using the compoundify tool based on the UMLS Specialist Lexicon as glossary [27]. More recently, Henry et al. [17] used association measures for estimating semantic similarity and relatedness between biomedical concepts on PubMed/MEDLINE transformed into UMLS concepts. The best performance results were obtained by [15-17]. Their respective approach relies either on MetaMap in order to transform the text corpus into UMLS concepts, or on additional external resources such as the Specialist Lexicon.

The MeSH-gram model we propose in this study relies on a straightforward approach: it computes the word vectors by only using the MeSH descriptors that are already included in the PubMed/MEDLINE corpus. The extension we propose in the MeSH-gram model replaces the neighbors by the MeSH descriptors of the abstract where each word occurs.

In order to evaluate MeSH-gram, we use publicly available manually annotated corpora: two subsets from Mayo Clinic (MiniMayoSRS) of the MayoSRS (Mayo Semantic Relatedness Set) developed by Pakhomov et al. [32], and two from UMNSRS (The University of Minnesota Semantic Relatedness Set) developed by Pakhomov et al. [33]. MeSH-gram results are first compared to skip-gram and are then compared to twenty existing solutions reported in [17], including the best ones [15-17]. The MeSH-gram model has several advantages: (i) it avoids considering uninformative and too frequent words; (ii) there are less MeSH descriptors than possible context words; and (iii) MeSH descriptors are manually assigned and curated, which assures the best quality of indexing.

Methods

Neural network language models learn word vectors by either maximizing the probability of a word given the context, referred to as the CBOW approach, or by maximizing the probability of the context given a word, referred to as the skip-gram approach.

Skip-gram Word Embedding Model

Given $w_1\ w_2\ ...\ w_n$ a text line of words w_i, the skip-gram model maximizes the following average log probability:

$$\frac{1}{2r}\sum_{i=1}^{2r}\sum_{-r\le j\le r,\, j\neq 0} log\, p\left(w_{t+j}\middle|w_t\right)$$

where w_t is the target word, w_{t+j} is the context, and r is the context window radius. The context words surrounding the target term are determined by the context window radius r.

The probability of a context word w_c given a target word w_t, is computed by:

$$p\left(w_c\middle|w_t\right)=\frac{exp\left(V_{w_c}^T V_{w_t}\right)}{\sum_{w=1}^{N} exp\left(V_w^T V_{w_t}\right)}$$

where N is the vocabulary size, and V_w represents the vector of the word w.

MeSH-gram word embedding model

The MeSH-gram word-embedding model proposed in this paper extends the skip-gram neural network model used in word2vec [11] and fastText [19] tools: it uses MeSH descriptors that are already included in the PubMed/MEDLINE corpus to compute the word vectors.

Given $w_1\ w_2\ ...\ w_n$ the words of a PubMed/MEDLINE abstract, and $m_1\ m_2\ ...\ m_k$ the MeSH descriptors associated to this abstract, the MeSH-gram model maximizes the following average log probability:

$$\frac{1}{k}\sum_{i=1}^{k} log\, p\left(m_i\middle|w_t\right)$$

where w_t is the target word and m_i is a MeSH descriptor.

The probability of a context MeSH descriptor m_c given a target word w_t, is computed by:

$$p\left(m_c\middle|w_t\right)=\frac{exp\left(V_{m_c}^T V_{w_t}\right)}{\sum_{m=1}^{M} exp\left(V_m^T V_{w_t}\right)}$$

where M is the number of MeSH descriptors, V_m represents the vector of the MeSH descriptor m, and V_w the vector of the word w.

We have adapted fastText [19] in order to feed the neural network with pairs of (word, MeSH descriptor). For each abstract included in PubMed/MEDLINE, every word occurrence in the abstract text is associated to each MeSH descriptor, which means that each word vector reflects all the MeSH descriptors seen by its word occurrences in all the PubMed/MEDLINE abstracts.

Vector Representation and Similarity Computation

Using our MeSH-gram model and skip-gram model for comparison, we built word vectors of dimension 300. For the skip-gram model, we computed the vectors considering several window sizes W of 2, 5, 10 and 25.

In order to quantify the relatedness of a pair of words, the cosine distance between the distributional context vectors of each word is used. In the case of a multi-word term, the vector is generated by computing the average of the component word vectors that compose the term. As an example, for the term *epilepsy attack*, the vector $V_{epilepsy\_attack}$ will be computed as $V_{epilepsy\_attack}=(V_{epilepsy}+V_{attack})/2$ where $V_{epilepsy}$ and V_{attack} represent the vector of each word *epilepsy* and *attack* respectively. Rather than combining word vectors after construction, multi-word term vectors may be constructed directly from a preprocessed training corpus in which multi-word terms have been identified [17]. Otherwise, this will involve huge cost in preprocessing and storage requirements.

Training Corpus

We used the PubMed/MEDLINE[1] corpus that contains the abstracts of each article and the associated MeSH descriptors. The corpus was parsed with *pubmed_parser*[2], a python XML parser for PubMed dataset. Each abstract was tokenized using *polyglot*[3].

As fastText needs all the data integrated into one file, we have concatenated all the tokenized PubMed/MEDLINE abstracts. Each line of the resulting file consists of an abstract with its MeSH descriptors. We have adapted fastText in order to feed the neural network with all pairs of (word, MeSH descriptor) of each file line.

Gold Standard

In order to compare the MeSH-gram word embedding model proposed in this study with other methods, we used two evaluation benchmarks: MiniMayoSRS [32] and UMNSRS [33]. MiniMayoSRS consists of 29 clinical term pairs. Two thirty pairs (66.67%) contain a multi-word term. The relatedness of each word pair is rated by medical coders and also by physicians. UMNSRS consists of 566 and 586 pairs of medical terms, for measuring similarity and relatedness respectively. The degree of association between terms in each dataset was rated by four medical residents from the University of Minnesota medical school. As suggested by Pakhomov et al. [33], we use a subset of the ratings consisting of 401 pairs for the similarity set and 430 pairs for the relatedness set. Twenty (4.99%) and seventeen (3.95%) of the term pairs contain multi-word terms for the similarity and relatedness subsets respectively. All these clinical terms correspond to UMLS concepts included in the Metathesaurus®.

The correlations between the generated relatedness scores and the human-assigned scores are calculated using Spearman's rank.

Results

Skip-gram Model versus MeSH-gram Model

The results of the experiments are in Table 1 in which a comparison is performed between the results obtained with skip-gram model and those obtained by the MeSH-gram model using our modified version of fastText according to the four gold standards: MiniMayoSRS rated by physicians (MiniMayoSRS phys.), MiniMayoSRS rated by medical coders (MiniMayoSRS cod.), UMNSRS for similarity (UMNSRS Sim.) and UMNSRS for relatedness (UMNSRS Rel.). The number of calculated term pairs (*n*) is lower than the number of pairs in the UMNSRS gold standards (*Sim.* and *Rel.*) because the embedding vectors could not be computed for low frequency terms and contexts on PubMed/MEDLINE using fastText. Using descriptors rather than words as context allows to computed more term pairs.

MeSH-gram Model compared to Previous Works

Table 2 gathers the results obtained by the MeSH-gram model we developed and twenty previous works' results. It allows a comparison between all the models and on the same gold standards (MiniMayoSRS and UMNSRS). Table 2 complete the Table 12 given by Henry et al. [17].

Table 1 – Spearman's rank correlations between human scores and computed similarities

	MiniMayo		UMNSRS	
	Phys. n=29	**Cod. n=29**	**Sim. n=380**	**Rel. n=397**
Skip-gram				
W=2	0.740	0.757	0.679	0.529
W=5	0.763	0.779	0.704	0.576
W=10	0.776	0.789	0.716	0.589
W=25	0.766	0.781	0.718	0.608
MeSH-gram	**0.811**	**0.855**	**0.724*** *n=387	**0.643**** **n=407

Note: W: window size; n: number of pairs

Discussion

As one can see in Table 1 for the skip-gram model, the more the window is extended, the more the results are improved on the UMNSRS gold standard. The best results of skip-gram are obtained with a window size *W*=10 for the MiniMayoSRS set. This suggests that word vectors are a better solution when we consider an important number of context words in the abstract. The best results are obtained with the MeSH-gram model that considers MeSH descriptors as context for each term, suggesting that MeSH descriptors catch the semantics of all the abstracts associated with it. We can conclude that taking MeSH descriptors instead of context words gives better results than considering a large window size: (i) bigger window size does not lead necessary to better results and (ii) MeSH descriptors are fewer than context words (50 context words for window size *W*=25) leading also a reduced computation time.

For example, the pair *synthroid* and *hypothyroidism* is misclassified by the skip-gram model but better treated by the MeSH-gram model. They are considered as very related in UMNSRS as *Synthroid*® (*levothyroxime sodium*) is used to treat *hypothyroidism*. This term pair has a human-assigned score of 1473, which corresponds to the seventh most related mono-term pair in UMNRRS. While the skip-gram model (with *W*=2) ranks this pair at the 160th position with a similarity score of 0.40, the MeSH-gram model puts it at the 64th position with a similarity score of 0.58, which means that the MeSH-gram model better captures the relatedness for this example. The apparent reason for this could be that *synthroid* occurs only 107 times in PubMed/MEDLINE corpus, which is insufficient to construct reliable vectors using context words in the skip-gram model, while the MeSH-gram model computes its vectors using the more informative MeSH descriptors. The absolute difference between the skip-gram rank (160) and the MeSH-gram rank (64) is 96 for this term pair, however it is lower in average (36.5 with a standard deviation of 33.5) when we consider the scores obtained by the two methods for all the UMNSRS pairs.

On the contrary, the pair of the terms *weakness* and *emaciation* (low frequency term equals to 1433) are better scored by the skip-gram model (84th position) than the MeSH-gram model (165th position), while they are considered closely related by human scores (64th position).

From our observations, the better results obtained by the MeSH-gram model are not due to significant improvements for any specific category of term pairs (e.g. less frequent terms), but to the overall improvement (moderate increase or decrease)

[1] ftp://ftp.ncbi.nlm.nih.gov/pubmed/ [accessed Apr 1st, 2019]
[2] https://github.com/titipata/pubmed_parser [accessed Apr 1st, 2019]
[3] https://github.com/aboSamoor/polyglot [accessed Apr 1st, 2019]

of the similarity scores for each pair. We can only conclude from this that MeSH descriptors are globally more informative than context words.

The comparison with twenty methods displayed in Table 2 confirms that the MeSH-gram model gives comparable results with best previous work methods on the four gold standard datasets. While the methods (1) and (2) rely on the translation of PubMed/MEDLINE text data into ULMS concepts, and methods (4) and (5) require additional steps or resources such as compoundify tool (4) and MetaMapped MEDLINE corpus (5), the MeSH-gram model uses only the raw text corpus as input. The best previous works' results are obtained by the method (2) and then the method (3). However, the method (2) is not recommended by the authors themselves as it uses concept expansion, which requires additional computation cost without significantly increasing the performances for any dataset [17]. MeSH-gram is comparable to method (3) with better results on three datasets. All those results allow us to conclude that UMLS information used by the methods (1) to (5) is already contained in the MeSH descriptors available in the PubMed/MEDLINE corpus and used by the MeSH-gram model. Using MeSH descriptors as context is a good solution for datasets founded on UMLS concepts. However, MeSH-gram should be evaluated on other types of similarities such as BioSimVerb and BioSimLex [34].

Note: n: number of pairs (inspired by [17]). The best result is highlighted in bold, the second best in italic and bold.

Conclusions

In this paper, we proposed a new method, MeSH-gram, to create distributional word vectors using MeSH descriptors as word context. We evaluated our results on four standard evaluation datasets, MiniMayoSRS Physicians, MiniMayoSRS Coders, UMNSRS tagged for relatedness, and UMNSRS tagged for similarity, and compared it against skip-gram model as a baseline and previous methods. All the obtained results of Spearman's rank correlations between human scores and computed similarities show that MeSH-gram (i) outperforms the skip-gram model and (ii) is comparable to the best recent methods, methods that need more computation and additional external resources.

We are trying different ways to combine the skip-gram model and the MeSH-gram model in order to improve the results. We also plan in our future works to include in MeSH-gram the MeSH qualifiers affiliated to the descriptors in order to have a more precise semantic meaning (e.g. the association *cancer/complications*, where *cancer* is a MeSH descriptor and *complications* is a MeSH qualifier, is more precise than *cancer* alone). A second step is to use fastText subwords and the evaluation of MeSH-gram for other kinds of similarities such as BioSimVerb and BioSimLex. MeSH-gram may also be used in other languages than English, for instance in French bibliographic corpora such as CISMeF [35], as well as in annotated electronic health records.

Abstract

Kidney transplantation is recommended for patients with End-Stage Renal Disease (ESRD). However, complications, such as graft rejection are hard to predict due to donor and recipient variability. This study discusses the role of machine learning (ML) in predicting graft rejection following kidney transplantation, by reviewing the available related literature. PubMed, DBLP, and Scopus databases were searched to identify studies that utilized ML methods, in predicting outcome following kidney transplants. Fourteen studies were included. This study reviewed the deployment of ML in 109,317 kidney transplant patients from 14 studies. We extracted five different ML algorithms from reviewed studies. Decision Tree (DT) algorithms revealed slightly higher performance with overall mean Area Under the Curve (AUC) for DT (79.5% ± 0.06) was higher than Artificial Neural Network (ANN) (78.2% ± 0.08). For predicting graft rejection, ANN and DT were at the top among ML models that had higher accuracy and AUC.

Keywords:

Kidney Transplantation; Graft Rejection; Machine Learning

Introduction

Kidney transplantation provides high-quality life years to patients with ESRD. Outcomes following kidney transplantation are evaluated by renal function and graft rejection. Recipients' clinical status and outcomes after the transplant are influenced by recipients' ages, Human Leukocyte Antigen (HLA) matching, HLA immunization, ethnic background, time on dialysis, and cardiovascular comorbidities [10; 19].

Graft rejection is the most common problem for kidney transplant recipients. Antibody-mediated rejection requires a distinct therapy as compared to the therapy for usual T-cell-mediated acute rejection. Renal function, based on estimated Glomerular Filtration Rate (GFR) and/or proteinuria values, is a result of these factors. Renal function impairment, whether in a stable condition or as a progressing dysfunction, also has an impact. Confirmation of graft rejection needs renal biopsy, which in turn requires expenditure and time. Antibiotics and immunosuppressive drugs could decrease acute graft rejection incidence, but chronic graft rejection is still a major problem [7; 28]. Specific and nonspecific (diabetes, nephrotoxicity, infection and cancer) conditions could have significant negative long-term consequences [23].

Due to the increased availability clinical data and rapid development of computing technology, artificial inteligence (AI) has been successfully applied in the healthcare domain. AI uses advanced learning algorithms to analyze large volumes of healthcare data that facilitates decision making in clinical practice. Various forms of clinical data (such as, diagnosis, screening, and treatment assignment) can be used as training data before AI systems can be applied in daily healthcare settings. By doing so, the system can learn and apply AI to similar groups of subjects, associations between subject features, and outcomes of interest. Training data is not only limited to clinical data, but it also includes demographics, medical notes, electronic recordings from medical devices, physical examinations, and clinical laboratory and images [15].

Machine learning (ML) techniques are used for specific purposes. Each unique feature of ML can be used for a different function, therefore different results may be obtained with different ML models. In the literature review, we did not come across any meta-analysis study specifically evaluating the use of ML algorithms for predicting kidney transplant outcomes [17]. The objectives of this study are: (1) to review the role of ML in predicting graft rejection following kidney transplantation, and (2) to specifically identify ML algorithms that have a higher accuracy and performance for predicting graft rejection following kidney transplantation, reported in the literature.

Methods

This review paper followed the flowchart and checklist provided by Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement [24].

Search Strategy and Data Sources

In order to get accurate results from the vast biomedical and health research databases—PubMed and Scopus, we used combined search keywords, such as "kidney transplants AND machine learning", "kidney transplants AND data mining", and "kidney transplants AND artificial intelligence". For covering the domain of computer science, we also used DBLP, which is a database for scientific journals in the field of computer science that are not yet indexed by PubMed, although the proposed published methods are applied on biomedical datasets [16]. In DBLP, we used the keyword "kidney transplants" to get all the related studies with this specific search criterion. We included all studies found in the

literature until July 9, 2018, and checked for duplicate findings.

Eligibility Criteria

The articles were included based on the following criteria:

1. Written in English.
2. Using ML techniques to predict graft rejection in patients who had undergone kidney transplantations.
3. Building model extracted on medical record (eg. renal registry).

Articles were excluded based on the following criteria:

1. Used features other than clinical features extracted from medical record (eg. –omics features, radiological imaging).
2. Using ML techniques other than graft rejection prediction purpose.
3. Did not mention the result of ML performance.

Data Extraction and Synthesis

The selected studies were summarized based on the author name, year of publication, number of patients, dataset details, types of input variables, used ML techniques, and also validation method. The aim of the summarizing process was to get a detailed description of each ML model generated by the studies. Performance of the ML models was also recorded by mentioning each performance metric (accuracy and AUC). Comparison of each ML techniques was analyzed based on a previous study done by Malhotra [22]. Performance was visualized for each ML techniques and performance metrics.

Results

By applying inclusion and exclusion criteria mentioned above, 14 articles were identified for detailed study analysis (Figure 1).

Datasets and Patients

From 14 selected studies, most studies used publicly available datasets, such as United States Renal Data System (USRDS), United Network for Organ Sharing (UNOS) and the Eurotransplant database. While other studies used self collected data from cohorts hosted by their organizations. Table 2 describes the datasets and number of patients used in each study. Number of patients used in studies ranged from 80 to 57,389. A total of 109,317 patients were described in this study.

USRDS is a national data system that collects, analyzes, and distributes information about ESRD and CKD in United States population [4]. It collects data on patient demographic characteristics, contact information, treatment, laboratory values, quality-of-life survey interviews and nutrition survey interviews for dialysis patients, and also facilitates data sharing by filling request form provided in their web page [9]. UNOS is a private, non-profit organization based in US focused on organ transplant procurement by maintaining contact with volunteers. UNOS also maintains Organ Procurement and Transplantation Network which contains pre-transplant data pertains to transplant candidates [3].

ANZDATA is a registry that holds records of the incidence, prevalence and outcome of dialysis and transplant treatment for patients with end stage renal failure in Australia and New Zealand population [1]. Like UNOS, Eurotransplant is also a non-profit organization that facilitates procurement organ transplant across Europe, especially post-mortem donor organs. It collects various data both from the donors' side and the recipients' side along with the outcomes of procedures [2]. The other included studies collected longitudinal data of kidney transplantation from local organization (e.g. teaching hospital) in order to conduct their research.

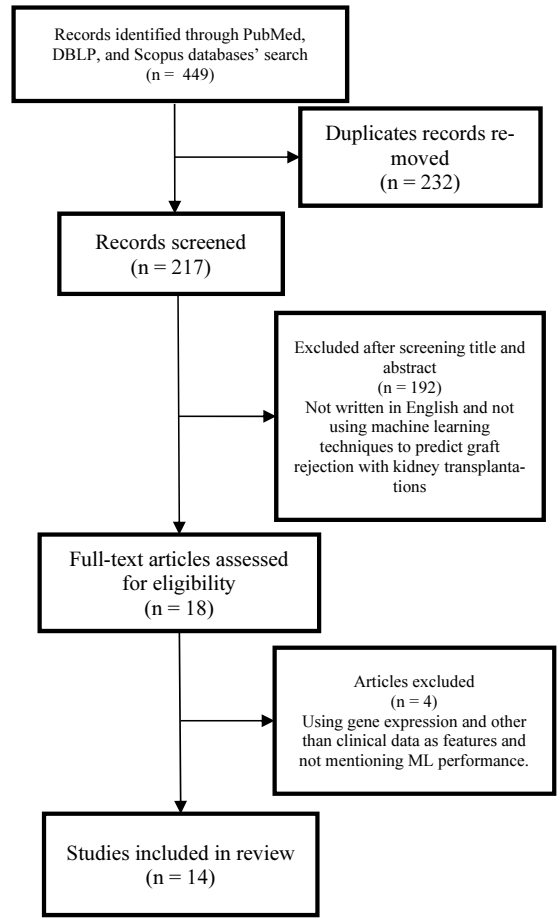

Figure 1. PRISMA Flow Diagram for Study Selection Process

ML Techniques and Overall Performance

Overall, 5 ML techniques that were used in the 14 included studies are: Artificial Neural Network (ANN), Support Vector Machine (SVM), Bayesian Belief Network (BBN), Decision Tree (DT) and an ensemble learning method called Random Forests. ANN was the topmost technique used in 7 studies. The second most commonly used technique was DT algorithm that appeared with different type such as C.50, Classification & Regression Tree (CART/C&RTree) and Random Forests.

Figure 2 describes the ML performances in the form of box plots. From the box plots, it is clear that DT and ANN mostly outperform all other techniques that had been used in studies. Tang et al [31] showed that ANN could perform better than statistical learning methods, such as Logistic Regression (LR). While Shaikhina et al. [27] showed that DT still can be the technique of choice even after being applied in ensemble methods, such as Random Forest. Study done by Esteban et al. [8] showed high performance by utilizing Recurrent Neural

Network (RNN). The model combined non-linear and linear features (medication perscriptions and laboratory results), along with with static features (gender, age, weight) showing 82% of AUC performance.

Discussion

This paper reviewed the role of applying AI techniques (ML methods) in predicting graft rejection following kidney transplantation, and described the algorithms used by critically reviewing their performances. It is important to be clear about the specific outcomes to be studied, before deploying ML methods.

Based on our results, ANN and DT were the most commonly used models. These techniques showed better performance than SVM, Random Forest and BBN. As DT has the robustness to noise, low computational cost, and ability to deal with redundant features; it has advantages over other learning algorithms. DT could be inducted in various ways, such as C5.0 and CART, but none have been shown to be superior to other methods [5].

ANN is an mathematical algorithm that represents the human neural architecture and resembling the function like learning and generalizing ability. Nowadays, these techniques are widely applied in various research fields because they can show good performance in finding relationship among unknown or complex variables, such as non-linear variables. ANN can be applied in various ways, the most used techniques are Multi-layer Perceptron (MLP), with 3 important layers: input layer, hidden layer, and output layer. This technique is described as being fully connected to every node in the next and previous layer. MLP are trained by selecting suitable connecting weights and transfer functions between the input and output vectors [11]. In this group, prediction model using RNN algorithm developed by Esteban et al. [8] are the most powerful in classification power. RNN are kind of neural networks that usually applied in sequential data such as voice recognition and natural language processing (NLP). The algorithm elaborate both dynamic and static data from medical record that are relevant to predict future outcomes [12].

While doing the literature search, we also found some other systematic reviews related to AI techniques and transplantation. Sousa et al. [30] has reviewed AI techniques used for analysing organ transplant databases from 2009 to 2010 from PubMed and Web of Knowledge. They inferred that the main techniques used were: ANN, LR, DT, Markov Models (MM), and Bayesian Networks (BN). ANN was most preferred for knowledge extraction. Singh et al. [29] provided a systematic review of clinical prediction models of patient and graft survival in kidney transplant recipient using Medline and EMBASE databases covering the time period from 1966 to 2013. They showed the model discrimination with 'C' statistics for patient survival models and graft survival models and reported calibration and external validation of the methods. They also deduced modest discriminatory ability in most clinical prediction models, variability in other measures of model performance, and inconsistency for external validation of models. While Sousa [30] focused on AI techniques that were applied to extract knowledge from transplantation databases, Singh [29] reviewed articles that developed clinical prediction models of patient and graft survival in kidney transplant recipients. In comparison to these articles, our review article specifically studied the role of AI techniques (ML methods) utilized in predicting outcomes following kidney transplantation, and also evaluated the performances of the algorithms used.

More studies are desirable to compare different models. Hybrid models could be used for prediction enhancements. Ensemble and deep learning methods could also be considered in the future.

Conclusions

Based on the PRISMA guidelines, this study evaluated the role of AI techniques (ML algorithms) in predicting treatment outcome following kidney transplantation by examining the available literature. From the literature and our results it was clear that there is no 'One size fits all' approach for applying ML methods. Selection of the right algorithm, provided input variables and volume, and accuracy of the training datasets are critical. Based on performance measured by sensitivity, specificity, accuracy, and AUC, we concluded that ANN and DT were the most suitable and prevalent methods to predict graft rejection following transplantation procedure. A new model built with features taken from both donors' and recipients' side is desirable. Comparison of various models, especially Ensemble method and Deep Learning is required for the future work.

[c] Birmingham VAMC; [d] University of Alabama at Birmingham, Birmingham, AL

Abstract

Hospital systems frequently implement quality measures to quantify healthcare processes and patient outcomes. One such measure that has previously been used is the Surgical Care Improvement Project (SCIP) quality measure of perioperative beta blocker continuation, SCIP-Card-2. The SCIP-Card-2 measure requires resource-intensive medical chart abstraction, limiting its application to a small sample of eligible patients. This paper describes a natural language processing (NLP) system for automatic extraction of SCIP-Card-2 quality measures in clinical text notes.

Keywords:

Natural language processing; Quality Indicators; Health Resources

Introduction

Quality measures are tools that healthcare systems frequently implement to assess the effectiveness, safety, efficiency, and timely care of various medical procedures and processes [1]. This study focuses on the Surgical Care Improvement Project's (SCIP) quality measure to assess perioperative beta blocker continuation, SCIP-card-2. Studies have shown that mortality in patients who discontinued taking beta blockers pre- or post-surgery is significantly greater than mortality in patients who continued taking beta blockers [2]. Recording the SCIP-card-2 measure allowed health care organizations to take appropriate steps to ensure that patients receive proper care [3].

While the SCIP-card-2 measure was retired as of 2015, this measure provides an important use case for measures that are complicated to assess and require more than just structured data. The SCIP-card-2 measure included patients with current outpatient beta blocker therapy undergoing non-laparoscopic surgery. The quality measure evaluated two periods: (1) the perioperative period, defined as the day prior to surgery through discharge from the post-anesthesia care unit and (2) the postoperative period, consisting of the first two postoperative inpatient days. If patients received beta blockers during both periods, the surgical care was considered to adhere to the guideline. The SCIP-card-2 measure indicated guideline adherence failure if the patient received no beta blockers and no reason for intentional non-adherence was documented. Patients were excluded if no beta blockers were received but the rationale was documented.

Assessing this quality measure has been done using resource-intensive manual chart abstraction to identify and classify the prescription status of beta blockers [4]. Manual chart abstraction required numerous person hours, which limits any study population to a relatively small set of patients. By automatically classifying the prescription status of beta blockers, this study aims to show the potential benefits of using natural language processing (NLP) when assessing adherence to quality measures.

Numerous studies have focused on the automatic extraction of medication mentions and medication features from text. Xu et al developed the NLP system MedEx to extract a drug name, strength, route, and frequency with F-measures above 90% for each concept [5]. The 2009 i2b2 NLP challenge resulted in the successful creation of several NLP systems that also focused on the identification of medication information including: dosage, frequency, treatment duration, mode of administration, and the reason for administration [6]. Much work has been put into automatically extracting drug information, while less work has been done to extract the prescription status of a medication. However, it has been shown to be feasible. Pakhomov et al. used NLP to identify outpatient aspirin usage and contraindications to aspirin; using a sample of 499 diabetic patients, their system successfully identified patients taking aspirin and those not taking aspirin with a sensitivity of 99% and a specificity of 91% [7]. Sohn et al contributed further by testing both machine learning methods and rule-based methods to extract prescription status, finding that rule-based methods could be improved by better discerning the difference between automatically generated medication lists and narrative text sections [8]. Meystre et al identified Angiotensin Converting Enzyme Inhibitors, and successfully classified the medications as being active, discontinued, or negated with an overall accuracy of 95.49%, finding minimal improvements using machine learning methods over rule-based methods for this specific task [9].

The identification and classification of beta blocker administration, specifically using data from the Department of Veterans Affairs (VA) electronic health record (EHR), has not been previously explored. The subsequent sections describe the methods used within the scope of a larger study to create a comprehensive dictionary of terms reflecting beta blocker medications, a custom sectionizer to discern automatically generated medication lists from narrative text, and a rule-based NLP algorithm; all used together to detect and classify mentions of beta blockers in clinical text.

Methods

Cohort definition

All work for this study was completed using VA Informatics and Computing Infrastructure (VINCI) resources. Using structured administrative data from the VA Corporate Data Warehouse (CDW), 8679 patients met the criteria for this study as having current outpatient prescriptions for beta blockers and having undergone non-laparoscopic surgery within the study time period. Additionally, this sample of patients was further limited to those who did not have pharmacy data indicating beta blocker administration at all periods to meet measure requirements, providing a set of potentially ambiguous cases requiring manual review or NLP. All documents for the day prior to an operation and two days post-operation were used to create a corpus of 400,534 documents. This set of documents was randomly partitioned into a 75% training and 25% testing set.

Dictionary definition

An initial dictionary of medication terms was created by identifying all known beta blockers, their synonyms, and varied trade names in RxNorm, a thesaurus, nomenclature, and coding system for clinical drugs [10]. The dictionary was further expanded with additional terms and abbreviations using an iterative manual bootstrapping process on documents in the training set [11]. Finally, clinical experts with knowledge relevant to the surgical subdomain reviewed and contributed to the initial dictionary, which contained 59 seed terms. (Appendix A)

Due to the frequency of misspellings and variation of terms that exist in clinical documentation, using a simple dictionary of keywords to capture instances of a medication did not provide an acceptable level of term coverage. Previous studies have shown the effectiveness of using edit distance algorithms in a clinical setting to improve the term coverage of custom dictionaries [9]. The Levenshtein edit distance is a well-established fuzzy matching algorithm that was shown to be an effective method for identifying medication terms. Additional work has shown that combining another popular method, the Jaro-Winkler distance metric, could further enhance the accuracy of a fuzzy matching algorithm [12]. Edit distance algorithms, however, can be extremely computationally expensive as each term must be compared to every other string in the dictionary along with the millions of possible strings that exist in a dataset. In an effort to create a high-throughput system that could be applied to future, increasingly larger corpora, a comprehensive dictionary was created. Having a comprehensive dictionary eliminates the need to include edit distance algorithms as part of the NLP pipeline. Using the VA CDW full text index, each individual token ever used in the VA EHR was ranked with a total count of the number of times each token has been used. Terms found in the indexed table were then mapped to terms found in our initial dictionary of beta blocker terms. After manual review of the candidate dictionary of terms, a threshold was then chosen for the indexed tokens that matched beta blocker terms with a Levenshtein edit distance of <=2 and a Jaro-Winkler edit distance of >90%. Any term that fell within this threshold was considered a candidate match and then manually reviewed for validity.

By applying the edit distance algorithms to the full text index, rather than to each individual document in our set, we created a comprehensive dictionary that could be used to identify mentions of beta blockers in VA clinical documents using simple string match, which is a significantly faster processing algorithm than applying more complex document processing for beta blocker term identification. Using both distance metrics and the additional manual review, our expanded dictionary was evaluated on the training documents and exhibited an initial precision and recall of 100%. Thus, this comprehensive dictionary was determined to be fully sufficient to find every possible mention of any beta blocker medication term in the complete VA EHR.

Annotation

To create a set of prescription status examples, all documents in the training set were manually annotated using terms from the expanded dictionary. The training set contained 2345 instances, which were annotated at the sentence level using the VINCI developed annotation tool Chex [13]. Chex is a browser-based application that allows rapid annotation at a mention level with a user-defined context window that can be expanded as needed.

The context for the mapped terms was then classified as being one of the following types:

1. Active Medication: Any medication found in a narrative format, and described as being actively taken, or given on the day of the note.
2. Medication List: Any instance of a medication term found within an automatically generated medication list.
3. Negated Medication: A medication found in the narrative section of a document that was not given, e.g. “Metoprolol not given”.
4. Discontinued Medication: A medication that was prescribed to a patient but discontinued on the day of the note.
5. Other beta blocker mention: Any mention of a medication without an explicit mention of the prescription status, which appears in medication warnings or discussion of the medication or other similar contexts, e.g. “Metoprolol is frequently associated with…”

The annotators were also given an option for irrelevant terms being mapped as a beta blocker, however, no instances of an incorrect or irrelevant term was found, which confirms the accuracy of the utilized dictionary. Table 1 displays the frequency of each classification type that was found in the training set.

Table 1 Training set Classification Labels

Classification Label	Frequency
Active Medication	1018
Medication List	990
Negated Medication	57
Discontinued Medication	104
Other Beta Blocker Mention	176
Irrelevant Term	0

Rule-based medication and phrase detection

Previous studies have shown that automatically generated medication lists do not provide an accurate representation of a patient’s current prescription status [14,15]. However, these lists are frequently included as a semi-structured text element inside a document. To get an accurate representation of th

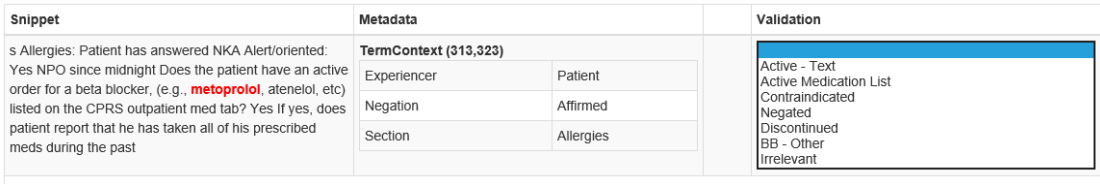

Figure 1. An example of the annotation interface using Chex that shows an instance of an "Active" beta blocker usage classification, it's span location within the document, and the options presented to an annotator.

prescription status on the day a note is recorded, the first step of the system distinguished these semi-structured lists from free text mentions found in narrative form. Medication mentions found in an automated list were detected using two methods. First, a custom sectionizer was created to locate the most frequently occurring section headers, many of which were specific to VA documents, e.g. "Veteran's Active Medication:".

After distinguishing medications in narrative format from those in medication lists, the NLP system focused on classifying those instances found in the narrative. To account for the diversity of terms, writing styles, document structures, and typographic errors that exist across individual clinicians, hospitals, and regions, our system relied on several sets of dictionaries used by separate modules throughout the NLP pipeline. These dictionaries contain numerous regular expressions compiled with manual knowledge engineering while also building upon the existing NLP systems and resources. Specifically, we utilized ConText [16], RxNorm [10], and MedEx [5]. The four concept dictionaries are:

- **Medication Term:** This dictionary consists of all known beta blocker terms as described in the dictionary definition section of this paper.
- **Modifier Terms:** These include terms that would commonly be associated with the noun phrase of a medication term such as: "*Oral* metoprolol", "*p.o* metoprolol" and "*home* atenolol". This list was created manually using examples found in the training set of documents and expanded using modified MedEx dictionaries.
- **Administration Terms:** This dictionary contains terms meant to describe the administration, discontinuation or negation of a medication such as: "Discontinued", "D/C", "held", "withheld", "stopped", "started", "began", etc. All terms in this dictionary were added using examples from the training corpus, their synonyms, and other known abbreviations and terms based on subject matter expert knowledge.
- **Context Terms:** This dictionary consists of terms found in the ConText algorithm to determine if a medication term is negated, hypothetical, historical, or experienced by someone other than the patient. The ConText dictionaries were also expanded using examples from our training set as well as other commonly occurring phrases specific to documentation in a VA healthcare setting.

After the terms from each dictionary were identified in a document, the system incorporated two pattern annotator modules [17]. The first pattern set combined instances of a beta blocker medication term and the modifying terms to create a medication phrase, e.g. "home metoprolol", "25mg oral atenolol". A second pattern set combined the medication phrases with administration terms to create a final administration phrase. Administration phrases were then normalized and labeled as being: Active, Active Medication List, Discontinued, Negated, or Other. One additional dictionary was included in the NLP system that captured terms describing the rationale for a discontinued medication e.g. "d/c atenolol due to" or "because of", however, there were very few instances of these patterns found in the training set. Due to the infrequency of examples, this dictionary was not included in the final validation. Figure 2 shows the basic structure used for combining all terms identified by different dictionaries into separate medication and administration patterns.

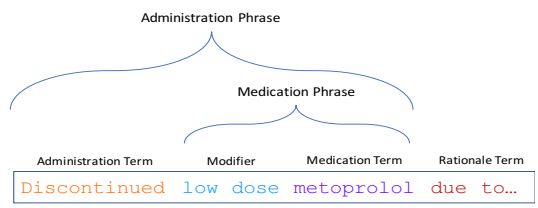

Figure 2. An example dictionary and pattern annotator structure for a discontinued administration phrase.

The rule-based NLP system to extract and classify the prescription status was implemented using Leo, a VINCI-developed set of services and libraries that aid in the development of NLP pipelines based on the Apache Unstructured Information Management Architecture Asynchronous Scaleout (UIMA AS) [18,19]. This system used simple regular expressions connecting the different concept dictionaries together into the relevant classification labels without the use of tokenizing, stemming, or additional parsing.

Results

System validation was performed using 200 random documents from the testing set that contained 274 mentions of beta blocker medication. The documents were processed by the final system and classification accuracy was evaluated.

Table 2. Confusion matrix of validation results

Actual labels Predicted labels	Active	Discontinued	Negated	Medication List	Other	Total predicted
Active	65	1	0	0	1	67
Discontinued	4	46	0	0	0	50
Negated	0	2	22	0	0	24
Medication List	13	0	0	59	4	76
No Status Found	33	1	3	10	10	57
Total actual	115	50	25	69	15	274

Table 3 Validation Results

	Precision	Recall	F-Measure
Active	0.970	0.565	0.714
Discontinued	0.920	0.920	0.920
Negated	0.917	0.880	0.897
Medication List	0.776	0.855	0.813

Error analysis revealed that a primary cause for error was due to patterns and terms present in the testing set that were previously unseen in the training set of documents, this is a known drawback when using rule-based NLP systems and is once again magnified in this work[20]. The "active" recall score was especially affected in this work as a result of the large variety of verbiage used by clinicians when notating documents in a narrative form.

Discussion

By using two edit distance methods and processing all terms ever used in the VA, we show the potential for creating comprehensive term dictionaries when a full-text index exists for the complete corpus. Incorporating these methods as a cached dictionary of terms prior to processing documents has a positive impact on the speed of processing. Through the use of existing and modified medication dictionaries, a light-weight targeted sectionizer, and a simple rule-based NLP pipeline, we were also able to show the potential for automatically extracting surgical quality measures.

Future work will be done to assess the feasibility of extracting the rationale for a discontinued medication as well as alternative methods of approaching the NLP pipeline to improve precision and recall. With a limited set of negated and discontinued examples in our training set, it was determined that in this specific study there would not be enough data to explore machine learning approaches as they generally require a larger example set for accurate training. Recent research has shown that this may still be improved using weakly labeled data[21], or alternative methods of dictionary creation[22], but those were not attempted for this work.

Conclusion

A comprehensive dictionary of terms associated with beta-blocker use in the VA clinical environment was developed and evaluated. A custom sectionizer to distinguish medication mentions in a clinical narrative from those created automatically using structured data was tested and applied to improve automatic prescription status extraction. This study showed that combining the dictionary creation methods with a custom sectionizer and a rule-based NLP pipeline can effectively classify the prescriptions status of the beta blockers, achieving a critical component of the SCIP-card-2 quality measure.

Abstract

Supported by the European Commission under Horizon 2020, mHealth4Afrika is co-designing and validating a modular, multilingual, state-of-the-art health information system addressing primary healthcare requirements in resource constrained environments. mHealth4Afrika has co-designed a comprehensive range of functionality and medical programs in partnership with Ministries of Health, district health officers, clinic managers and primary healthcare workers from urban, rural and deep rural health facilities in Ethiopia, Kenya, Malawi and South Africa. This paper provides insights into how mHealth4Afrika is leveraging HL7 FHIR to support standards-based data exchange and interoperability between Electronic Medical Records and DHIS2. This work is currently being validated in the field.

Keywords:

Health Information Interoperability, Electronic Health Records, HL7 FHIR

Introduction

While electronic patient records are gradually being introduced into larger hospitals in Ethiopia, Kenya, Malawi and South Africa (current mHealth4Afrika beneficiary countries), paper-based registries [1, 2, 5-7] remain the default data capture method in resource constrained urban, rural and deep rural health facilities. mHealth4Afrika supports the objectives of UN Sustainable Development Goal 3 (SDG3) by co-designing a comprehensive, patient-centric health platform that is adaptable and extensible, modular and multilingual [1 - 6]. It integrates Electronic Medical Record (EMR) and Electronic Health Record (EHR) functionality, with the use of medical sensors and data visualization tools at the point of care [5, 6]. It supports the automatic counting of aggregate program indicator data required by Ministries of Health, SMS appointment notifications and lab system integration.

In some resource constrained environments, including Africa, donors have adopted a silo-based application approach, addressing requirements for specific programs they fund, including ART (HIV/AIDS) and Tuberculosis (TB) [6, 8].

Standards and interoperability are key enabling environment components of the WHO and ITU National eHealth Strategy Toolkit [9]. As the number of patient centric technology-enabled health applications (eHealth and mHealth) grow, the importance of interoperability becomes ever more critical to avoid unnecessary duplication of effort and fragmentation of electronic health record data. mHealth4Afrika has taken a standards-based approach to data interoperability to support data exchange between applications and systems.

The South African National Department of Health published the National Health Normative Standards Framework for Interoperability in eHealth in South Africa (HNSF) in 2014 [10]. This aims to provide a framework supporting the development of interoperable health systems. It proposed that Health Level Seven (HL7) is used as the messaging standard for the exchange and integration of electronic clinical healthcare information between systems.

In April 2017 the Ministry of Health of Kenya published the Kenya Standards and Guidelines for mHealth Systems [11] to support data and information sharing across multiple health systems. It is even more specific than South Africa, requiring that eHealth/mHealth solutions used in Kenya should leverage HL7 FHIR (Fast Healthcare Interoperability Resources) APIs (Application Programming Interfaces) [12].

mHealth4Afrika research objectives include to co-design a comprehensive, patient-centric health platform leveraging some of the functionality of District Health Information System 2.0 (DHIS2) [6] and support standards-based data exchange to transfer medical sensor readings and lab requests to and from the patient medical record, and import and export of patient records between EMRs. DHIS2 and the Tracker Capture application have several limitations. As a result, mHealth4Afrika has designed a comprehensive and extensible patient-centric, multi-program custom platform and user interface for use in medical facilities which interacts with the mHealth4Afrika data model set up in DHIS2 via the native DHIS2 WebAPI [6].

mHealth4Afrika has co-designed a comprehensive range of medical programs supporting easy and systematic data capture, storage and searching of patient centric data. Based on priorities of initial intervention countries (Ethiopia, Kenya, Malawi and South Africa) [1, 2, 5, 6], medical programs currently implemented and validated include: medical history, maternal health, family planning, cervical cancer screening, child under 5, tuberculosis, antiretroviral therapy, diabetes, general and specialist outpatient department (OPD). mHealth4Afrika supports single registration of a patient at a health facility and subsequent enrolment in a range of different programs based on their health conditions over time [1, 6].

mHealth4Afrika has applied a standards-based approach to data interoperability, taking account of state-of-the-art standards and international good practices, while respecting national policies and legislation in intervention countries. In the context of introducing medical sensors at the point of care, mHealth4Afrika developed a HL7 FHIR Service in 2017 to authenticate users and support data transfer of readings from BLE medical sensors to the appropriate patient record in the

mHealth4Afrika data model stored in the DHIS2 server via the DHIS2 API. We are not aware of any other project to date that has used HL7 FHIR for data transfer of readings from medical sensors (e.g. for blood pressure, blood glucose, SpO2, heart rate, weight, temperature) with a data model set up in DHIS2 or similar implementations designed for use in primary healthcare facilities in resource constrained environments.

During 2018 the mHealth4Afrika HL7 FHIR service was extended to support standards-based data exchange of lab requests to a laboratory system and the transfer of lab results into the appropriate mHealth4Afrika patient medical record.

A design requirement for mHealth4frika was to support standards-based data exchange of patient clinical data between health information systems. The target use case is to support a hospital referral or a patient moving temporarily or permanently from one health facility to another. Currently DHIS2 does not support exporting or importing the health record of a specific patient. mHealth4Afrika has extended its HL7 FHIR service to support import and export of a patient's health records between mHealth4Afrika platform instances and to support HL7 FHIR data exchange of patient's records with other EMR and EHR being used nationally.

This paper provides an overview of the design of the standards-based approach to support the import and export of patient health records by extending the mHealth4Afrika HL7 FHIR Service. The methods section provides insights into mHealth4Afrika compliance with Continua Design Guidelines (CDG) by Personal Connected Health Alliance (PCHA), the two-way data mapping between the mHealth4Afrika data model set up in DHIS2 and HL7 FHIR STU3 resources. The following section summarizes and discusses early results, while the last section presents the conclusion.

Methods

The mHealth4Afrika FHIR Service is designed as an independent service to achieve full HL7 FHIR based interoperability without disrupting how the mHealth4Afrika browser-based custom application communicates via the native DHIS2 WebAPI with the mHealth4Afrika data model set up in the DHIS2 server. The service supports exporting and importing data. The mHealth4Afrika application has been extended to include a user interface to support import/export functionality and interaction with the FHIR Service.

Data flow is explained below in Figure 1.

For authentication between the service and DHIS2 server, the mHealth4Afrika application passes the 'Cookie' header in each call made to the Import / Export service. The appropriate 'Cookie' header is obtained through the user login process.

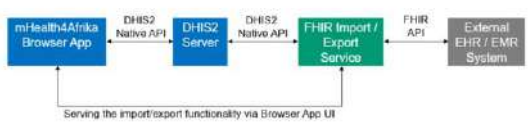

Figure 1 – mHealth4Afrika Import / Export Service Data Flow

Continua Design Guidelines Compliance

The mHealth4Afrika FHIR Service has been implemented with the purpose of achieving standards-based interoperability between the DHIS2 server and other EHR/EMR systems. Figure 2 briefly summarizes mHealth4Afrika compliance with the Continua Design Guidelines (CDG) by Personal Connected Health Alliance (PCHA) [13].

The Personal Health Devices Interface already implemented between medical devices supported by mHealth4Afrika and the mHealth4Afrika application, and the Services Interface already implemented between mHealth4Afrika applications and DHIS2 server, are beyond the scope of this paper.

This paper focuses on the mHealth4Afrika HL7 FHIR Service, which acts as a Healthcare Information Service (HIS) Interface between DHIS2 server and EHR / EMR systems.

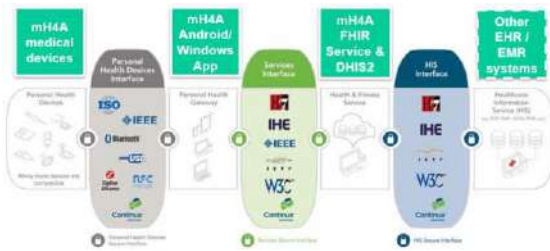

Figure 2 – mHealth4Afrika Compliance with Continua Design Guidelines

DHIS2 Data Model

Two-way data mapping between the DHIS2 data model and HL7 FHIR STU3 resources is required to support import and export capabilities based on FHIR. In this context the DHIS2 data model has been analyzed and data model elements which must be mapped to FHIR resources have been identified:

- DHIS2 OrganisationUnit represents healthcare facilities.
- DHIS2 TrackedEntityInstance represents patients.
- DHIS2 User represents practitioners or clinic managers.
- DHIS2 ProgramStage defines the content of the program specific forms, i.e. which DataElements should be presented in each mHealth4Afrika program stage (e.g. In Maternal Health program expected date of delivery should exist in Antenatal Care visits but not in Postnatal Care visits).
- DHIS2 Event represents patient visits corresponding to a program stage, i.e. filled-in program data.
- DHIS2 DataElement represents the leaf-level patient data definitions, such as vital sign measurements (e.g. blood glucose reading) as well as observational questions (e.g. Does the patient have edema?), which are all used in program stage definitions.
- DHIS2 Enrollment represents patient enrollments to mHealth4Afrika programs (Maternal Health, Tuberculosis, etc.). A patient may be enrolled in multiple programs.

Mapping of Resources

TrackedEntityInstance and Event are the two main DHIS2 resources directly related to patient healthcare records. TrackedEntityInstance contains demographic information about patients, while Event contains medical information captured during clinical (or program stage) visits by patients.

FHIR Patient resource is used to represent DHIS2 TrackedEntityInstances. TrackedEntityInstance attributes are mapped to respective FHIR Patient attributes. Standard FHIR attributes are used where possible and some extensions are defined for mHealth4Afrika specific attributes, e.g. patient type (adult or child). Figure 3 provides an example of some of the mHealth4Afrika TrackedEntityInstance set up in DHIS2 with the corresponding FHIR Patient resources presented in Figure 4. To date, a total of 61 TrackedEntityInstance attributes have been mapped to FHIR Patient attributes.

Figure 3 – mHealth4Afrika Tracked Entity Instance

FHIR QuestionnaireResponse resource is used to represent DHIS2 Events. Events contain multiple dataValues that are similar to the QuestionnaireResponse attribute "item". As mentioned before, Events represent program stage visits and each dataValue contains a dataElement attribute which references the respective dataElement in the ProgramStage resource. In other words, ProgramStage contains a template of what the visits should contain (i.e. metadata) and Event contains actual values that is gathered in a visit (i.e. instances). The structure is similar in FHIR Questionnaire and QuestionnaireResponse. Questionnaire resource contains questions and, in some cases, possible values and option sets of the questions and QuestionnaireResponse resource contains answers to those questions defined in the Questionnaire. Having a very similar structure, Questionnaire resources are used to represent ProgramStages and QuestionnaireResponse resources are used for Events. Mapping of attributes, and the relations between ProgramStage, Event, Questionnaire and QuestionnaireResponse resources can be seen in Figure 5.

Event attributes are mapped to respective FHIRQuestionnaireResponse attributes. Similar to TrackedEntityInstances, standard FHIR attributes are used where possible and some custom extensions are defined for mHealth4Afrika specific values such as program. ProgramStage attributes are mapped to respective FHIR Questionnaire attributes.

FHIR Organization and EpisodeOfCare resources are used to represent OrganisationUnits and Enrollments for the purpose of having a complete and consistent FHIR Bundle. As outlined in Figure 4, FHIR Patient resource contains a reference to the managing organization with its id. Without including an Organization resource with the same id in the FHIR Bundle, the bundle will fail referential integrity. Hence, respective FHIR Organization resources are created corresponding to the OrganisationUnits in DHIS2. It is similar with Enrollments and Events, which contain enrollment references.

Figure 4 – HL7 FHIR Patient Resource

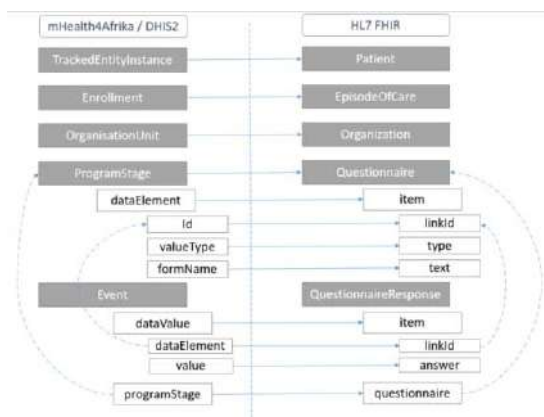

Figure 5 – DHIS2 Data Model to FHIR Resource mapping

FHIR Export

The service provides an endpoint that is used to export HL7 FHIR bundles containing information about the demographics and medical visits of the patients. The program, organizationUnit and the individual patient is specified at the request call to customize the output. The service uses several methods from the DHIS2 Native API to gather relevant data from DHIS2, transforms the gathered data to FHIR resources based on the mapping explained in the previous section, and finally returns a HL7 FHIR Bundle containing HL7 FHIR resources. The export can include all patient specific medical records or only a specific program, depending on the permission provided by the patient and why the electronic medical record is being provided to a different health facility.

The bundle contains several types of FHIR resources.

- Patient: This resource contains demographic information about the patient.
- QuestionnaireResponse: This resource contains actual data about the program stage visits of the patient.
- Questionnaire: This resource contains metadata about the program stage visits.
- Organization: This resource contains information about related Organisational Units.
- EpisodeOfCare: This resource contains information about program enrollments of the patients.

FHIR Import

The service provides an endpoint that is used to import HL7 FHIR bundles containing information about the complete or partial medical history of the patients. It enables patients to receive medical care in different health facilities as required and request that their electronic medical record is transferred between facilities and kept up to date.

The output of the FHIR Import, i.e. FHIR bundle, is parsed and relevant resources are mapped to the mHealth4Afrika DHIS2 data model. Several DHIS2 API calls are used sequentially to preserve referential integrity, e.g. patient demographic information must be imported before a lab result.

Initial Results and Discussion

The mHealth4Afrika platform has been co-designed and validated with Ministries of Health, District Health Offices, Clinic Managers and nurses in Ethiopia, Kenya, Malawi and South Africa over the past three years. It is currently being used in a mix of primary health care facilities and hospitals.

The initial focus of this extension to the mHealth4Afrika FHIR service commenced with a mapping of patient centric data attributes and data elements to FHIR resources. As outlined above, it has been necessary to use some extensions based on specific mHealth4Afrika program requirements. When the export and functionality was implemented, this required a modification of the mHealth4Afrika platform to engage with the extended FHIR service.

The standards-based approach being implemented builds on an existing HL7 FHIR service that mHealth4Afrika developed in 2017 to support data exchange of medical sensors readings and lab requests and lab results to and from the patient's electronic medical record. It takes account of national policy and legislative requirements in intervention countries, while leveraging the most up to date international standards.

In the current mHealth4Afrika beneficiary countries, individual patient medical records are only stored within the health facility that provides the healthcare services.

This interoperability work will enable mHealth4Afrika to both export and import complete individual patient records (as well as specific programs from individual patient records) from an instance in one health facility to an instance in another health facility. This ensures that existing electronic medical records can be transferred as required between health facilities, based on patient consent. This is a practical requirement that is not currently supported within DHIS2 standard tools.

It is normal in many countries that a pregnant mother may move from her place of normal residence to another location closer to family members towards the end of her term. In this context, it is important that the healthcare facility where she is currently receiving care has access, with her consent, to her full medical record - medical history, details of medical data captured during antenatal visits etc. The mHealth4Afrika platform allows the health facility managers to print off reports of data captured across antenatal visits. However, if the healthcare facility providing delivery and postnatal care are using the mHealth4Afrika platform or another EMR that supports data exchange using HL7 FHIR, it is more efficient if the electronic health record can be imported, updated and then exported as a FHIR bundle. This will allow the patient's health record to be kept fully up to date when they return to the health facility where they are normally resident.

This functionality will also support patients with medical conditions, such as TB, HIV, Diabetes, and Chronic Hypertension, to move their electronic health records for the purposes of referral or when transferring to another facility.

This import / export functionality is exposed to the clinic manager role via the mHealth4Afrika custom interface. This functionality is currently field tested in the intervention countries and will be adapted as necessary going forward.

Related Work

Healthcare system interoperability is an essential topic in the domain as modern medical care is inherently distributed. Standards-based transfer of medical information is researched and developed over decades and more recently HL7 FHIR based interoperability solutions are being implemented. OpenMRS FHIR Module is such an example [14].

When the FHIR HL7 service work commenced in mHealth4Afrika during 2017 and the import / export work described in this paper commenced during early 2018, there was no implementation of such a FHIR based interoperability service in DHIS2. In September 2018, DHIS2 started work on a use case focused on importing TrackedEntityInstances (patient data) with Observations and Immunisations as Events into a DHIS2 server using HL7 FHIR. This will allow EMRs and applications to connect to a FHIR repository to upload patient data. An adapter can then connect to the FHIR repository and enroll patients in the DHIS2 server. It is proposed mapping is done through a transformation engine.

While this use case was only a sub-set of our current requirements, mHealth4Afrika had meetings with DHIS2 to learn more about this proposed approach and share insight about the approach we have been implementing since 2017.

Recently, the DHIS2 team started to implement an interface based FHIR adapter, similar to the mHealth4Afrika

import/export service. This has the objective of eliminating the need of a FHIR repository to simplify integration of the interoperability functionality into non FHIR repository related use cases. This work is initially focused on import.

Conclusions

This paper provides insight into some of the research objectives of mHealth4Afrika, including designing a standards-based approach to support both import and export of patient health records by extending the existing mHealth4frika HL7 FHIR Service. It outlines two-way data mapping between the mHealth4Afrika data model set up in DHIS2 and HL7 FHIR STU3 resources.

Some of the mapping decisions are designed to be as generic as possible. For example, FHIR QuestionnaireResponse is used to represent program stage visits, as it allows multiple types of items that can cover all program stage data elements. While some of the data elements exactly fit to questionnaire questions, some of them represent specific laboratory tests or vital sign measurements which might be more suitable to be mapped to more specific FHIR medical resources such as Observation or DiagnosticReport. This has been implemented within mHealth4Afrika as an import mechanism, while acquiring vital sign measurements from patients via Bluetooth LE medical sensors, with the mHealth4Afrika Android Application acting as a sensor gateway. This initial import capability was extended within the context of the full program set, extending the FHIR service to support exporting individual patient records using specific FHIR resources.

The import/export functionality for individual patient's medical records was completed in February 2019 and is currently being field tested in the mHealth4Afrika intervention countries.

Bridging the Gap Between Consumers' Medication Questions and Trusted Answers

Asma Ben Abacha, Yassine Mrabet, Mark Sharp,

Abstract

This paper addresses the task of answering consumer health questions about medications. To better understand the challenge and needs in terms of methods and resources, we first introduce a gold standard corpus for Medication Question Answering created using real consumer questions. The gold standard[1] consists of six hundred and seventy-four question-answer pairs with annotations of the question focus and type and the answer source. We first present the manual annotation and answering process. In the second part of this paper, we test the performance of recurrent and convolutional neural networks in question type identification and focus recognition. Finally, we discuss the research insights from both the dataset creation process and our experiments. This study provides new resources and experiments on answering consumers' medication questions and discusses the limitations and directions for future research efforts.

Keywords:

Health Informatics, Data Collection, Natural Language Processing

Introduction

Digital information and the World Wide Web make it possible to find information on demand, helping both patients and professionals to find relevant and valuable medical information. With these benefits come growing concerns about the potential misinformation of patients and non-expert consumers. Harmful consequences include self-diagnosis and unfounded anxiety about common symptoms after reviewing online health information (i.e., cyberchondria) [1]. The Pew Research Center reports that 72% of U.S. internet users (over 200 million) have gone online in the past year specifically for health-related information. Of that group, 77% say that their research started with search engines such as Google, while only 13% say they began at a specialized website such as WebMD[2].

Safe and efficient search alternatives are needed to protect non-expert consumers from misleading health information found online. Specialized Question Answering (QA) systems are a potential solution for the medical domain and the consumers' need for reliable health information [2]. Several research efforts tackled the problem of QA in the (bio)medical domain and highlighted the challenges related to question understanding, answer retrieval, and ranking [3-6]. To the best of our knowledge, no studies were previously dedicated to QA about medications.

Figure 1– Word Cloud Representing the Consumer Questions about Drugs that We Used to Create the Gold Standard Corpus.

While several previous studies included such questions as a part of larger and more heterogeneous QA tasks, we argue that questions about medications have specific characteristics that need to be analyzed and evaluated in a focused study. These aspects include (i) different question types (e.g. action, storage, usage time, stopping, and tapering), (ii) more conditional answers (e.g. ingredients and appearance depend often on the manufacturer), (iii) different answer sources having a specific data structure (e.g. websites recommended by the FDA such as DailyMed[3]), and (iv) potentially more difficult questions (e.g. drug alternatives, questions about not formalized/written medical knowledge such as usage time), and a higher sensitivity to error (e.g. drug interactions that cannot be confirmed online).

Several efforts focused on methods for medical question answering [7-10] as well as the creation of relevant datasets. For instance, Kilicoglu et al. [11] introduced a dataset of 2,614 medical questions annotated with the question focus, type and triggers of the question types. In that dataset, "Problems" are the most frequent named entities, while "treatment" and "information" are the most common question types. Ben Abacha et al. [12] organized a medical QA task at the TREC 2017 LiveQA track and published training and testing datasets including consumer health questions received by the NLM, annotations and reference answers retrieved by medical informatics experts. The coverage of questions about medications in the above collections, however, was insufficient to train and develop efficient systems to answer questions about

[1] https://github.com/abachaa/Medication_QA_MedInfo2019
[2] http://www.pewinternet.org/2013/01/15/health-online-2013
[3] https://dailymed.nlm.nih.gov/

medications. In this paper, we present a study of consumers' medication questions with the following contributions:

1. The development and publication of a manually annotated dataset of medication question-answer pairs based on real consumer questions submitted to MedlinePlus.
2. A synthesis of the manual annotation effort summarizing the insights obtained by a variety of experts from annotating and answering those questions.
3. New experiments using deep learning networks trained specifically for the tasks of identifying the main focus in the user's question, and the question type.

In what follows, we first describe our annotation methodology and the baseline approaches in the Methods section. We present the statistics and characteristics of the developed dataset and the empirical results in the Results section.

Methods

In this section, we describe the guidelines used in the manual annotation process and our first empirical evaluation methods based on the dataset.

Data Creation

Selecting Consumer Questions about Drugs. We selected anonymized consumer questions submitted to MedlinePlus[4]. We first performed Medical Entity Recognition using MetaMapLite [13]. We restricted the recognized entities to the following UMLS semantic types associated with medications: Antibiotic [antb], Clinical Drug [clnd], Neuroreactive Substance or Biogenic Amine [nsba], Pharmacologic Substance [phsu], Steroid [strd], and Vitamin [vita]. Finally, we manually selected the questions that (i) were deemed understandable and potentially answerable and (ii) have a drug name as focus. Figure 1 presents a word cloud of the most frequent terms in the selected consumer health questions.

Annotating the Questions. In a study conducted recently on consumer health question answering, Deardorff et al. [14] showed that for 62% of the questions, it was possible for librarians to find an answer in the top 5 search results in MedlinePlus using only the focus and question type. Given the importance of these two elements for QA, we, therefore, focused our efforts on manually annotating each question with a:

- Question focus (always a Drug name in this dataset),
- Question type (e.g. Dose, Interaction, Side effects).

Searching for Reference Answers. For each answerable question, annotators had to retrieve manually a correct and complete reference answer (with its URL and section title):

- **Correct** with regards to the question's explicit and implicit information (e.g. a question about a drug in the UK, a specific form or dose), and extracted from **reliable** websites or scientific papers.
- **Complete** with regards to all possible answers (e.g. all doses, ingredient lists from all manufacturers), and preferably written in **a consumer-friendly** language.

To select our answer sources, we followed the FDA recommendations suggesting[5] MedlinePlus-Drugs as a consumer-friendly website for consumer drug information and DailyMed for trustworthy information about FDA-approved and marketed drugs in the United States. Our final guideline was to search the following sources sequentially until an answer is retrieved:

1. MedlinePlus and DailyMed.
2. Other NIH or U.S. government websites.
3. Other trustworthy websites (e.g., the Mayo Clinic) or academic institutions' websites.
4. Other websites returned by a Google search.

Four annotators participated in the manual annotation and answering process. Then, a medical doctor and an expert in question answering reconciled the annotations of the question types and validated the retrieved answers.

Baseline Methods

Focus Recognition. We adapted, extended and evaluated Bi-directional Long Short-Term Memory (Bi-LSTM) networks[6] on the task of recognizing the question focus (i.e., main drug name) according to the state-of-the-art architecture proposed by Xuezhe and Hovy [15]. The network includes a first Bi-LSTM network to build character-level embeddings, and a second Bi-LSTM taking as input both word embeddings built from the UMLS and pre-trained embeddings built with GloVe [16] and the character-level embeddings built during training with the first Bi-LSTM layer. The token labels were generated with a final Conditional Random Fields (CRF) layer. Our UMLS embeddings consist of binary vectors, where each word is tagged as the Beginning, Inside, Outside, End, or Single token (BIOES) of each semantic concept in the UMLS.

Question Type Identification. We implemented and evaluated a Convolutional Neural Network (CNN) on the task of identifying the question type (e.g., dosage, usage, contraindications). The input embeddings include UMLS BIOES embeddings and a randomly initialized vector of 128 dimensions updated with back-propagation during training.

Answer Retrieval. We conduct a first qualitative study on answer retrieval using twenty questions randomly selected from our dataset and the CHiQA question answering system[7]. CHiQA is the first online medical QA system for consumer health questions from reliable sources such as NIH websites (e.g., MedlinePlus, GARD, NCI), Mayo Clinic and DailyMed. The system relies on different machine learning and knowledge-based methods to recognize the question's focus and type [17-18] and uses the extracted information to retrieve answers with the Lucene search engine and a question-entailment recognition approach [19-20]. Figures 2 and 3 present the first answers returned by CHiQA to two questions selected randomly from the gold standard.

Results

Characteristics of the Dataset

The final gold standard contains **674** question-answer pairs with their associated annotations. These annotations include 25 question types, reported with examples in Table 1, and the answer sources, summarized in Figure 4. In particular, on the 674 answers, DailyMed was used to answer 290 questions, MedlinePlus for 128 questions, and other websites were used to answer 256 questions (e.g. cdc.gov, mayoclinic.org, health.harvard.edu, and PubMed abstracts and articles). Table 2 presents token-and-sentence-level statistics about the questions and the answers in the dataset.

Table 1 – Question Types in the Gold Standard

Question Type	#	Example
Information	112	what type of drug is amphetamine?
Dose	70	what is a daily amount of prednisolone eye drops to take?
Usage	61	how to self inject enoxaparin sodium?
Side Effects	60	does benazepril aggravate hepatitis?
Indication	55	why is pyridostigmine prescribed?
Interaction	51	can i drink cataflam when i drink medrol?
Action	39	how xarelto affects in the process of homeostasis?
Appearance	38	what color is 30mg prednisone?
Usage/time	36	when is the best time to take lotensin?
Stopping/tapering	31	how to come off citalopram?
Ingredient	28	what opioid is in the bupropion patch?
Action/time	23	how soon does losartan afffect blood pressure?
Storage and disposal	13	in how much temp bcg vaccine should store?
Comparison	11	why is losartin prescribed rather than a calcium channel blocker?
Contraindication	11	if i am allergic to sufa can i take glipizide?
Overdose	10	what happens if your child ate a tylenol tablet?
Alternatives	8	what medicine besides statins lower cholesterol?
Usage/duration	7	how long should i take dutasteride?
Time *(other time-related types)*	6	how long are you protected after taking the hep b vaccine?
Brand names	3	what is brand name of acetaminophen?
Combination	3	how to combine dapaliflozin with metformin?
Pronunciation	3	how do you pronounce humira?
Manufacturer	2	who makes this drug nitrofurantoin?
Availability	1	has lisinopril been taken off the market?
Long term consequences	1	what are the side effects and long term consequences of using nicotine?

Table 2 – Statistics about the Questions and Answers

Average number of tokens per question	**7.16**
Average number of tokens per answer	**69.06**
Average number of sentences per answer	**3.23**
Percentage of questions tokens present in answers	**34.72%**

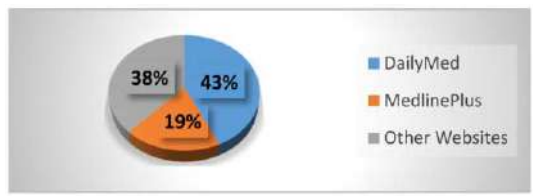

Figure 4 – Websites Used to Answer the Drug Questions

Evaluation Results

We report the average performance on 5 runs and the variation range for focus recognition and question type identification.

Focus Recognition. The Bi-LSTM-CRF network was implemented with Python 3.5 and Tensorflow 1.4. We trained the network with a random subset containing 80% of the data, using 10% for hyperparameter tuning and the remaining 10% for the final test. All data were represented in the BIOES token annotation format. The results on the test set are summarized in Table 3. We used a learning rate of 0.01, a dropout of 0.5, a batch size of 40, and the Adam optimizer [21] to minimize the CRF-based loss function.

Table 3 – Bi-LSTM-CRF Results for Focus Recognition

Results (%)	F1	P	R
Exact entity match	74.07 [+/-2.1]	78.12	70.42
Partial entity match	90.37 [+/- 3.4]	95.31	85.92

Question Type Identification. Our CNN network was also implemented using Python 3.5 and Tensorflow 1.4. Data were split according to same 80/10/10 percent subsets for training, development and test. To have enough training samples per class, we reduced the question types into the 14 most common types by aggregating the subtypes into their hypernym types: Information, Dose, Usage, Tapering, Interaction, Side effects, Indication, Action, Ingredient, Alternatives, Contraindication, Comparison, Manufacturing, and Appearance. We used a learning rate of 0.005, a dropout of 0.6, a batch size of 100, and the Adam optimizer to minimize the softmax-based loss function. The CNN network achieved an average accuracy of 75.7% on 5 runs with a variation in the [0, 2.5%] range. Despite using fixed random seeds for Tensorflow in both experiments, the relatively small size of the training data made them more

susceptible to the non-deterministic implementation of GPU reduction operations and the Adam optimizer in TensorFlow[8].

Answer Retrieval. In our qualitative study of the answers returned to 20 random questions from the dataset, CHiQA found the correct answer in the top four results in 35% of the cases, only related answers for 35% of them and irrelevant answers for the remaining 30%. While this limited evaluation must be taken with caution, our independent observations from the annotation process also hint that classical QA systems may not be the best fit for medication questions.

We discuss these insights and potential ways to improve answering questions about medications in the following section.

Table 4– Example Questions and Answers from the Dataset

ID	Question (Q) / Answer (A)
1a	(Q) "*what does prednisone do to the body?"*
1b	(Q) "*what would a normal dose be for valacyclovir?"*
1c	(Q) "*how much gravol to kill you?"*
1d	(Q) "*what time should take memantine?"*
2a	(Q) "*what color is phenytoin?"* (A) [depends on the manufacturer] • PINK • WHITE (/Light Lavender) • ORANGE
2b	(Q) "*why would my urine test be negative for benzodiazepines when i take Ativan?"* (A) "Common limitations exist for screening benzodiazepines when using traditional immunoassay (IA) tests. IA testing for benzodiazepines often targets nordiazepam and oxazepam (…)" **AND** "Some commonly prescribed drugs have limited cross-reactivity (…)"
2c	(Q) "*is it alright touse fluticasone when using oxygen?"* (A) "Pharmacological therapy can influence morbidity and mortality in severe chronic obstructive pulmonary disease (COPD). Long-term domiciliary oxygen therapy (LTOT) improves survival in COPD with chronic hypoxaemia. Oral steroid medication has been associated with improved survival in men and increased mortality in women, while inhaled steroid medication has been associated with a reduction in the exacerbation rate (…)."
2d	(Q) "*how long does vicodin stay in breast milk?"* (A) "Following a 10 mg oral dose of hydrocodone administered to five adult male subjects, the mean peak concentration was 23.6 ± 5.2 ng/mL. Maximum serum levels were achieved at 1.3 ± 0.3 hours and the half-life was determined to be 3.8 ± 0.3 hours."

Discussion

Difficulty and Ambiguity of Medication Questions

In our annotation and answering efforts, questions about medications showed traits common to consumer health questions such as **linguistic ambiguity** due to misspellings, or wrong grammar leading to unclear meaning or multiple interpretations. For instance, in Table 4, example 1a, it is unclear whether the question is about the side effects or the action of "prednisone". In addition, a distinct pattern emerged with many questions lacking essential information or context, making them too **underspecified** [22] to answer. For instance, in example 1b, finding a relevant answer about the right dose of "Valacyclovir" requires additional information about the patient and the condition or purpose of administration. **Circumlocution** [23] was another phenomenon that we encountered, i.e., the use of many words or general terms to express a medical term. For instance, in example 1c, the medical term "toxic dose" or "overdose" is replaced with the expression "how much X to kill you?". In several cases, we also encountered a **knowledge barrier** when the requested medical information/knowledge was not formalized or written online (e.g. Table 4, 1d).

Complexity of Manual Answer Retrieval

Our annotators reported **conditional answers** frequently. These include answers that depend on the manufacturer, on the disease, or on patient information. For instance, in Table 4, 2a, four different answers are possible according to the manufacturer of phenytoin. **Distributed answers** were also encountered in several cases. These are answers that can be formed only by combining different text snippets from different answers and/or sources (e.g., Table 4, 2b). Many answers also required an understanding of **expert terminology**. These include answers that need to be translated to consumer-friendly language and questions that required rephrasing to expert language in order to find relevant answers (e.g., Table 4, 2c). Other answers could not be found without **expert inference** based on background knowledge (e.g., Table 4, 2d). External resources like *eHealthMe* were needed for specific types of questions such as Interaction questions. Answering some of the questions was also time consuming even for medical experts. For example, an hour was necessary to answer the question "is it alright to use fluticasone when using oxygen?" from PubMed.

Challenges of Automating Medication QA

Prior to our study, the lack of gold standard datasets for medication QA was the major bottleneck in automatic QA for drug questions. This new dataset opens new opportunities for both qualitative studies and quantitative evaluation of QA systems. In addition, systems relying on big training data can use it both (i) as a development set for fine-tuning the hyperparameters and testing different architectures and (ii) as a test benchmark.

In question understanding, our baseline networks achieved an encouraging performance despite the limited training data, with (i) 74% F1 score in question focus recognition for exact span matching and 90% for partial span matching, and (ii) 75.7% accuracy in identifying the question type. Several improvements can be considered for future developments, such as a richer set of embeddings, or a relevant language model. A more fine-grained adaptation of the UMLS can also be applied by restricting to the list of relevant semantic types either through pre-filtering or through trainable masks.

In answer retrieval, insights from both our annotation process and our CHiQA-based evaluation provide additional guidance on the relevant solutions and ways of improvement for medication question answering. In particular:

- Medical text translation [24] and simplification [25] are often needed to find relevant answers and make the retrieved answers readable for non-expert users.
- More data and resources are needed to cover information about drug interactions and usage guidelines. Such information can be extracted from both the scientific literature and clinical sources [26].
- Conditional answers require different solutions such as providing a list of answers or interacting with the user in a dialogue-based approach.

[8] https://www.twosigma.com/insights/article/a-workaround-for-non-determinism-in-tensorflow

- Due to the frequency of these conditional answers, fully unsupervised approaches are less likely to succeed than approaches based on (advanced) inference methods that can rely on explicit context semantics.

Conclusions

We studied consumers' questions about medications. We created a new gold standard corpus for question answering about drugs that we shared in the scope of this paper[9]. We presented statistics, insights and conclusions based on the manual annotation process, deep learning experiments, and preliminary evaluation of automatic answer retrieval. We hope that this new benchmark and initial experiments will foster new approaches and additional community efforts in addressing the growing need for reliable information about medications online.

Abstract

Non-compliance situations happen when patients do not follow their prescriptions and take actions that lead to potentially harmful situations. Although such situations are dangerous, patients usually do not report them to their physicians. Hence, it is necessary to study other sources of information. We propose to study online health fora. The purpose of our work is to explore online health fora with supervised classification and information retrieval methods in order to identify messages that contain drug non-compliance. The supervised classification method permits detection of non-compliance with up to 0.824 F-measure, while the information retrieval method permits detection non-compliance with up to 0.529 F-measure. For some fine-grained categories and new data, it shows up to 0.65-0.70 Precision.

Keywords:

Patient Compliance, Information Storage and Retrieval, Machine Learning

Introduction

Drug non-compliance situations happen when patients do not follow instructions given by their doctors in the prescriptions. Among current situations, we can, for instance, mention modification of dosage, refusal to take prescribed drugs, use of drugs prescribed to other persons. The misuse of drugs, which is part of non-compliance, covers more precise situations, like use of drugs with different intents than those for which drugs are prescribed. We can thus mention recreational or suicidal use of drugs. Such situations are dangerous because they endanger patients and their health. Yet, patients do not inform their doctors or the authorities that they do not follow the instructions. Hence, it is necessary to study other sources of information to gain some insights into patients' lives. We propose to study social media, in which patients are producing large amounts of contents on various subjects [1], including the use of drugs.

Currently, social media have become an important source of information for various research areas, such as geo-localization, opinion mining, event extraction, translation, or automatic summation [2]. In the medical domain, social media have been efficiently used in information retrieval for epidemiological surveillance [3,4], in studying patient's quality of life [5], and drug adverse effects [6].

Yet, very few projects are focused on drug misuse and non-compliance. We can mention here non-supervised analysis of tweets about non-medical use of drugs [7], and creation of a semantic web platform on drug abuse [8]. Both of these projects are dedicated to one specific case of misuse, that is, drug abuse. In our work, we propose to study non-compliance and misuse situations, and more particularly to identify messages related to such situations in health fora. To reach these objectives, we propose two different methods: machine learning and information retrieval.

In what follows, we first detail the methods, then present and discuss the results. Finally, we conclude with directions for future research.

Methods

We propose to address the automatic detection of messages related to drug non-compliance as a categorization problem, and to use two methods: supervised machine learning and information retrieval. We first introduce the reference data used and then describe the two methods.

Reference and Test data

The reference and test data were built from corpora collected in several health websites in French. Several fora were collected from the Doctissimo[1] website (pregnancy, general questions on drugs, back pain, accidents in sport activities, diabetes). Doctissimo is indeed the most well-known and used health website and forum in French. We also used data from three other fora: AlloDocteur[2], masante.net[3], and Les diabétiques[4].

The contributors in all the fora were mainly diseased persons and their relatives, who joined the community to ask questions or provide accounts of their disorders, treatments, etc. Overall, these people may be affected by chronic or non-chronic disorders.

To build the reference data, we used two fora of Doctissimo (pregnancy and general questions on drugs). We collected messages written between 2010 and 2015, and kept only those messages that mentioned at least one drug. This gave a total of 119,562 messages (15,699,467 words). For the test data, we collected 145,012 messages from other corpora. In each message, the occurrence of drugs was detected with specific vocabulary containing French commercial drug names from several sources: base *CNHIM Thériaque*[5], *base publique du médicament*[6], and *base Medic'AM*[7] from Assurance Maladie.

Each drug name was associated with the corresponding ATC code [9]. For the manual annotation process of the reference

1 http://www.doctissimo.fr
2 http://www.allodocteur.fr
3 http://masantenet.com
4 http://www.lesdiabetiques.com
5 http://www.theriaque.org
6 http://base-donnees-publique.medicaments.gouv.fr
7 https://www.ameli.fr/l-assurance-maladie/statistiques-et-publications/donnees-statistiques/medicament/medic-am/medic-am-mensuel-2017.php

data, messages longer than 2,500 characters were excluded because they provided heterogeneous content difficult to categorize and process, both manually and automatically. Then, three annotators were asked to assign each message to one of the two categories:

- *Non-compliance* category contained messages that reported on drug non-compliance or misuse. When this category was selected, the annotators were also asked to shortly indicate what type of non-compliance was indicative (overuse, dosage change, brutal quitting). This indication is written as free text with no defined categories. For instance, the following example shows non-compliance situation due to the forgotten dose of medication: "*bon moi la miss boulette et la tete en l'air je devais commencer mon "utrogestran 200" a j16 bien sur j'ai oublier! donc je l'ai pris ce soir!!!!*" (*I blundered the missed dose and with the head in the clouds I had to start the "utrogestran 200" on d16 and I forgot of course! so I took it this evening!!!!*)
- *Compliance* category contains messages reporting normal drug use ("*Mais la question que je pose est 'est ce que c'est normal que le loxapac que je prends met des heures à agir ???*" (*Anyway the question I'm asking is whether it is normal that loxapac I'm taking needs hours to take effect???*)) and messages without use of drugs ("*ouf boo, repose toi surtout, il ne t'a pas prescris d'aspegic nourisson??*" (*ouch boo, above all give me a break, he didn't prescribe aspegic for the baby??*))

When annotators were unable to decide, they marked up the corresponding messages accordingly. The categorization of these messages as well as the categorization of annotation disagreements are discussed later. The three annotators involved in the process were: one medical expert in pharmacology, and two computer scientists familiar with medical texts and annotation tasks. Because this kind of annotation was a complicated task, especially concerning the decision on drug non-compliance, all messages annotated as non-compliant were additionally verified by one of the annotators.

The manual annotation process permitted to double-annotate 1,850 messages, among which we counted 1,717 messages in the compliance category and 133 messages in the non-compliance category. These numbers indicated the natural distribution of non-compliance messages (approximately 7%). Within the non-compliance category, we counted 16 types of non-compliance: they contained between 1 and 29 messages. For example, the *change of weight* type contained 2 messages, *recreational use of drugs* 2 messages, *suicide attempt* 2 messages, and *overuse* of drugs 20 messages. Concerning the annotation into *compliance* and *non-compliance* categories, the inter-annotator agreement [10] was moderate (0.46) [11]. It seemed that the task at hand was quite complicated and the sparsity of data for some types of non-compliance made the task even more difficult.

The corpus was pre-processed using Treetagger [12] to obtain its tokenization (typically, segmentation of words and punctuation), POS-tagging (assigning syntactic categories to words, such as *anxiétés/Nom (anxieties/Noun)*)), and lemmatization (normalization to canonical forms and removal of inflections for plurals, feminines, such as *anxiétés/anxiété (anxieties/anxiety)*). The corpus was used in three versions: (1) in the *forms* corpus, the messages were only tokenized and lowercased (eg, i'm taking 3 pills each day); (2) in the *lemmas* corpus, the messages were also lemmatized, the numbers were replaced by a unique placeholder, and diacritics were removed such as in a*nxiété/anxiete (anxiety)*; (3) in the *lexical lemmas* corpus, we kept only lemmas of the main lexical categories (verbs, nouns, adjectives, and adverbs) (eg, take pill day). Each message was also indexed with the three first characters of the ATC categories of drugs occurring in the message. We obtained 18355 distinct words, 12231 distinct lemmas, and 12096 distinct lemmas in the *forms* corpus, the *lemmas* corpus, and the *lexical lemma* corpus respectively.

Categorization with Supervised Machine Learning

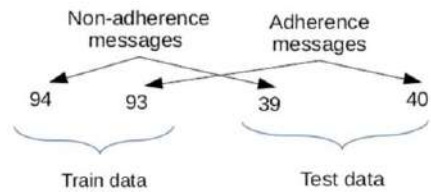

Figure 1 – Datasets Used for Machine Learning

With this method, the supervised machine learning algorithms learn a language model from manually annotated data, which can then be applied to new and unseen data. The categories aimed were drug *compliance* and *non-compliance*. The unit processed was the message. Several sets of features were exploited: the vectorized text of messages (forms, lemmas, and lexical lemmas) and the ATC indexing of drugs. The train set contained 94 non-compliant messages and 93 compliant messages. The test set contained 39 non-compliant messages and 40 compliant messages: we used two thirds of the reference data for training and one third for testing as shown in Figure 1.

We used the Weka [13] implementation of several supervised algorithms: NaiveBayes [14], Bayes Multinomial [15], J48, Random Forest, and Simple Logistic. These algorithms were used with their default parameters and with the string to word vector function.

Categorization with Information Retrieval

The information retrieval system was exploited to make the distinction between relevant and irrelevant messages with this method. This approach was unsupervised, although we took advantage of the reference data as well. We used the Indri information retrieval system in two ways:

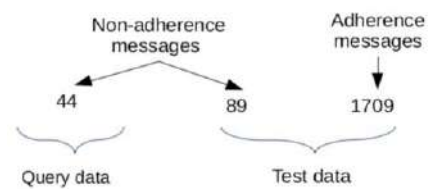

Figure 2 – Datasets Used for Global Information Retrieval

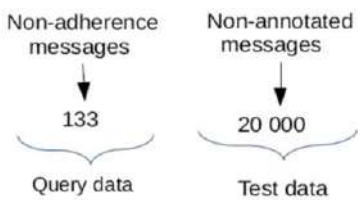
At the global level, we distinguished between drug compliant and non-compliant messages. The corpus was split into two sets: (1) 44 non-compliance messages (one third of the whole non-compliance category) were used for the creation of queries, and the query lexicon was weighted proportional to its frequency in the messages; (2) All compliance messages and 89 non-compliance messages (two thirds of the whole non-compliance category) were used for the evaluation as shown in Figure 2. The question we wanted to answer was whether the subset of non-compliance messages permited to retrieve other non-compliance messages. The evaluation was done automatically, computing Precision, Recall, and F-measure

with each version of the corpus (forms, lemmas, and lexical lemmas). This may give an idea of the performance of this method when searching similar information in new non-annotated data.

At the fine-grained level, we looked for various types of drug non-compliance. The question we wanted to answer was whether the messages already assigned to each non-compliance type can help in retrieving other similar messages and enrich the reference data through this unsupervised approach. This issue was particularly important for types with scare data availability: as we indicated above, some types contained only two messages. As previously, the messages from different non-compliance types were exploited to create queries. All of the annotated non-adherence data was used to build the queries. These queries were applied to a large corpus of 20,000 randomly selected messages that contained at least one mention of a drug. The results were evaluated manually computing the Precision, which mainly allows query optimize the queries. This is described in Figure 3.

Figure 3 – Datasets Used for Fine-grained Information Retrieval



Results and Discussion

Table 1– Machine Learning Results Obtained for the Categorization of Messages into the Non-compliance Category

Categorization with Supervised Machine Learning

The results of categorization of messages into the *non-compliance* category, obtained with supervised machine learning algorithms, are presented in Table 1. We tested several algorithms but show only the results for the two best algorithms, Naive Bayes and Naive Bayes Multinomial. We can observe that the best results (up to 0.824 F-measure) are obtained on the lexical lemmas corpus. In all the experiments, Recall is higher than or equal to Precision.

Among the errors observed with NaiveBayes, 12 messages were wrongly categorized as *non-compliant* and 9 as *compliant*. Within these 12 messages, four contained terms associated with excess and negative effects (such as "*Je n'imaginais pas que c'était si grave*" (*I didn't imagine it was that bad*) or "*s'il vous plait ne faites pas n'importe quoi*" (*please don't make a mess*), usually specific to *non-compliance* messages.

Categorization with Information Retrieval

The results obtained with the information retrieval system Indri are presented in Table 2. The evaluation values are computed for the top 10, 20, 50 and 100 results. With lower cut-off (10, 20, 50), the Recall is limited by the efficiency of the system and also by the cut-off. As a matter of fact, the optimal Recall would be 0.112 at 10, 0.225 at 20 and 0.561 at 50, although it is hardly possible to reach such results. With this experiment, the best results (up to 0.529 F-measure) are obtained with the lexical lemmas corpus. Besides, the lemmatization shows an important improvement over the forms corpus, which means that lemmatization is important for information retrieval applications because it provides linguistic normalization of the corpus. As expected, the values of Recall and Precision are improved with the increase in the evaluated sample. Hence, there is more probability that the 89 relevant messages are found among the top 100 messages. With up to 0.5 of Precision, a human user is able to quickly find relevant messages, making this solution usable as an exploration tool. Overall, we can see that this information retrieval system can find non-compliant messages although the results are noisy.

At the fine-grained level, we tested several queries focusing on precise types of non-compliance and misuse of drugs. We will present queries and their results related to important drug misuse situations such as gain and loss of weight, recreational drug use, suicide attempts or ideas, and overdoses. The top 20 results are analyzed for each query. On the basis of messages that convey the expected contents similar to a given query and related to the aimed drug misuses, we can compute the Precision of the results.

Gaining/losing weight. The keywords used were *poids, kilo, grossir, maigrir* (*weight, kilo, gain weight, lose weight*), such as suggested by the manually built reference data. This query was applied to the lemmatized corpus. We expected to find mainly messages related to the use of drugs with the purpose to intentionally lose or gain weight and also some messages related to weight changes due to side effects of drugs. In reality, among the top 20 messages, 17 were about weight change as side effects of drugs, one message was about the use of drugs to lose weight intentionally, and two messages were about weight loss but with no relation to drugs. This means that, among the top 20 messages, only one new relevant message was found. It may correspond to the reality (misuse of drugs for weight changes was less frequent than weight change due to drug side effects) or to the corpus used (several messages were related to antidepressant drugs that have common side effect of weight change). This query gives 0.05 Precision.

Table 2 – Information Retrieval Results for the Categorization of Messages into the Non-compliance Category

	Precision	Recall	F-mesure
	Top 10 Results		
Forms	0.100	0.011	0.020
Lemma	0.400	0.045	0.081
Lexical lemmas	0.400	0.045	0.081

	Top 50 Results		
Forms	0.340	0.191	0.244
Lemmas	0.400	0.045	0.081
Lexical lemmas	0.420	0.236	0.302

		Top 100 Results	
Forms	0.480	0.539	0.508
Lemmas	0.480	0.539	0.508
Lexical lemmas	**0.500**	**0.561**	**0.529**

Recreational drug use. The main purpose was to find messages in which prescription drugs were used with recreational objectives, such as looking for high sensations, hallucinations, sensations of happiness. We tried several queries:

- First, the keywords *drogue, droguer* (*non-medical drug, to take non-medical drugs*) were used. In French, the word *drogue* usually refers to street drugs, and not to prescription drugs. Yet, in the corpus, people use this word for neuroleptic medication particularly, in order to illustrate their feeling that these drugs open the way to addictions and have the same neuroleptic effects as the street drugs. Hence, we could find messages such as "*J'ai été drogué pendant 3 ans au xanax*" (*I was drugged with xanax for 3 years*) or "*Sa soulage mais ses une vrai drogue ce truc !!!*" (*It helps but this stuff is really a drug!!!*) These queries found interesting results (15 out of 20) but provide different insights than those expected;
- The keywords *hallu, allu, hallucination* (*hallucination*) were used. Among the top 20 messages, 2 messages were about intentionally seeking hallucination effects caused by some drugs, 7 messages were about people experiencing hallucinations but as unwanted side effects, 11 messages were about people suffering from hallucinations and taking drugs to reduce them;
- Finally, the keyword *planer* (*to be high from drugs*) was used. Among the top 20 messages, 19 were about the high effect of drugs, be it intentional (9 messages) or non-intentional (10 messages). For instance, "*J'ai déjà posté quelques sujets à propos de ce fléau qu'est le stilnox (...) je prends du stilnox, pour m'évader, pour planer*" (*I already posted a few topics about this plague that is stilnox (...) I take stilnox, to escape, to get high*).

Overall, these three queries related to recreational use of drugs gave 0.35 Precision on average.

Suicide. The keyword used was *suicide* (*suicide*). The query was applied to the lemmatized corpus. We expected to find messages in which people report on taking drugs (like antidepressants) or planning to do that with suicidal intentions. Among the top 20 results, 9 messages were about drugs and suicide with no particular relation between them, 5 other messages were about the fact that some drugs may increase the risk of suicide, 5 messages were critical about the fact that drugs may increase the risk of suicide, and one message reported on a real suicide attempt caused by drug withdrawal. Discussions on relation between drugs and suicide, and of course reporting on suicide attempt, may be important for our research because they represented the importance of these topics in the analyzed fora. This query gave 0.7 Precision.

Overuse. The keyword used is *boites* (*boxes*) because it often represented the quantity of drugs taken, in case of overuse, in the reference data. This query was applied to the *forms* corpus because it was important to preserve plural forms for this query. Among the top 20 messages, six messages were directly related to drug overuse, three messages were related to high dosage that corresponded to overuse, two messages related to the suicide attempts by ingestion of large amounts of drugs, two messages proposed to share unused prescription drugs, and seven messages were unrelated to overuse. This query gave 0.65 Precision.

Comparison of the Two Categorization Approaches

On one hand, supervised machine learning shows better results for the specific categorization task, but it heavily depends on the availability of manual annotations that are costly to produce. On the other hand, information retrieval methods provide lower precision. Yet, manual filtering of the information retrieval results may be less costly than manual annotation of the data. Besides, information retrieval provides results that are more easily understandable and usable by users. Hence, depending on users and availability of the reference data, either of the approaches may be preferred. The Machine Learning method reaches high Recall, suggesting that this method can detect up to 80% of non-adhering patients, provided that they talk about it in the forums.

In relation to small categories (types of misuses, such as those related to drug overuse or recreational use of drugs), supervised machine learning usually performs poorly, while information retrieval may achieve interesting results due to the definition of suitable queries: 0.45 average Precision, and up to 0.65-0.70 Precision for some queries. This may be useful for human users when they want to quickly find relevant messages. We can see that Precision numbers obtained for these small categories are higher than those obtained at the more global level (*compliance* and *non-compliance* categories) and presented in Table 2. This means that more precise and targeted information may be more reliable for the information retrieval process, and also for enriching categories for which there is little data available.

Overall, we assume that these two approaches are complementary: combination of their results may provide an efficient way to enrich the reference data. Besides, the approaches can also be combined: information retrieval queries can bootstrap the enrichment of categories and thus help supervised machine learning to perform better.

Limitations of the Current Work

The main limitation related to the machine learning categorization is the reduced size of the reference data. It contains indeed only 133 messages in the *non-compliance* category. Yet, these reference data allow the creation of quite efficient categorization models, which reach up to 0.824 F-measure. We assume that availability of larger reference data will improve the overall performance of the results. As explained above, one of the main motivations to exploit information retrieval methods is the possibility to enrich the reference data with this unsupervised approach.

Yet, the information retrieval approach requires manual analysis and evaluation of the retrieved messages. As we have seen, at the global level, the increase in size of the top sample improves overall results, but relevant messages are found together with irrelevant messages. When information retrieval is used at a fine-grained level, the results vary according to the types of non-compliance and the keywords used. We propose that information retrieval methods can be used for targeted enrichment of the corpus (for instance for some types of non-compliance), for manual exploration of corpora by health professionals (the results can be easily understood comparing to the results provided by machine learning algorithms), and for combining the results provided by this and other methods.

Another limitation of the work is that messages detected as cases of non-compliance are not currently fully analyzed by medical doctors, pharmacists, or for pharmacovigilance. This

method needs to be packaged into a software application easy to use by medical professionals in clinical settings. On one hand, the messages found further in our experiments permit to have clear insights in the real use of drugs, which is a very important issue that motivates our work. On the other hand, when methods are efficient enough, their results can be used by concerned experts (pharmaceutical industry, public health, general practitioners) to prepare and provide prevention and education actions to patients and their relatives. For example, packaging of drugs can be further adapted to their real use, dedicated brochures and discussions can be done with patients on known and possible drug side effects, and on necessary precautions.

Conclusions

This work presented exposition of two approaches for the detection of drug non-compliance situations in Internet fora. We used the French forum Doctissimo together with other fora to cover several disorders. The messages were first manually assigned to *compliance* and *non-compliance* categories. Automatic categorization with machine learning approach using NaiveBayes showed 0.824 F-measure, while with information retrieval approach using Indri, it showed 0.60 Precision at top 10 results and 0.34 at top 50 results. Information retrieval was also used for a more fine-grained categorization of messages at the level of individual types of non-compliance. Four topics were addressed with different queries suggested by messages available in the reference data. This provided 0.45 average Precision, and up to 0.65-0.70 Precision for some queries, as computed for the top 20 results. We also observed that with information retrieval, precise and targeted categories showed better Precision than the one obtained at a more global level of compliance and non-compliance messages. We considered this as encouraging point for the processing of categories with few messages available. We also proposed some thoughts on combination of two approaches (supervised machine learning and information retrieval) for enriching the reference data and for generating more efficient supervised models.

The main objective of the current work was to enrich the reference data and to work more closely with health professionals for their use.

Acknowledgements

This work has been performed as part of the DRUGSSAFE project funded by the ANSM, France and of the MIAM project funded by the ANR, France within the reference ANR-16-CE23-0012. We thank both programs for their funding. We would also like to thank the annotators who helped us with the manual annotation of misuses, Bruno Thiao Layel for extracting the corpus, Vianney Jouhet and Bruno Thiao Layel for building the list with drugs names, and The-Hien Dao for the set of disorders used. Finally, we thank the whole ERIAS team for the discussions.

Abstract

Clinical research studies often leverage various heterogeneous data sources including patient electronic health record, online survey, and genomic data. We introduce a graph-based, data integration and query tool called Carnival. We demonstrate its powerful ability to unify data from these disparate data sources to create datasets for two studies: prevalence and incidence case/control matches for coronary artery disease and controls for Marfan syndrome. We conclude with future directions for Carnival development.

Keywords:

biomedical research, cohort studies, information storage and retrieval

Introduction

In biomedicine, clinical research studies are conducted to understand how best to prevent, diagnose, or treat disease in patients. A fundamental step to conducting a clinical research study is aggregating data and abstracting facts (i.e., clinical variables and treatment outcomes pertinent for defining a patient population for study). Patient data containing clinical facts (e.g., administrative, clinical, and genomic data) are generated at various points of care, and subsequently are stored across disparate, siloed resources. For example, large academic medical centers may store patient data within clinical registries, electronic health records, document stores, survey tools, and biobanks. Once study data have been integrated, the patient data must then be modeled to accurately represent and classify the patient's clinical case according to each study arm (i.e., case/control). For example, in a matched case/control study design, a clinical researcher might match patients based on age, biological sex, race, and genes, then their clinical data (disease, treatments, and outcomes) might be queried to understand disease progression and/or the effectiveness of therapeutic interventions. More complex match criteria can include periods of time, geographical locations, and environmental exposures. These clinical facts are stored in structured (hospital billing codes, laboratory, and medications) and/or unstructured (clinical notes) data formats.

Integrating such diverse data and aggregating patient clinical facts in a traditional relational database is challenging for several reasons. First, complex relationships of the data cannot easily be modelled into a sufficiently expressive relational schema. Second, complex relationship queries for generating and matching patient cohorts using relational databases could be hindered by suboptimal query responses (e.g., stalled or unfulfilled requests due to multiple-join statements) [1]. Graph databases such as Neo4j have been shown to support both semantic integration of disparate data [2] while improving query times over traditional relational databases such as MySQL [1]. Although graph databases have been used to integrate and represent biological disease networks (protein-protein interactions and drug-target pairs) and represent genotype-phenotype associations, few have demonstrated how graph databases might be leveraged to query heterogeneous data, clinical and genomic, to generate patient cohorts for clinical research studies [3–6].

In this work, we present ***Carnival***, a data unification technology that takes a novel approach — a strictly-formatted property graph database with a data model inspired by the Open Biological and Biomedical Ontology (OBO) Foundry ontologies — towards the integration of disparate data into a unified graph data resource. Carnival leverages this model to support the execution of common investigatory tasks, i.e., patient cohort identification, automated case/control matching, and the production of data sets for scientific analysis. For this work, we aim to 1) provide an overview of Carnival's infrastructure, 2) review a menu of predefined operations that can be combined and stacked to query, integrate, and reason over clinical and genomic data for creating case/control study populations, 3) present two case/control cohorts generated by Carnival, and 4) preview how Carnival will support semantic interoperability and intelligent queries using ontologies, leverage textual variables using natural language processing, and improve its usability with a graphical user interface for wider adoption by clinical research partners.

Methods

We describe the infrastructure, functionality, and utility of Carnival for supporting case/control studies from clinical and genomic data collected from the University of Pennsylvania Health System (UPHS). UPHS includes the first university-owned teaching hospital (Hospital of the University of Pennsylvania est. 1874) and the first hospital in the United States (Pennsylvania Hospital est. 1751). As part of the Penn Medicine BioBank (PMBB), over 60,000 UPHS patients have been consented for their clinical (EHR) and genomic (blood and tissue samples) data to be studied for clinical research. These biological specimens have been whole-exome sequenced by Regeneron Genetics Center and the context of their collection is represented using the Ontology for BioBanking (OBIB) [7]. Carnival leverages data from UPHS sources (e.g., Penn Data Store, a clinical data warehouse) and PMBB to generate datasets for clinical research studies.

Carnival

We describe our graph-based data unification tool named Carnival, so named because Carnival is a party of information and inspired by the squash. Carnival is a multi-layered, Groovy-powered application that includes data source adapters (*vines*) that extract lightly-processed data from their sources, a set of relational database utilities, and caching functions for querying source data, graph data writers (*reapers*) that attach extracted data to the Carnival data store (*graph)*, logical rule engines (*reasoners*) that modify and validate data within the graph, sample stratifiers (*algorithms*) to perform common tasks such as case-control matching, and data writers (*sowers*) that write data to external resources (see Figure 1).

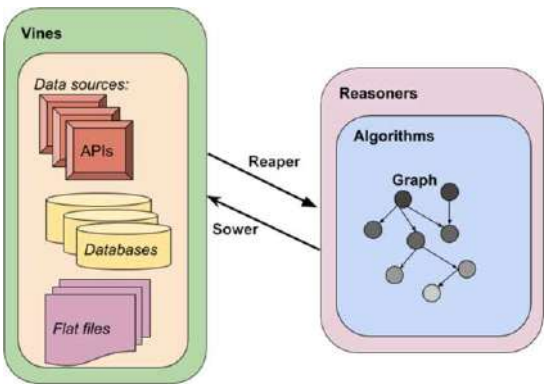

Figure 1– Carnival's Conceptual Framework

Vines

Data are pulled as needed from source systems (i.e., relational databases--Oracle, Microsoft SQL Server), application programming interfaces (API), or flat files (comma-separated value files). Typically, the vine contains methods (functions) that converse with the associated data source in its native language (e.g., SQL, Java, HTTP, etc.) to extract data. Each method produces a single matrix of data. Although there is nothing besides scale issues preventing the wholesale transfer of data from a source to the Carnival graph, vine functions are designed to extract the minimum data necessary for scientific study. For example, a vine for an EHR source might include an ICD Ever/Never method that accepts a set of ICD codes and patient identifiers then returns only the patient identifiers for patients whose medical record was assigned one or more of the ICD codes in the set.

Performing queries against large disparate data sources can be problematic for a variety of technical reasons: 1) connections can be dropped, 2) complex queries can take hours to return a result, and 3) queries that contain long lists of codes or identifiers can be cumbersome to compose. Carnival provides a suite of supportive classes and methods to address these difficulties, including SQL utilities for query composition, automated caching of vine method results, incremental caching to support restartable queries, and monitor threads that estimate time-to-completion of long-running queries.

Reapers

Reapers contain methods that extract data from source systems via vines and attach those data to the Carnival graph in a standardized way. A reaper method may be parameterized to limit its scope and call upon any number of vines to gather source data. The execution of the reaper method itself is recorded in the graph, including the inputs and outputs of the process. For example, an ICD Ever/Never reaper method that accepts a set of ICD codes and patient identifiers would execute a series of tasks: 1) create a vertex in the graph to represent the execution of the reaper method, 2) record the start time, finish time, and input ICD codes, 3) create links to the patient identifiers as inputs, 4) create vertices to represent the ICD Ever/Never status for each patient, 5) link those statuses to the appropriate patients, and 6) create links to those statuses from the execution vertex to mark them as outputs.

Graph

All data about a patient and metadata describing Carnival's processes are represented in Carnival's property graph structure. These highly-connected graphs contain meta information regarding the execution of the reapers, algorithms, and sowers queried and traversed using Tinkerpop-Gremlin and Cypher. We drew upon previous work in ontology modelling as inspiration for the Carnival graph data model: the Ontology for Biobanking (OBIB), the Ontology for Biomedical Investigations (OBI), and the Basic Formal Ontology (BFO) [7–9]. For example, BFO introduces the term Process, which denotes an event that occurs in a time and place. OBI introduces Planned Process, which extends Process to include a pre-defined plan, participants, inputs, and outputs. In the Carnival graph, healthcare encounters are modelled as planned processes, where participants include the patient and clinician and the outputs may be diagnoses and medications.

Reasoners

Reasoners apply logical rules to the graph to make modifications or additions to data. Reasoners execute their logic against the graph to validate that the graph is consistent with the reasoner logic. For example, a reasoner might assign a Boolean classification to patients as having or not having a disease state based on whether they have ever been assigned any of a set of ICD codes. The reasoner logic would check the ICD Ever/Never statuses of each patient and assign the appropriate Boolean disease state classification. The validation functionality might check that no patients have been assigned to both the have-disease and does-not-have-disease classes in the final dataset, which represents a logical inconsistency.

Operational Algorithms

Carnival leverages a graph-based, stratified-sampling case/control algorithm to match case patients with control patients for clinical research studies (i.e., case and control strata groups with equal numbers of males between the age of 35-40). Strata creation is managed by a strata manager class that takes as input the criteria for group partitioning, creates strata and strata group vertices in the graph, and assigns patient vertices to the appropriate groups.

First, the strata sampler groups patients by primary strata. In each stratum, patients are exhaustively grouped into disjoint sets. Strata can be defined along any singular value extracted from a patient: a *numeric* (e.g., current body mass index [BMI]), a *string* (race), a *Boolean* (e.g., FBN1 gene loss of function), or an *enumerated value set* (e.g., the existence of 2 or more ICD codes). Strata can be defined by a range (e.g., 20-29) for numerics and by multiple values grouped into the same strata group for enumerated values or strings. Each stratum also has a group for undefined or unknown values. Second, the cohort matcher then takes as input: patient cohorts for cases, candidate controls, and the primary strata that correspond to the desired matching criteria. The primary strata are combined to make a compound stratification that characterizes the cohorts for matching. For each strata group in the compound stratification, a number of patients in the candidate control cohort are selected as controls

corresponding to the number of patients in the case cohort from the same strata group. Additional criteria can also be provided to prioritize which of the controls within a group would be selected if there are more potential controls than necessary. For example, in a study where specimens associated with the patients will be expended, it may be advantageous to prioritize controls that have more specimens available to maximize the utility of PMBB specimens.

Sowers

Sowers extract data from the Carnival stratified case/control population graph and write it to external resources (e.g., databases, applications, and flat files). Data imported from disparate sources and linked in the Carnival graph may be queried producing data views useful for export to external systems. For example, an investigator may have an approved study that monitors patients who have a specific disease state, the data for which are tracked in a REDCap project. A Carnival sower can query the graph for disease states and write those data to the REDCap project via the REDCap API. In this way, Carnival supports extract, transform, and load (ETL) operations. This functionality can be leveraged to add new patient information (e.g., genomic facts into the EHR).

Clinical Data Elements for Case/Control Matching

Currently, case/control cohorts can be defined and analyzed using several clinical data elements shown in Table 1.

Table 1– FBN1 Controls

Clinical Data Element	Example
Demographics	current age, biological sex, race/ethnicity
Vital signs and risk factors	current BMI, weight, height, blood pressure, smoking status
Medications	administered at a given time or during time window
Specimen collection contexts	age or BMI at the time of specimen collection, medications administered before/after date of specimen collection
Hospital administration	ICD9/10, CPT procedures, DRG codes, and fee codes
Clinical status	death status
Genetic data	loss of function genes

Building a Cohort Using Operational Building Blocks

Carnival contains a number of operational algorithms or building blocks that can be combined to support cohort identification and case-control selection: *graph building, reasoners,* and *patient cohort algorithms*. *Graph building algorithms* aggregate data, via vines and reapers, and attach those data to the graph, examples include:

- Instantiating patients and encounters with identifiers
- Computing phecode assignments according to Phewas.org
- Computing BMI closest to the patient's PMBB recruitment date
- Obtaining the most recent and earliest healthcare encounter for each patient
- Calculating each patient's date of birth
- Gathering each patient's available specimens.

Reasoners operate over data in the graph. To support cohort building, Carnival contains a patient stratification algorithm that assigns patients to specific strata, which currently correspond to their current age and biological sex. A case-control matching algorithm creates a cohort of controls for a predefined set of cases based on a cohort of candidate controls and selected strata. *Patient cohort algorithms* facilitate the creation of patient cohorts and perform set operations on them. Current patient cohort algorithms include:

- Creating a cohort based on a set of identifiers, e.g., medical record number (MRN), enterprise master patient index (EMPI), or encounter identifier
- Creating a complement cohort that contains all patients not in an existing cohort
- Creating a cohort containing all patients who have been diagnosed with any of a set of ICD codes
- Creating a cohort containing all patients who have a loss of function mutation for a given gene.

We describe how Carnival uses clinical data elements and operational algorithms to support two case/control studies leveraging patient data from UPHS and PMBB.

Identifying Markers for Coronary Artery Disease

For the first case/control study, Carnival was leveraged to define the study populations for discovering biological markers for coronary artery disease. In the PMBB, blood specimens are collected at the time of enrollment. *Cases* are defined as patients without coronary artery disease (CAD) codes (410, I21) before enrollment into PMBB, and subsequently, have a myocardial infarction (MI), coronary revascularization, or another CAD event. *Controls* are defined as individuals without CAD codes who have had no MI or CAD events after PMBB enrollment.

Both cases and controls must have plasma and either buffy coat or DNA specimens available. A report of demographic and phenotype data relative to the date of enrollment was requested. Carnival was leveraged to generate the case/control list and report the following patient-specific information:

- Age at PMBB enrollment
- Current age
- Biological sex
- EHR race
- PMBB recruitment location
- Height, weight, and BMI measurement closest to PMBB enrollment
- Count, min, max, and median of lab results for: glucose, fasting glucose, hemoglobin A1C
- Count of distinct dates diabetes codes were assigned before PMBB enrollment
- Code and age of the patient for the first code matching the time filter for the most recent CAD codes before PMBB enrollment, most recent MI code before PMBB enrollment, first MI or CAD code after PMBB enrollment, and first revascularization code after PMBB enrollment.

The principal investigator (PI) manually reviewed the report and patient charts for the final case selection. When patient cases were chosen, Carnival generated two sets of controls. *Control group 1*: a 1:1 control instance matched to the case population on biological sex, current age +- 4 years, BMI closest to enrollment +- 6 points, and recruitment location. *Control group 2:* a frequency control matched to the case population on sex,

recruitment location, current age, and BMI closest to PMBB enrollment.

Defining Marfan Syndrome Study Controls

For this second case/control study, *Cases* were predefined by using the MRNs of patients provided by the PI. *Controls* were defined by Carnival. The Marfan Syndrome gene loss of function data value was critical for defining the control cohort. Candidate control matches were queried from PMBB based on age and biological sex. For each patient, Carnival determined whether a genetic assessment was conducted for the Marfan syndrome FBN1 gene and validated whether the outcome was negative to ensure that all patients within the control set were FBN1 negative.

Results

We leveraged Carnival to generate cohorts for two diseases: coronary artery disease and Marfan syndrome.

Identifying Markers for Coronary Artery Disease

Based on the CAD definitions for prevalence and incidence and specimen availability, Carnival identified 425 candidate case and 5,872 candidate control populations. The principal investigator conducted chart review to create the final 170 selected cases, then Carnival generated the final control groups 1 (n=170 cases) and 2 (n=60 cases) for these cases. Carnival identified a 1:1 case/control match (see Table 2).

Table 2– Coronary Artery Disease Cases and Controls

Sex	Age	Candi-date Cases	Selected Cases	Candi-date Controls	Control Group 1	Control Group 2
Female	<20	0	0	7	0	0
Female	20-29	0	0	486	0	1
Female	30-39	5	2	681	2	1
Female	40-49	8	7	599	6	2
Female	50-59	13	11	731	13	6
Female	60-70	39	20	814	23	3
Female	>70	68	31	450	27	10

Male	20-29	2	2	98	1	0
Male	30-39	3	2	156	2	2
Male	40-49	15	9	272	9	3
Male	50-59	40	24	529	23	5
Male	60-70	92	27	682	30	18
Male	>70	140	35	366	34	9
Totals		**425**	**170**	**5,872**	**170**	**60**

Defining Marfan Syndrome Study Controls

Using the exclusion criteria of patients who are not cases (case distribution not shown) and who do not have a loss of function mutation in the FBN1 gene, Carnival identified a 2:1 control/case match resulting in 146 selected controls (see Table 3).

Table 3– Marfan Syndrome Controls

Sex	Age	Selected Controls	Candidate Controls
Female	20-40	2	294
Female	40-50	12	300
Female	50-60	10	667
Female	60-70	18	1154
Female	>70	20	1718
Male	20-40	4	175
Male	40-50	12	343
Male	50-60	12	1004
Male	60-70	26	1892
Male	>70	30	2627
Totals		**146**	**10,174**

Discussion and Future Work

We demonstrated how Carnival's multi-layered framework, OBO foundry-inspired data model, and graph-based functionality can be leveraged to generate case/control matches and resulting datasets using PMBB and UPHS sources for two clinical research studies. We envision expanding Carnival's functionality 1) to improve semantic integration and intelligent query of data using ontologies, 2) to incorporate clinical data elements generated from clinical texts, and 3) to create a user-friendly interface to promote wider adoption of this tool by clinical research partners.

Improve Semantic Integration and Query using Ontologies

Carnival is a graph-based query tool that operates at the data level. We have partnered Carnival with TURBO technologies to provide richer semantic integration and reasoning among clinical data elements [10]. For example, patient diagnoses are currently defined using logical rules that operate over discrete diagnosis billing codes (e.g., ICD9 or ICD10). A single code rarely encapsulates a diagnosis for investigative purposes. Furthermore, compiling a list of diagnosis codes relevant to a particular disease or disease classification can be a daunting task. To accurately identify a diagnosis, TURBO has integrated ontologies (e.g., Monarch Disease Ontology) [11], to semantically link ICD codes to disease concepts. To provide semantic information services (i.e., returning a set of ICD diagnosis codes for a given disease classification), we have integrated Drivetrain [12], a TURBO technology that uses an RDF triple store and OBO Foundry ontologies [13]. This integration has permitted Carnival to operate at both the disease classification and diagnosis code levels.

Medication prescriptions have similarly benefitted from integration with Drivetrain. The Chemical Entities of Biological Interest (ChEBI) ontology [14,15] contains a rich semantic network of medication names, ingredients, and roles that Drivetrain links with medication order names in the UPHS EHR. Carnival operates over these elements, obviating the need for investigators to spend time deciphering individual medication order names. We aim to provide semantic integration over laboratory test results as well, when Drivetrain services for lab results become available.

Incorporate Clinical Data Elements from Clinical Notes

A wealth of clinical facts are locked within clinical free-text notes (e.g., discharge summaries, progress notes, radiology exams, and surgical pathology reports) [16]. We aim to integrate outputs from natural language processing tools including symptoms, signs, treatments, outcomes as well as their associated contexts

(negation, subject, temporality, uncertainty) to provide a richer clinical profile to infer each patient's disease state [17–21]. We will leverage the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM) to promote interoperability with entities both within and outside UPHS.

Create a User-Friendly Interface to Promote Adoption

The current implementation of Carnival leverages server-side technology. There is currently a text-based command line interface that supports basic operations. Future work will include the addition of a web-services API and a browser-based Javascript user interface [22]. We will integrate Neo4j-based user interfaces to the graph (e.g., Neo4j Browser) [23]. We will also employ Javascript libraries (e.g., D3) [24] for graph visualization and user-driven data exploration.

Conclusions

We conclude that graph-based technologies can be utilized to integrate and query disparate patient health data to support complex, clinical research studies.

Abstract

Assessing a patient's risk of an impending suicide attempt has been hampered by limited information about dynamic factors that change rapidly in the days leading up to an attempt. The storage of patient data in electronic health records (EHRs) has facilitated population-level risk assessment studies using machine learning techniques. Until recently, most such work has used only structured EHR data and excluded the unstructured text of clinical notes. In this article, we describe our experiments on suicide risk assessment, modelling the problem as a classification task. Given the wealth of text data in mental health EHRs, we aimed to assess the impact of using this data in distinguishing periods prior to a suicide attempt from those not preceding such an attempt. We compare three different feature sets, one structured and two text-based, and show that inclusion of text features significantly improves classification accuracy in suicide risk assessment.

Keywords:

Suicide, Risk Assessment; Natural Language Processing

Introduction

Suicide is a serious public health problem, with almost one million people ending their lives worldwide each year [1]. In the United Kingdom, although suicide rates have dropped slightly since the early 1980s, in 2017 the Office for National Statistics nevertheless registered 5,821 suicides [2]. More than a quarter are in receipt of mental health services at the time of death [3], yet suicide risk remains immensely difficult for clinicians to assess, given the wide range of contributory factors, with the majority (88%) judged to be at 'low or no immediate risk' of suicide by clinicians at their final service contact. Current clinical methods for assessing when someone is at risk of a suicide attempt have been reported to be little better than chance [4]. New approaches to individualised risk assessment that integrate data from different sources are needed. With the availability of population-level patient data in the form of electronic health records (EHRs), novel methods for suicide risk assessment based on data mining and machine learning have been explored in recent years [5]. Indeed, machine learning models can capture complex associations between variables, making them particularly well-suited to the task of predictive analysis.

Different approaches to modelling the problem of suicide risk assessment have been explored. Several recent studies have focused on developing models that detect the suicide risk of individual patients in large historical population samples. For instance, Barak-Corren et al. (2017) trained a Naïve Bayes classifier on a cohort of more than 1.7 million patients (16,588 of whom had recorded suicidal behaviour) using a rich set of structured EHR features, including demographic, diagnostic, procedure and medication data [6]. Simon et al. (2018) combined structured EHR data and standard health questionnaire responses in a logistic regression model to predict suicide attempt and death in a cohort of nearly 3 million patients [7]. Similar work has also been carried out using state-of-the-art neural networks. For example, Bhat and Goldman-Mellor (2017) trained neural network classifiers on historical structured EHR data to detect the presence of a suicide attempt by individual patients in a given year [8].

A common factor in the aforementioned work and, more generally in the majority of research using machine learning for suicide risk assessment, is that it has relied exclusively on features derived from the structured fields of EHRs. However, much valuable data about patients is stored in EHRs as unstructured text [9]. To date, relatively little research on suicide risk has been done on mining this rich data source for features, although momentum is building. For example, Metzger et al. (2017) tested a series of machine learning classifiers to determine the prevalence of suicide-related emergency department admissions in a French hospital [10]. They used structured EHR data, as well as features extracted from clinical notes. Ben-Ari and Hammond (2015) performed a text search to identify Gulf War veterans who have made a suicide attempt [11]. They then used textual and structured features with a Random Forest classifier to predict first suicide attempts by patients in this cohort within a given year. McCoy et al. (2016) also used text-based features along with structured EHR data to gauge suicide risk after discharge [12]. They used an "off-the-shelf" Natural Language Processing (NLP) tool to extract the polarity of valence-conveying words (positive or negative) within the records and used this in regression models, finding that positive valence words were correlated with reduced suicide risk. Downs et al. (2017) used NLP to identify suicide-related mentions in a cohort of adolescents with Autism Spectrum Disorder, including a previously-developed negation detection module [13, 14]. Finally, Fernandes et al. (2018) used NLP to identify and classify mentions of suicidal ideation and suicide attempts in mental health records [15].

Methods

Classification for Suicide Risk Assessment

Most epidemiological case-control studies have used data spanning much wider time periods, typically years, and the risk factors have either been static (e.g., male gender, family history of psychiatric disorder) or lifetime ever variables (e.g., previous attempted suicide, any misuse of alcohol or drugs) [16]. In this study, we take a rather different approach, exploring whether it is possible to predict suicide attempts by building classification models based on structured and textual data from the 30-day period leading up to the event, when

there is an opportunity to intervene as it can be a time of crisis. To the best of our knowledge, our approach is novel in using this critical time period. We tested a machine learning classifier to distinguish the 30-day periods prior to a hospital admission linked to a suicide attempt (hereafter referred to as 'suicidal window') and similar periods not preceding a suicide attempt from age- and sex-matched control patient records ('non-suicidal windows') extracted from a large database of EHRs. We used a linear-kernel Support Vector Machine (SVM) [17] classifier given this algorithm's well established performance in dealing with the high-dimensionality of text data [18]. We modelled the task using supervised binary classification. A further novel aspect of our work lies in our assessment of the impact of three different sets of features, namely, structured fields from the EHRs, a rich set of binary features derived from the clinical notes, and a bag-of-words representation of the full text of these same documents.

CRIS Clinical Cohort

We studied the de-identified EHRs of over 250,000 patients from the South London and Maudsley (SLaM) NHS Foundation Trust using the Clinical Record Interactive Search (CRIS) computer system comprising both structured data and over 3.5 million text documents [19]. Data from CRIS has been linked with the UK Hospital Episode Statistics (HES) data for Admitted Patient Care within a secure 'safe haven', and it is through this linkage that admission information was extracted. The documents in CRIS have been substantially enhanced, in particular, through the application of NLP (e.g. to identify symptoms) [20].

Our dataset was derived from the EHRs of 17,640 patients. It consisted of 21,175 suicide-related (case) and non-suicide-related (control) admissions, sampled according to a 1:4 case-control ratio. Cases were defined as any admission (acute physical or specialist mental health) where there was a suicide attempt (indicated by the presence of any of the following ICD codes: X6*, X7*, X80-4*, Y1*, Y2*, Y30-4*, Y87*) with the admission lasting at least 24 hours (starting and ending on different dates). Only admissions with a start date after the 1st of April 2006 and an end date before or including 31st March 2017 were considered. Of these case admissions only those which had at least 1 document in the 30 days prior and including the date of the hospitalised suicide attempt were retained. We also removed admissions with empty documents[1]. This left a total of 4,235 suicide-related admissions in the final dataset. Each control was matched by sex, had to be alive at the admission start date of the case, and were grouped into the same age group as cases (5 year age bands < 16, 16-19, 20-24 to 80-84, 85+ years). Each control also had at least one document in the 30 days prior to and including the date of their matched case's hospitalised suicide attempt. The total number of controls was 16,940. The controls were chosen to be as representative as possible of the population from which the cases were drawn and the ratio was based on the epidemiological principle that little statistical power is gained by further increasing the number of controls beyond approximately 4 per case [21]. Key descriptive characteristics of the dataset are shown in Table 1.

Features for Classification

Features examined included standard sociodemographic and clinical descriptors selected by a clinical academic psychiatrist (RD) *a priori* (e.g. ethnic group, marital status, employment status), as well as those shown in prior work to be associated with suicide attempts (e.g. past and current substance abuse) [22]. We used 14 (categorical) features from structured fields of the EHRs, including total document counts for the 30 days prior to but excluding the day of admission, based on the hypothesis that the volume of documentation would increase prior to a risk event such as a suicide attempt due to greater service use. We also included features derived from NLP applications routinely run on CRIS. Most of these applications are built using GATE, an open source NLP toolkit [20, 23]. All of these applications combine both rule-based pattern matching algorithms and supervised machine learning models, and some detect contextual information, such as negation or family history. We derived 68 binary features from these, one per application, each feature indicating the presence or absence of at least one match by the application on at least one document in the window, excluding the admission date. Applications included the detection of positive mentions of suicide attempt by the patient, mentions of the patient having disturbed sleep, and feelings of hopelessness and paranoia, to cite a few. Finally, we also included as features the concatenated text from all documents in each window, excluding the admission date, represented as a TFIDF (term frequency-inverse document frequency) vector or "bag-of-words". TFIDF is a statistical weighting that reflects how important a particular term is in a given document in a collection, adjusted for the fact that some words occur more frequently than others [24]. When calculating word vectors, we applied the L2-Norm [25] to scale the vectors to unit length. This compensates for discrepancies in document length, such as those in our dataset. The total number of unique words in our document set was 201,538, making it a high-dimensional feature space.

	Cases	**Controls**
Patients	2,913 (16.5%)	14,727 (83.5%)
Female	1,730 (59.4%)	8,971 (60.9%)
Male	1,183 (41.6%)	5,756 (39.1%)
Admissions	4,235 (20%)	16,940 (80%)
Female	2,598 (61.3%)	10,392 (61.3%)
Male	1,637 (38.7%)	6,548 (38.7%)
Mean age (SD) years	34.4 (15.3)	34.4 (15.4)
EHR features for 30-day pre-admission windows		
Mean tokens (SD)	3455.5 (5732.4)	1344.5 (3179.9)
Total tokens	14,634,223	22,775,227
Mean docs (SD)	16.9 (31.4)	7.5 (18.1)
Total docs	71,404	127,047

Table 1: Characteristics of the dataset for suicide attempt related cases and non-suicide-related controls. Note that each window for EHR features is a 30-day period prior to the case admission date (inclusive).

Henceforth, we refer to the set of structured data as STRUCT, the text-based features derived from NLP applications routinely run on CRIS as GATE, and the bag-of-words features as TFIDF. For STRUCT and GATE, we encoded all features either as integers (e.g. age, marital status, employment status) or binary (0 or 1) values (e.g. sex, presence of the keyword *depression*). We list details of all 82 features in an online annex[2].

Results

Experimental Setup

We randomly split the data into a training set (80%) and a test set (20%), ensuring the distribution of each class was the same across both sets (i.e., 1 case to 4 controls). The test data was held out until the final run in order to reduce the risk of overfitting and to provide a realistic estimation of performance on unseen data. We scaled all features to have zero-mean and unit-variance to ensure a balanced contribution of all features. We implemented the classifier and prepared data using the Scikit-learn (version 0.20.0) machine learning library for Python [26]. Our first step was to estimate the optimal parameters for the classifier (model tuning). We did this using grid search and ten-fold cross-validation on the training data, with F1-score as the evaluation metric[3]. F1-score is the harmonic mean of precision (positive predictive value) and recall (sensitivity), a metric often used in information retrieval and NLP [27]. For each tuning instance, we varied the feature set so as to tune the models to each representation of the data. This resulted in 7 different feature combinations: STRUCT, GATE, TFIDF, STRUCT+GATE, STRUCT+TFIDF, GATE+TFIDF, STRUCT+GATE+TFIDF. A flowchart of the general architecture is provided in the online annex. To gauge whether the differences in pairwise comparisons of feature sets were statistically significant, we used McNemar's test [28] (α=0.05) for classification disagreements on the training dataset.

Finally, we examined the text features that were most significant in distinguishing the two classes. For the final run on the held-out test data, we calculated the F1-score for the suicidal and non-suicidal windows and the mean of both.

Intensity of Documentation

As shown in Table 1, the mean number of documents for cases during the 30-day window is 19.9 (SD=34.0) and a lower 8.3 (SD=19.4) for controls. This divergence in mean document counts for each class supports the decision to include the number of documents in a window as a feature for classification. See Feature Importance for further comments.

Classification

In this section, we present results obtained on the held-out test data for each of the different feature sets. We report performance in terms of precision (P), recall (R) and F1-score (F). Where we make a comparison of results obtained on two feature sets, we also report the *p*-value of McNemar's pairwise test between them. Although we calculated figures for each of the two classes (suicidal windows and non-suicidal windows) separately, we are only interested in assessing the identification of suicidal windows. The correct classification of non-suicidal windows was relatively much simpler given the prevalence of this class in the dataset (mean F1-score for this class was 0.86, SD=0.08). Therefore, the figures we report are for suicidal windows only.

The classifier's performance using only structured features (STRUCT feature set) was relatively low (P=0.26, R=0.59, F=0.36). This increased with the addition of features extracted by GATE (STRUCT+GATE feature set) (P=0.49, R=0.58, F=0.53, p<0.001). However, best performance was obtained with the addition of the bag-of-words features (STRUCT+GATE+TFIDF feature set) (P=0.61, R=0.63, F=0.62, p<0.001), showing a good balance between precision and recall. Interestingly, bag-of-word features alone (TFIDF) provided the next best results (P=0.59, R=0.61, F=0.60, p=0.0042), only slightly lower than the combination of all feature sets, suggesting the importance of the bag-of-words representation. The use of GATE features on their own performed less well (P=0.50, R=0.57, F=0.54, p<0.001). This indicates that the TFIDF features captured a signal in the data

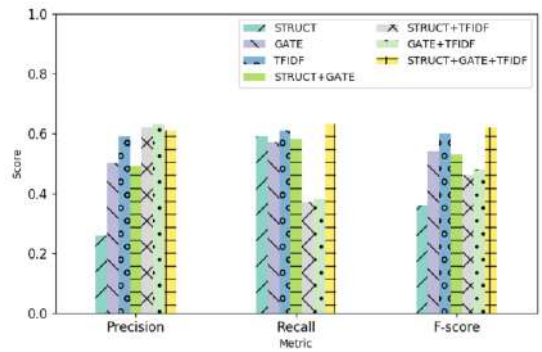

Figure 1 – Performance on the positive class (suicide attempt) in terms of precision (P), recall (R) and F1-score (F) on the test set for all feature sets.

that the targeted NLP applications did not. Using the combination of GATE features and bag-of-words (GATE+TFIDF), recall was heavily penalised, resulting in a significant reduction to the model's F1-score, despite increased precision (P=0.63, R=0.38, F=0.48, p<0.001). The combination of structured and bag-of-words features (STRUCT+TFIDF) provided a significant improvement over structured features alone (P=0.62, R=0.37, F=0.46, p<0.001), but also with a sharp increase in precision to the detriment of recall. Figure 1 provides a visual comparison of these results while Figure 2 shows a summary of all pairwise McNemar's tests across all feature sets.

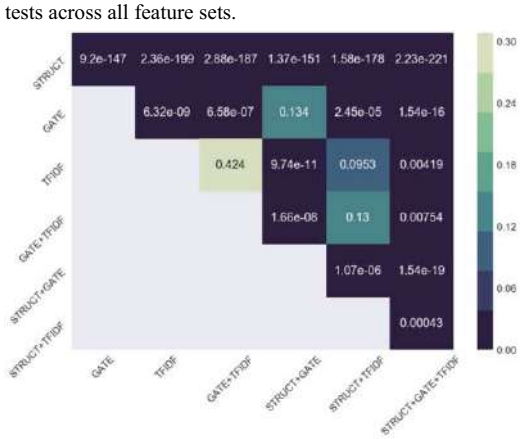

Figure 2 – Full results of pairwise McNemar's tests across feature sets on the training data. Cells show p-values (α=0.05), dark cells are more statistically significant, while lighter cells indicate the converse.

Feature Importance

During training, the (linear) SVM calculates a maximum-margin hyperplane to separate (as much as possible) the two classes in the data. The feature weights representing the coordinates of the vector orthogonal to the hyperplane are stored and their direction indicates the predicted class. We

[3] All tuning parameter ranges and the final tuned configurations are provided in the online annex.

compared the values of these weights for each of the feature sets. The number of documents within the window is among the top-ranking features in the STRUCT feature set, indicating the importance of this feature in discriminating between classes. The most discriminating feature in the GATE feature set was the presence of a positive mention of a suicide attempt by the patient. These were also the top features in the STRUCT+GATE feature set. The top two features for the TFIDF feature set were the words *overdose* and *self-harm*, while other words, such as the adjective *suicidal*, and the medication names *paracetamol* and *zopiclone*, ranked among the top 15 discriminating features. More diverse keywords, as well as other features, ranked highly when TFIDF was combined with either STRUCT or GATE, or both. Given these results, we quantified and visualised the relative frequency of these terms within the texts of the suicidal and non-suicidal windows. To offset the imbalance in the dataset (differing mean number of tokens between the two groups) we calculated per-token frequencies for each day and divided term counts for control by 4 (to adjust for the 1:4 case-control ratio). Figure 3 shows a comparison for the term *overdose*. Mentions of this term are approximately four to six times more frequent for cases than for controls across the 30-day window. Plots for the other aforementioned terms showed the same trend. These preliminary findings on the TFIDF feature set suggest that significant mentions of suicide-related behaviour (overdose, self-harm, etc.) have been recorded in the suicidal windows, but not in the non-suicidal windows. Furthermore, despite the relatively low per-token frequency of the significant terms, the TFIDF weighting allowed for these to be picked up as important features by the classifier. A more in-depth and systematic examination of the occurrences of these terms would establish whether they represent independent suicide attempts that are not recorded using ICD codes in the HES data linked to the EHRs. Nevertheless, these preliminary results support the use of such word features in classification to inform suicide attempt risk assessment.

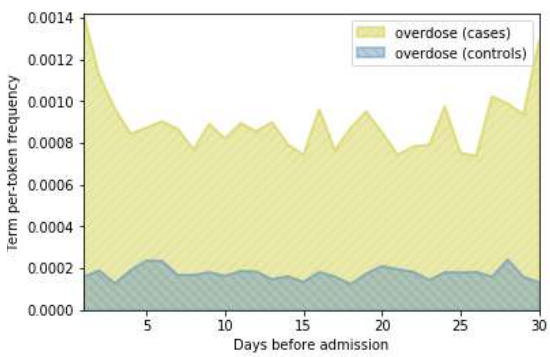

Figure 3 – Normalised relative per-token frequency of the term "overdose" for suicidal (case) and non-suicidal (control) windows.

Discussion

Using a case-control study design, we carried out an exploratory experiment on binary text classification to assess how this might help to inform suicide risk assessment. We evaluated the relative contributions of three different types of features, namely structured data, binary features derived from NLP applications routinely run on CRIS, and a TFIDF bag-of-words representation. Our results show that the use of text features significantly improves classification results, and the combination of structured and text-based features provided the best performance. An examination of the top textual features used in classification revealed the importance of certain terms for discriminating suicidal and non-suicidal windows.

The variety of ways in which the suicide risk assessment task has been modelled previously, including differences in data sets, algorithms and features, makes meaningful comparison of results between studies difficult and such was not the aim of this work.

Despite interesting results, clearly this work does have limitations. Firstly, the 14 structured features were selected to represent only a small sample of all available structured data. This means that although these features are clinically relevant for assessing suicide risk, certain features with less complete data were not tested. A broader selection of structured data may have led to better results with the STRUCT feature set. Another drawback lies in the two representations we used for the textual features. The binary (GATE) feature set is unable to account for the relative frequencies of identified terms. Thus, a single match by an application has the same "weight" as multiple matches in the document set. Although the TFIDF bag-of-words representation addresses this weakness, it does not capture the order and combination of words (e.g. multiword expressions such as *suicidal ideation*), or phenomena such as negation (e.g. *no suicidal ideation*). Furthermore, our bag-of-words approach did not enable us to distinguish terms relating to the patient from those concerning other people (e.g. *family history of suicide, father took an overdose*). Whilst this was accounted for to some extent in the GATE features, more nuanced and targeted NLP could improve performance.

Conclusions

We have shown that the inclusion of text features in classification to inform suicide risk assessment using EHR data provides a statistically significant increase in performance over a dataset containing only structured data. Including the text allows access to word features that appear to be potential markers of impending suicide risk (*overdose, self-harm, suicidal*) that are also clinically plausible. Strikingly, the intensity of documentation within the 30-day period prior to an event may also be a significant factor in determining times of increased risk.

Abstract

The aim of the study was to build a proof-of-concept demonstratrating that big data technology could improve drug safety monitoring in a hospital and could help pharmacovigilance professionals to make data-driven targeted hypotheses on adverse drug events (ADEs) due to drug-drug interactions (DDI). We developed a DDI automatic detection system based on treatment data and laboratory tests from the electronic health records stored in the clinical data warehouse of Rennes academic hospital. We also used OrientDb, a graph database to store informations from five drug knowledge databases and Spark to perform analysis of potential interactions betweens drugs taken by hospitalized patients. Then, we developed a machine learning model to identify the patients in whom an ADE might have occurred because of a DDI. The DDI detection system worked efficiently and computation time was manageable. The system could be routinely employed for monitoring.

Keywords:

Computing Methodologies, Drug Interaction, Machine Learning.

Introduction

Drug-drug interactions (DDIs) are a critical issue in patient care because they can lead to adverse events and ultimately increase care costs and patient mortality. Therefore, these events must be identified and prevented as early as possible [1]. However, many new drugs are released each year, and therefore, it is very difficult for healthcare professionals to be informed and to consider all DDIs. Moreover, the alarm functionalities of drug computerized physician order entry (CPOE) systems are frequently not used because they do not focus on clinically relevant DDIs and lead users to alarm fatigue. Although focused on specific interactions, studies on DDI prevalence show the existence of risks for polymedicated patients and highlight the importance of pharmacovigilance programmes [2,3].

With the unprecedented development of digital health and hospital clinical data warehouses (CDW), data produced during the healthcare process are now easily reusable [4]. Electronic health records (EHR) contain real-time information on drug prescription/regimens during hospitalization as well as all clinical information. Such data could be analysed to estimate DDI prevalence, to facilitate health professionals' practice assessment and to detect the occurrence of DDI-linked adverse drug events (ADE). In France, pharmacovigilance currently relies mainly on the spontaneous reporting by physicians or/and detection of diagnoses that could be related to ADE from the hospital billing system (diagnosis related group, DRG, database). New data sources, such as national claim databases, are also leveraged to improve DDI and ADE detection [5,6]. EHR data-mining also could help pharmacovigilance professionals to improve drug safety assessment.

All these health-related databases fit perfectly with the big data paradigm because they contain voluminous, highly complex and heterogeneous information that is produced in real time [7]. In the last few years, many big data technologies have been developed. However, their implementation in a hospital information system for processing healthcare big data in real-world condition of use is still largely uncharted.

Here, we describe a method, which propose to use big data technology to improve drug safety monitoring in a hospital and could help pharmacovigilance professionals to make data-driven targeted hypothesis on ADEs.

Methods

Figure 1 presents the overall approach of the study and the big data technologies used in each step.

Patient Data

We used the Rennes academic hospital EHRs that are stored in a CDW called eHOP (entrepot HOPital). This CDW includes both structured data (e.g., laboratory results, drug prescriptions and regimens) and unstructured data (e.g., operative reports, discharge summaries), and is dedicated to data reuse for clinical research [8]. The eHOP's star schema architecture and graphic user interface allows researchers, even without any database language knowledge, to quickly access and efficiently search information within millions of patient records.

For this study, we used information about drug administrations (used drug(s) and regimens) and laboratory results (date, nature of the test and results: normal, abnormally high, or abnormally low).

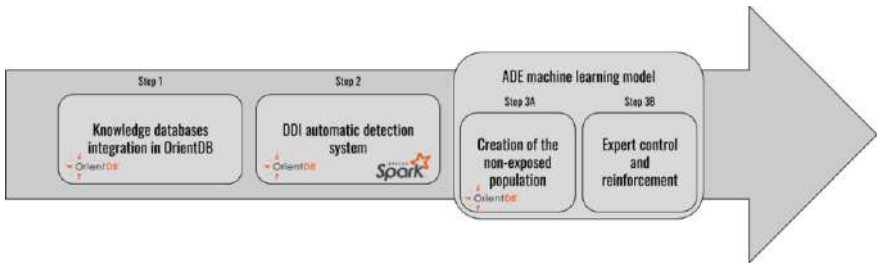

Figure 1 - Overall approach of the study

Knowledge Databases Integration (step 1)

To identify and collect information on potential DDIs, and also to compare information from different sources, we selected five drug knowledge databases: Thesaurus, Vidal, Theriaque, Micromedex and Drugs.com [9–13]. These databases are commonly used by health professionals, but are not specifically targeted to DDI detection. They are available via a web application programming interface (API) that requires a specific procedure because each database stores data with its own structure. To avoid this, we extracted the relevant information from these databases and stored it in OrientDB, a graph-oriented model database [14] that fits well with our objective because a DDI can be modelled as an edge between two drugs. Thus, once the information is stored in a single OrientDB database, no more computation is required to access such information.

DDI Automatic Detection System from Patient Records (Step 2)

For DDI identification, we collected drug data from the patient EHRs stored in eHOP and computed the active interval (i.e., the period during which a drug was effective) for all drugs taken by a patient during the hospital stay. If two active intervals overlapped (fully or partially), then analysis of the data collected in the OrientDB database allowed determining whether the two drugs interacted. In this case, the potential DDI event was stored in eHOP. As these are independent processes (each drug pair is checked independently), the Spark cluster-computing framework was used to perform distributed computing [15,16]. As all the potential DDI events can be stored in eHOP, then we could compute the prevalence of a DDI for any specific drug, molecule, or population.

Creation of a Machine Learning Model (Step 3a)

The data stored in the CDW eHOP do not allow direct confirmation of whether a patient reported a DDI-linked ADE or not. Indeed, this needs to be validated by the pharmacovigilance experts who do not have the proper means to check all the patient records. Therefore, we wanted to create a system to report to drug safety professionals only the most interesting cases among all DDIs detected by the DDI automatic detection system (i.e., patients in whom an ADE might have occurred because of a DDI).

We assume that laboratory results will change if an ADE occurs. So, we can train a machine learning model with two populations: those who experienced an ADE and those who did not. Unfortunately, we cannot identify manually who experienced an ADE. For this reason, we performed one of the research design presented by Hennessy et al. [17]: we choose to compare the population exposed to a DDI with another population non-exposed to this DDI and who did not experience an ADE, by design. There are likely many patients who do not experience an ADE in the exposed population, but the model will present only the most suspected cases and this problem will be solved with the gradual feedback of drug safety professionals: the system will adjust weights of patients in the model, giving a greater weight to the well-predicted patients.

We developed an artificial neural network system that allows us to predict an output. This system has a single hidden layer and the number of perceptrons was decided during cross-validation. Our machine learning model works in two phases. First, it uses all data available for patients who experienced a specific DDI and those who did not (exposed and non-exposed populations) to classify them as having reported an ADE or not. Then, the model is reinforced with information coming from drug safety professionals who infirm or confirm the previous classification (Fig. 2).

We then had to form the non-exposed population. Within a DDI, we called "Object" the drug under study, and "Precipitant" the other drug. Moreover, we called "Control-precipitant" any drug that has the same therapeutic use as the Precipitant, but that does not interact with the Object. For a given Object, we compared the exposed population, found with the DDI automatic detection system, to the non-exposed population. The non-exposed population included all patients, who were not in the exposed population and who had an overlap (fully or partial) between the action interval of the Object and of the Control-precipitant. We created this non- exposed population using the same process as for the exposed population.

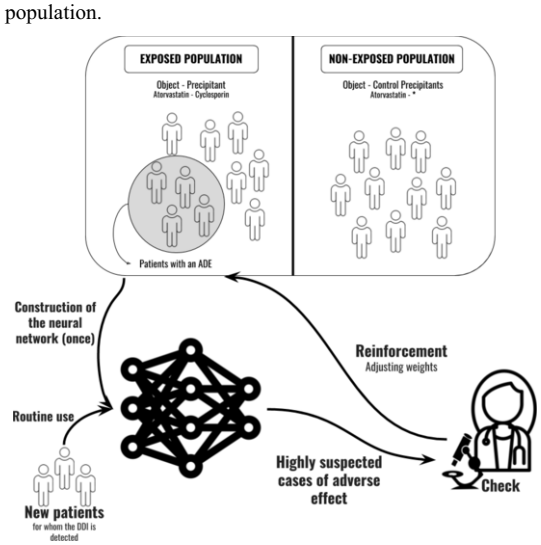

Figure 2 - Creation and use of the artifical neural network

Data processing was performed with Java 8, Spark 2.10 and OrientDB 2.2.4 on Intel(R) Xeon(R) CPU E5-2609 1,90GHz computer with 32,0 Go of RAM.

Big Data Technologies: Convenient Tools for Complex Data Processing

Here, we proposed a complete automated data treatment system, from the collection of heterogeneous data to their enhancement in a machine learning model. This system can monitor DDI prevalence and try to identify patients with a possible DDI-linked ADE, without the intervention of drug safety professionals. To achieve this, we used several convenient tools:

OrientDB is an easy-to-use tool to store pre-computed data. The OrientDB database model includes two main classes: vertices and edges that connect two vertices. In our study, the "vertex" interface represented the class "Drug" and included drug name, ID-code and half-life. The "edge" interface represented the class "Interactions" and included DDI severity level. We also specified from which drug database the information on the DDI came. Thus, via OrientDB, each drug knowledge database can be interrogated separately. The "edge" interface is also used to represent the class "Control-precipitant".

Figure 3 presents the database model through an example: Drug1 has an interaction with Drug3 according two different databases (two edges of class "Interaction"). Let consider the Object-Precipitant couple Drug1-Drug3, then Drug4 is a control-precipitant of Drug3 (one oriented edge of class "Control-precipitant"). An example of query would be: "give all the drugs that have an interaction with Drug1 according Micromedex and where the severity level is 1".

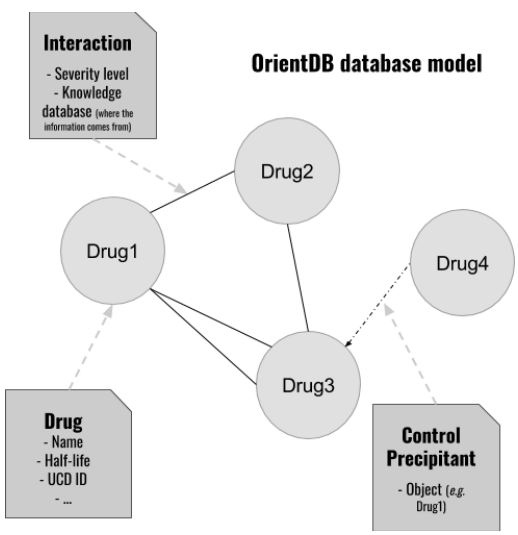

Figure 3 - OrientDb database model

The query language was very close to the structured query language (SQL) and allowed searching a vertex that walks along edges to another vertex, according to the chosen conditions. Data uploading is fast and based on a convenient Java Graph API. We manipulated a graph Java object that is automatically committed at the end of the process. Moreover, if access to a part of the graph is required (e.g., all the drugs that interact with pravastatin according to a severity level of 2), we used this object as a temporary store before processing.

Switching between different knowledge databases, stored in the same OrientDB database, involves only a variable on an edge. Ultimately, the little amount of time spent for the pre-calculation facilitates the storage and the access to multiple data sources. Only one kind of request is needed for all five databases. We could easily add information from other data sources (for example, composition of a drug and half-life of the active substances), or more precise information about DDI-linked ADEs (such as the relevant laboratory tests). Nevertheless, this task demands a manual work for each group of drugs [18].

Spark allows parallel processing easily. As many processes are independent from each other, their parallel treatment with Spark leads to a big time saving[19].

Evaluation (Step 3B)

To evaluate our DDI detection system (step 2 in Fig 1), we focused on a class of drugs called statins that are prescribed (long-term treatment) to patients with cardiovascular diseases, and particularly to elderly patients who are usually polymedicated and consequently prone to DDIs. We selected the study population (i.e., all patients taking statins) from all patients included in eHOP from January, 1 2015 to July, 8 2016. It included 10,506 hospitalized patients with a median hospitalization of 7 days, and a median age of 72 years (range: 19 to 98 years).

We defined statins as the "Object" and all the drugs that interact with them were considered as candidate "Precipitants". We selected as Control-precipitants (symbolized by * in fig 3) all the drugs that are in the same fifth level (i.e., chemical substance) as the Precipitant in the Anatomical Therapeutic Chemical (ATC) classification [20], but do not interact with the Object. Thus, Control-precipitants have the same (or a similar) therapeutic usage as the Precipitant. We stored all these data in OrientDB because each DDI is a link (i.e., edge) between drugs (i.e., two vertices).

Concerning the action intervals, we chose a period of seven half-lives for each statin molecule and arbitrarily selected one day for the Precipitant, because this information could not always be extracted automatically from the five drug knowledge databases.

To determine how well the machine learning model can identify patients who may have a DDI- linked ADE (step 3B in Fig 1), we evaluated the model prediction error using the out-of-bag (OOB) error method: several models are built with a bootstrapped dataset, the OOB error is the mean of the errors computed with non-used data in each model.

The neural network gives the probability to belong to a class. We used cross-validatin resampling to optimize the threshold separating the two class. We chose to study a specific DDI in which atorvastatin was the Object and cyclosporine the Precipitant (i.e., exposed population). The non-exposed population consisted of patients who took atorvastatin and a Control- precipitant (Fig 3). The used variables were: demographic data, pathologies (ICD-10 codes) and laboratory test results. We used all the laboratory test results included between the beginning of the event and 3 days later. If a laboratory test appeared more than once, we took the mode of the results.

The reinforcement phase was not evaluated because it is currently under construction in collaboration with drug safety specialists.

Results

DDI identification with the automatic detection system was very fast due to the use of a graph- oriented model. For instance, for the simple query "is there an interaction between these two drugs?", or the more complex query "select all drugs that interact with this specific drug", the OrientDB database was always faster (less than 20ms) than the Theriaque SQL database (several seconds). Moreover, switching to another drug knowledge database was very easy with OrientDB because it only needed to change a condition in the query (which database = 'Theriaque').

The time required to create these graph databases was reasonable: for instance, the information coming from the Theriaque database, which is equivalent to 18,800 vertices and 23 million edges, was integrated in one hour. Afterwards, data access was immediate.

Once the OrientDB database was ready, from the eHOP CDW, we checked the DDI occurrence for all drug couples in the study population. To this aim, we computed all the fully or partially overlapping action intervals for all drug couples involving a statin. For each patient, we visualized all the detected DDIs: between 22.5% and 52.2% (depending on the drug knowledge database) of the 10,506 patients who were taking statins presented at least one DDI involving a statin.

Computation time was reduced with the use of the Spark framework: the processing time of 800,000 rows of patient records decreased from 60 minutes initially to only 12 minutes with Spark.

To test the ADE prediction performance of the machine learning model, we then focused only on one specific DDI (atorvastatin-cyclosporine) to create the training sample. We could identify 102 patients with atorvastatin-cyclosporine DDIs (i.e., the exposed population) and 150 patients without this DDI (i.e., the non-exposed population) (Table 1).

Table 1- Demographic data of the exposed and non-exposed population samples

	Exposed population (n=102)	**Non-exposed population (n=150)**
Age (mean ± Sd)	72.1 ± 11.6	72.9 ± 10.9
Sex (% of men)	79.8	83.5
Cardiac pathology (%)	38.2	37.8

For the optimal threshold, the neural network out-of-bag error was 17.06%, sensitivity and specificity were 90.20% and 78% respectively, and the AUC was 0.757. The processing time was short (less than 30 seconds) and could be easily performed again during the reinforcement phase.

Discussion

DDI Automatic Detection System: A New Source of Refined Data for Drug Safety Professionals

With this DDI detection system and the CDW, we can compute the overall DDI prevalence for any drug pairs, and also according to a chosen interaction severity level, or for a specific population subset. These data are useful for drug safety monitoring/research and have been already used in a study on the use of statins [21-22]. Moreover, currently, pharmacovigilance studies use different case report databases [23]. We find DDIs directly in the patient EHRs. Therefore, after DDI detection, we can link this information to other data included in the EHR (e.g., demographic data, laboratory test, etc.) to contextualize the case.

However, our DDI detection system cannot identify all DDIs. This could be due to several reasons. First, the choice of the drug knowledge database is important, and we actually observed heterogeneity between these databases that might lead to variability in DDI detection [22]. Moreover, with more information concerning the changes in the blood concentration (and half-life) of the involved drugs, we could compute more precise action intervals, thus improving the identification of overlapping treatment periods. However, this would require extensive manual search of literature data. Finally, our system cannot detect a DDI caused by a drug prescribed/administered outside the hospital. For instance, the regular treatment is usually stopped when a patient is hospitalized in the emergency service and is recorded in the emergency report. Accessing this information requires a specific treatment of unstructured text. Another option could be to link data on the drugs prescribed in primary care settings (i.e., the national health insurance database) to the hospital data (e.g., eHOP). Despite the linkage problems and the issues due to the national health insurance database features (data only on refundable drugs and only on the drug purchase but not the regimen), the analysis of the entire patient path could bring useful information on treatment ruptures, which could suggest DDIs.

A machine learning model for search reinforcement

The automatic way used to create the non-exposed population works and selects a population similar to the exposed group in terms of demographics and pathology. If the sample is big enough, we can ask the system to select the most similar patients.

Although the study of the temporal correlations between laboratory test changes and drug administration is relevant for ADE detection [24,25], we chose a robust prediction-oriented machine learning model that can work without requiring too many adjustments. Indeed, we expect that clinical variables in the exposed population will change in the presence of a DDI. However, we do not know whether the detection of a DDI implies automatically an ADE, and accessing the information to confirm the ADE involves a considerable work for drug safety professionals that we want to avoid. Therefore, to automate the monitoring of DDI-linked ADEs, we took the data immediately available from eHOP.

As they have very similar demographic characteristics, comparing exposed and non-exposed populations seemed to be an effective way to initialize the system. An improvement would be to take into account also the information included, for example, in ADE report databases. However, this system can be easily improved even without more data. Indeed, the model predicts candidate ADE cases that are likely to have been caused by DDIs and proposes them to drug safety professionals. If these cases are confirmed by drug safety professionals, they are included in the training sample to automatically enhance the model.

On the other hand, and like for any automatic detection model, our neural network model does not allow understanding which anomaly led to the prediction of an ADE and for this the analysis of the patient record is required. A machine learning model requires a lot of work, especially the choice of the model and the features engineering. In particular, a larger sample could ollow other resampling strategies to be used, that do not require the out of bag error, which is prone to overestimation of

the true prediction error [26]. These questions need a suitable study including a better evaluation with drug safety specialists.

Conclusions

This study shows how to employ healthcare data for automated DDI monitoring and ADE prediction. It involves the complete data processing chain: data collection, processing and enrichment as well as the creation of a machine learning model. The developed statistical model is the first step for a simple and convenient use of data, and could be enriched with additional information from other databases that must be integrated (more specific drug knowledge databases, ADE report databases …).

Although no drug safety professional is required during the monitoring, their expertise is essential to properly understand the data and put them into context. Their recommendations were also important to build the monitoring system and to improve the model.

Abstract

Suicide is a growing public health concern in online communities. In this paper, we analyze online communications on the topic of suicide in the social networking platform, Reddit. We combine lexical text characteristics with semantic information to identify comments with features of suicide attempts and methods. Then, we develop a set of machine learning methods to automatically extract suicide methods and classify the user comments. Our classification methods performance varied between suicide experiences, with F1-scores up to 0.92 for "drugs" and greater than 0.82 for "hanging" and "other methods". Our exploratory analysis reveals that the most frequent reported suicide methods are drug overdose, hanging, and wrist-cutting.

Keywords:

Suicide, attempted; Natural Language Processing; Social Media

Introduction

Social media platforms, such as Twitter, Facebook, and Reddit, are bringing important challenges for a variety of social- and health-related phenomena. The widespread use of these modern means of communication creates a potential to identify and characterize users behaviors by analyzing content shared online. Recent studies have shown that people are more likely to seek support from informal online resources, rather than seeking formal treatment from professionals [1] and reported a positive correlation between suicide rates and the volume of social media posts related to suicidal ideation [2]. This research suggests that online sources may contain valuable information about specific cohorts, such as vulnerable populations, and their suicidal behavior.

In this paper, we focus on the content analysis of forums dedicated to a specific population -- suicide survivors, or which is defined here as those who have had suicide attempts. Our work aims to contribute to the literature by understanding and analyzing communications on the topic of suicide in the social networking platform, Reddit.[1] As of February 2018, Reddit is a highly trafficked website[2] with more than 542 million monthly visitors, 725.85 million comments, and 6.89 billion up-votes from its users.[3] Reddit provides users anonymity while sharing and discussing information about almost everything, without any bias on the expressed opinions and feelings. In contrast to other social media, it provides domain-specific discussion forums that are moderated by a number of users and that carry health-related knowledge expressed by various cohorts.

In our work, we analyze a serious Reddit thread[4] detailing extremely personal and traumatic experiences of suicide survivors. This thread is moderated by 41 users and includes only serious comments about the topic of suicide attempts. We argue that the study of this dataset is an important step towards the development of automated methods to identify suicide risk factors that could help mental health professionals and psychiatrists to understand and prevent suicide.

Our main objective is to identify methods used to commit suicide such as drug overdose, hanging and to quantify their evocation in social media.

Our research contributions include: (1) extraction and analysis of linguistic characteristic and key aspects of the language used by suicidal individuals to describe suicide methods; and (2) development of a set of machine learning algorithms to extract methods used by suicide attempters and classify the Reddit comments.

State of the Art

Suicide is one of the most common health issues impacting the world's population. According to the Centers for Disease Control and Prevention [3], more than 40,000 suicides were reported in the United States in 2012, which positioned Suicide as the 10th leading cause of death in the country.

A rich collection of work has been done on social media as an effort to identify and understand communications about mental health problems, including depression, mental disorder and suicide. While most of the research from literature is done on suicide notes [4], more recent work demonstrated that evaluating suicidal risk factors in social networks can be used to prevent suicide and detect suicidal ideation in its early stages.

For example, the Durkheim[5] project studied the online activities and shared content of group of US war veterans on Twitter, Facebook, and LinkedIn in order to identify markers of harmful behaviour. The group developed linguistics-driven prediction models to estimate the risk of suicide using text from the clinical notes [5]. Results showed that people who committed suicide frequently recorded behaviours indicative of fear, agitation and delusion, with around 65% accuracy.

[1] www.reddit.com
[2] https://redditblog.com/2015/12/31/reddit-in-2015/
[3] https://en.wikipedia.org/wiki/Reddit
[4] https://redd.it/4e8oip/
[5] http://www.durkheimproject.org/research/

In the same line of research, Sueki [6] examine a panel of young (early 20s) Twitter users to evaluate the association between suicide-related tweets and suicidal behaviour. The authors investigated the linguistic features of suicidal ideation and identified the most important markers of future suicide. For example, phrases such as *"want to commit suicide*" were found to be strongly associated with lifetime suicide attempts, while phrases that suggest suicidal intent, such as *"want to die*," were found to be less strongly associated. For a complete summary of literature on suicidal thoughts and behaviours, the reader may refer to the recent pioneering work of [7], who conducted a meta-analysis of 365 studies from the past 50 years.

Most closely related to the current paper, Ghitsis [8] investigate the linguistic characteristics of Reddit posts that need urgent attention. The authors focussed on subreddits in which users post comments about *Addiction, Anxiety, Dementia, Depression, self-harm* and *suicide ideation.* However, the work does not focus specifically on serious suicide posts, and, most importantly, does not investigate the classification of methods of suicides, which in turn could allow the understanding of several potential warning signs.

With the present work, we consider a broad range of linguistic, lexical, and semantic features to facilitate the task of methods classification. We specifically address the following research questions:

1. How do suicidal individuals communicate about the method used during suicide attempt experiences?
2. What are the most popular methods used by suicidal individuals to end their life?
3. How to recognize a comment dealing about suicide method?

Methods

Step 1: Data acquisition

Our dataset consists of all the comments of the Reddit thread, "*[Serious] Suicide survivors of Reddit, what was your first conscious thought after you realized that you hadn't succeeded?*"[6] We have scraped all the comments using the Python Reddit API Wrapper. The topic has been tagged with the keyword "[Serious]", which means that it is monitored by a group of moderators who remove any off-topic and irrelevant comments in the thread, keeping only serious comments about suicidal ideation. In Reddit, all the comments are organized as a big tree of comments with the parent comment as the top level node and the comments about the parent comment as their child nodes. Table 1 reports statistics about the dataset.

The lack of informed consent given by social media users for data usage leads to ethical questions. In particular, confidentiality with respect to the publication of research results is an issue. We adhere to the guidelines of [9]. Results are presented with a degree of detail that does not permit drawing conclusions on individual users.

Step 2: Data Preprocessing

We initially preprocessed the data to remove HTML tags, white spaces, pipe symbols and carriage returns. We expand English word contractions such as won't, can't, to will not, cannot, respectively using regular expressions. These steps are essential to tokenize words properly and for negation identification. We lemmatize the words using both the Python's NLTK Wordnet lemmatizer.

Table 1– Dataset statistics

Total number of comments	6,229
Number of top-level comments	1,833
Number of sentences	12,782
Average number of sentences per comment	7
Number of unique users	3,58

Step 3: Feature Extraction

In the following, we define the features used in the classification process: Trigrams, NLTK POS Tags and Customised POS Tags.

Trigrams: Lemmas on their own have very little meaning and cannot be used as an independent criteria for annotating a sentence according to a method. Hence, we used trigrams to explore sentences and find recurring patterns. Some examples include: have to kill, going to bleed, tried to slit.

NLTK POS Tags: We tokenized and tagged all the words using NLTK POS tags. We obtained a total of 5,229 verbs, 10,901 adjectives and 24,815 nouns. We used NTLK POS-tagger.

Customised POS Tags: We have also manually defined Customized POS Tags described in Table 2. Due to space restrictions, we only reported the most frequent words associated with these tags. All the Customized POS Tags are self-explanatory, except for 'Ability' categories which represent the words that usually tend to be used by people who are expressing support need such as 'I need support'.

Table 2– Customized POS Tags

Customized POS TAG	Meaning	Common Tokens
FPRP	First Personal Pronouns	I, my, myself
SPRP	Second Personal Pronouns	You, him, he, it
WPRP	Group First Personal Pronouns	We, us, our
NEG	Negations	Not, note, never
SWR	Swear words	Wtf, ass, poop
INTSFR	Intensifiers	Really, so, very
NEGINTSFR	Negative intensifiers	Awfully, horrifyingly
POS	Positive words	Adore, affirmation
NEG	Negative words	Depression, sacrifice
ABLT	Ability words	Handle, support
METHOD	Suicide methods	Hang, drug, shotgun
POSEMO	Positive Emojis	Lol, LMAO, ROFL

extracted from an internal API using 8 online synonym dictionaries[7] and we keep a synonym only if it is find at least 3 in 3 dictionaries. After manually removing irrelevant tokens, we obtain a list of 218 tokens mapped to 15 suicide methods as mentioned in Table 3.

[6] https://redd.it/4e8oip/

[7] Reverso www.reverso.net, Bab.la fr.bab.la/dictionnaire, Atlas dico.isc.cnrs.fr, Thesaurus www.thesaurus.org, Orto-lang www.cnrtl.fr/synonymie/, SensAgent diction-naire.sensagent.com/synonyme/en-fr/, The FreeDictionary www.thefreedictionary.com and the Synonym www.synonym.com, all retrieved on July 13, 2018

Table 3– Most frequent tokens associated with each suicide method label and its distribution in the dataset

Methods	Most frequent tokens	Distributions
Alcohol	Drunk, Liquor, boost	9,9
Bleed	Bleeding, blood	6
Carbon monoxide	Monoxide, gas-poisoning	0,2
Cut	Slit, cleave, tear	10,5
Starve	Starvation, famine	0,2
Disease	Illness, Sickness	4,7
Drown	Drowning, underwater	1,6
Drug	Overdose, pills, dope	36,1
Electrocute	Electrocution, electrocute	0,1
Gun	Shotgun, shoot, revolver	6
Hang	Hanging, noose, strangle	17,8
Hypothermia	Hypothermia	0,1
Jump	Leap, jump-over, jumping	4,2
Vehicle	Collision, speed, car	2,5
Suffocate	suffocation	0,1

FPRP, SPRP, WPRP and ABLT are self defined. POS and NEG list have been compiled from 4 lexicons [1,10-12].

The tag 'NEGINTSFR' is used when a word occurs in both the Negative words dictionary and the Intensifier dictionary such as 'awfully', 'horrifyingly'.

To build the METHOD list, first, we defined a list of 34 suicide methods obtained from dedicated mental health websites[8]. Then we enriched this list by using synonyms

The POSEMO list contains regular expression rules to detect positive social networking emotions including emojis and common slang such as *lol, lmao*... We also use regular expressions in order to include repeated letters as *looooooool, lol.*

Step 4: Classification

We applied supervised machine learning algorithms in order to automatically predict and extract suicide methods at the comment level. Because a comment could be annotated with one or more of the labels listed in Table 3, the task is a multi-label classification task. Every comment containing at least one annotation was extracted. We obtained a training dataset of 874 annotated comments.

We used a One VS Rest Classifier with four different models: Support Vector Machine, Logistic Regression, SGD and Perceptron.

We perform automatic cross validation with 611 comments used as training set and 263 comments used as test set (30% of the dataset).

We tuned the hyper-parameters of the model for the four different models. Global system performance is measured with micro-averaged F1-score because of the use of a skewed dataset.

[8] https://en.wikipedia.org/w/index.php?title=Suicide_methods&oldid=788573333 http://regretfulmorning.com/2011/08/the-7-most-common-drugs-people-overdose-on/ both retrieved on July 13, 2018 Reverso www.reverso.net, Bab.la fr.bab.la/dictionnaire, Atlas dico.isc.cnrs.fr, Thesaurus www.thesaurus.org, Orto-lang www.cnrtl.fr/synonymie/, SensAgent diction-naire.sensagent.com/synonyme/en-fr/, The FreeDictionary www.thefreedictionary.com and the Synonym www.synonym.com, all retrieved on July 13, 2018

Results

POS Tagged Sentence Sequence:

We tagged all the sentences with the Customised POS Tags mentioned above and look for regularities. In the following, we list two prominent examples:

- 'FPRP', 'VBD', 'TO', 'METHOD' (First Personal Pronoun followed by a verb, a preposition and the method) : "I decided to hang", "I tried to - slit, strangle, jump, or drown".
- 'FPRP', 'VBD', 'INTSFR', 'NEGATIVE' (First Personal pronoun followed by a verb, an Intensifier and a Negative Word) gives us the emotional state the person: "I felt more alone", "I became more depressed", "I was completely helpless"...

Customized POS Tagged Sequences are very useful to identify and extract patterns to characterize the way individuals communicate about the methods they used to commit a suicide attempt (RQ1).

Method Labelling

The distribution of the labels in the training set is also presented in Table 3. It is apparent that some methods to commit suicide are much more frequent compared to others. Some of the most frequent labels are, in order, *drug, hang, cut* and *alcohol*. It is interesting that most Reddit users who have commented on this submission preferred to commit suicide through *drug overdose* (RQ2).

Comment classification

Table 4 gives the comparison of the 4 used estimators along with their classification features (RQ3).

Table 4 – Classifier performances

Estimator	Accuracy	Micro-precision	Micro recall	F1-Score
Logistic Regression	0.452	0.726	0.534	0.615
Perceptron	0.631	0.863	0.709	0.778
SGD Classifier	0.642	0.856	0.722	0.783
Linear SVC	0.684	0.912	0.722	0.806

As seen in many different NLP tasks, Linear SVC has the best performance in comparison to Logistic Regression, Perceptron and SGD Classifier. Table 5 gives the classification report of Linear SVC for each individual suicide method label.

Label frequency determines classifier performance considerably. For all comments with support above 20, we can see that we have an F1-score of at least 50%. Unsurprisingly, classifiers for rare examples such as *Carbon Monoxide, Electrocute, Drown* perform worst because of the low number of samples. Classifier performance would likely improve for the low-frequency labels if more training data were obtained, without the need for new features.

Some labels (*gun, jump* and *disease*) perform better than would be expected from frequency alone, indicating that they are easier to learn than others, possibly because they are lexicalized more often, or more consistently.

Table 5 – Classification performance per methods

Methods	Precision	Recall	F1-score	Support
Alcohol	0.97	0.57	0.71	53
Bleed	1	0.52	0,69	42
Carbon monoxide	0.00	0	0	0
Cut	0.94	0.59	0,72	51
Disease	1	0.39	0,56	23
Drown	0	0	0	7
Drug	0.89	0.95	0,92	154
Electrocute	0	0	0	0
Gun	1	0.6	0,75	15
Hang	0.86	0,79	0,82	71
Hypothermia	0.94	0,81	0,87	21
Jump	1	0,5	0,67	2
Vehicle	1	1	1	1
Suffocate	1	0,29	0,44	7

Discussion

Based on the feature extraction process, we find that there are many prominent methods used by leading individuals to attempt suicide. Our analysis reveals that most of these causes appear in sentences either as a negative word or after an intensifier word. In table 6 we report some examples of comments with the number of votes as scored by Reddit. The user names of the authors are removed in order to preserve privacy.

Now, it would be interesting to combine this information about suicide methods with other dimensions such as sentiment analysis or causes such as "bullying" (User 1), "ptsd," "depression," and "divorce" (User 3). These others dimensions could be extracted from the text with a similar approach to the one used for the methods. Such signs could be used as an important signal to prevent suicide.

Table 6– Examples of comments

Author	Comment	Score
User 1	Well I **had attempted to hang myself** when **I was 15**. I have a **birth defect** (deformed legs) and **just could not take the bullying anymore**. So...	7,455
User 2	**I'am a diabetic.** I can remember deciding **to use insulin to go**. Figured that passing out and dying of a seizure due to hypoglycemia would be a **quick and easy way to go.**	1,460
User 3	**I deal with ptsd and depression** at the time I was dealing with my issues that I did after coming home from over seas **my divorce** and **I was getting close to losing my apartment I got drunk as helle got in a fight...**	709

On the other hand, the distribution of suicide method labels in the dataset (Table 3) shows that drug overdose is the most common method used to commit suicide followed by hanging, cutting, and alcohol poisoning, respectively. Since drug overdose is a growing cause of suicide, suitable precautionary methods should be taken to avoid it as much as possible. Some suggestions would be to identify the most common drugs used to commit suicide and to prescribe them to individuals only after throughly assessing their mental health.

The Reddit comment classification reveal that classifier performance depends on frequency of labels in the dataset. In order to limit the annotation effort, methods such as active learning [13] could be used to select the example to annotate in order to improve the model more rapidly.

Conclusions

In this paper we developed a set of methods based on natural language processing and machine learning in order to study the suicidal behavior of individuals who attempted suicide. We built a set of linguistic, lexical, and semantic features that help in capturing relevant language clues. These new features have been successfully used to improve the classification of suicidal thoughts, experiences, and, most importantly, suicide methods. We found that POS tagging features are important to identify and understand users' communications in forums especially when used as features within a machine learning method.

We also created and annotated a dataset that can be used by researchers to investigate others questions about suicide attempts. For future research, we plan to undertake large-scale experimental evaluation to assess the language of suicide across different types of data, such as microblogs and forums. It may be also instructive to determine whether users' classification could reveals similar profiles, suggesting similar suicide methods and comparable risk factors. The classification of the language used could also be informative.

Electrocardiogram Beat-Classification Based on a ResNet Network

Cláudia Brito, Ana Machado, António Sousa

HASLab, INESC TEC & University of Minho, Braga, Portugal

Abstract

When dealing with electrocardiography (ECG) the main focus relies on the classification of the heart's electric activity and deep learning has been proving its value over the years classifying the heartbeats, exhibiting great performance when doing so. Following these assumptions, we propose a deep learning model based on a ResNet architecture with convolutional 1D layers to classify the beats into one of the 4 classes: normal, atrial premature contraction, premature ventricular contraction and others. Experimental results with MIT-BIH Arrhythmia Database confirmed that the model is able to perform well, obtaining an accuracy of 96% when using stochastic gradient descent (SGD) and 83% when using adaptive moment estimation (Adam), SGD also obtained F1-scores over 90% for the four classes proposed. A larger dataset was created and tested as unforeseen data for the trained model, proving that new tests should be done to improve the accuracy of it.

Keywords:

Electrocardiogram, Deep Learning, Arrhythmia

Introduction

Real-time monitoring has become one of the most important and clinically relevant tasks in medical settings, yet one of the most repetitive and tiresome tasks is the analysis of 24-hour ECG records. One of the ways to automate this long task is to convert this process into a real-time process with the automatic classification of the heart rate and with this, the classification of arrhythmias.

Arrhythmias are the most common diagnoses in this medical area and are composed of electrical changes that cause the normal heart rhythm to change. These changes can cause the heart to beat faster (tachycardia), slower (bradycardia), or at an irregular beat. Arrhythmias are widely classified, and their classification may depend on the factors described above and, where they occur, ventricles or atria. These changes can even lead to sudden death from stroke or cause other types of damage because of the inability of the heart to pump enough blood into the body and consequently cause damage to the brain, heart, or other organs [1,2].

To this extent, the importance of monitoring systems increases with the extra goal of improving patient care as well as the speed with which such care is provided.

Over the years, several approaches to this topic have been built. Going from the detection of the R-peak with high precision [3] to the creation of frameworks for this subject [4,5], the heart rhythm has been deeply studied. More recently, researchers have jumped from the classification of the heart beats with traditional methods to machine learning methods and even further, deep learning methods [6,7].

It is palpable the need to not only disclose the heart rhythm as tachycardia, bradycardia or irregular rhythms but to classify each of the beats into a defined category. Although being a deafening task, several works have presented great results when performing this task. Many researchers have spent their time around this subject using several methodologies as Roopa, C. and Harish B. [7] and Salem, A. et al [8] made notice in their survey. Support vector machines [9], genetic algorithms [10], rough set theory, and hidden markov models [11] and more lately neural networks [12–19], several other works mixing different methodologies have also been proposed [20].

In the second semester of 2017, Rajpurkar et al. [21] proposed a ResNet architecture of 34 layers to classify ECG batches of 30 seconds. This work exceeded the performance of high qualified cardiologists in a dataset 500 times larger than the overall datasets and set the classification task a step further to the automated analysis.

On the other side, researchers have also been focusing their efforts in patient-specific methodologies. The neural networks are trained individually for each patient allowing to classify future holters from the same patient [22,23]. Both works show promising outcomes and present a basis for future studies.

We intend to propose a new deep learning model to classify three distinct types of heart beats (four different classes) while analysing differents perspectives from the related works hereby addressed. This paper presents an overview of the dataset used as well as the architecture of the deep learning model built, providing insights on how the model was trained, and the results obtained with prospects of future work to be done. The dataset created, from records obtained from a local hospital, provided new insights about the model. The results obtained for the MIT-BIH Arrhythmia Database were promising with the arrhythmia classification yielding 96% accuracy in the classification of each beat in each one of the four classes used. The same network was used in the larger dataset, being able to classify the arrhythmias with an accuracy of 81%.

Materials and Methods

Data Selection

The MIT-BIH Arrhythmia Database presents 48 records, where the last 23 records became online only in 2005. The 48 records were chosen from a set of over 4000 long-term Holters recorded in the laboratories of the late Boston's Beth Israel Hospital, now known as Beth Israel Medical Center, between 1975 and 1979. The first 23 records were chosen randomly from inpatients and the 25 other records were chosen from the same set yet to contain a diversity of uncommon but clinically important

conditions. The two groups have different purposes since the first one is to serve as a representative sample of waveforms and artifacts which most of the arrhythmia detectors might encounter normally. While the second set of records presents more complex arrhythmias and other conduction abnormalities.

The signals were sampled at 360Hz and recorded with a two-channel recorder. The annotations were made based on a simple slope-sensitive QRS detector and by two cardiologists, who added additional beat labels missed by the QRS detector and changed all the labels of abnormal beats. Nevertheless, during the following years many records had their beats relabeled by users who reported errors in the annotations [24,25]. These records are composed by three files, an .hea format file, .dat format file and a .atr format file.

The new dataset proposed comprises 113 records from 24-hour holters from a local hospital. These records were sampled at 125Hz. This dataset presents 2172 hours of data, while the first dataset, comprises only 48 records with 30 minutes each making a total of 24 hours of data. While the first dataset, after some preprocessing and discarded beats ended up with 97737 beats on all 4 classes, each record from the local hospital presented 100000±20000 beats (Figure 1). The created dataset was first analysed by the system's software and corrected by a technician. Then, each signal's classification was validated by a cardiologist.

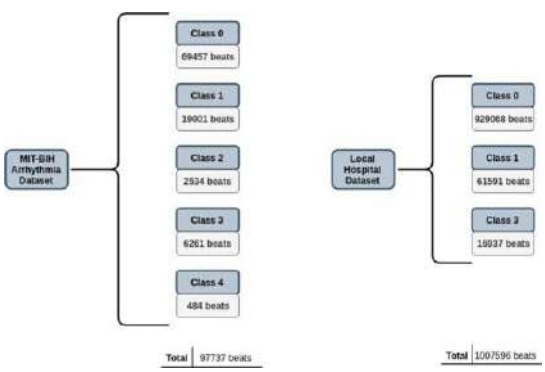

Figure 1 – Summary of Number of Beats of Each Class for Both Datasets

Later, it was disclosed the need to perform data augmentation in the classes proposed. The second and third classes were augmented since the number of beats belonging to these classes were low.

Data Treatment

The first step to analyze an ECG record begins with the load of the record and posterior filtering. These two processes were performed with the help of the CardIO library, an open-source Python library which was built to create "end-to-end machine learning models for deep research of electrocardiograms" [4].

The CardIO library relies in the WFDB package [26] to read and load files in the MIT-BIH format, this library can be executed via command line and also as a python library (the code is publicly available on Github). Using the capabilities of CardIO library, the signals were resampled to a frequency, of 125Hz. Then the signal was filtered, the filtering used in this preprocessing was based on several works that proved to be efficient [27-30]. Thus, it uses a band-pass filter, a finite impulse response filter (FIR filter [31]) which uses a frequency of 0.5Hz and 60Hz, in accordance with the theoretical foundations, yeat the new dataset was filtered with a frequency of 50 Hz and not 60Hz due to the specifications of the country's baseline wandering.

Nevertheless, in order to build the final datasets for training and testing, after these transformations, the ECG is sliced by beats and labeled with the annotations available creating the datasets for training and testing. The annotations were carefully reviewed and converted accordingly to the types of arrhythmias that were intended to classify. Therefore, the annotations were converted into four classes: normal beats as 0, other rhythms as 1, atrial premature contractions as 2 and premature ventricular contractions as 3, as seen in Table 1.

Table 1 – Representation of Each Type of Beat According to its Class

Type of Beat	Class
Normal beats	0
Other Rhythms	1
Atrial Premature Contractions	2
Premature Ventricular Contractions	3

The records were then split, based on the correct detection of the R-Peak and since it is sampled at 125Hz, it was decided to use a window with a size of 120 data points.

Model

We built a ResNet architecture (Figure 2 presents the high-level architecture of the network) based on Convolutional 1D layers for the classification task since this was the model that

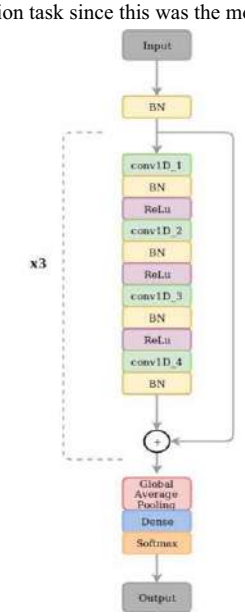

Figure 2 – Network Structure of the Model for the Classification Task. Overall the network contains 12 layers of convolution followed by a fully-connected layer and a Softmax.

surpassed the first tests performed. Initially, it was created a multilayer perceptron model and a version with 2D convolutional layers of the current model. It takes as input a time-series of 120 data points that represents the beat and outputs its label prediction. The model is composed by an initial input in a BatchNormalization layer, followed by four blocks of

Convolution1D layers (conv1D_1, conv1D_2, conv1D_3 and conv1D_4) with BatchNormalization, ReLU as activation function and a stride of 1. The conv1D_1, conv1D_2, conv1D_3 and conv1D_4 layers have a filter size of 8, 5, 3 and 1, respectively. The model could also use a Dropout schema, but considering the model complexity, we believe that we could obtain good results with BatchNormalization.

Evaluation Metrics

The effectiveness of a deep learning model for classification is usually measured by several parameters. Four of the most common are i) accuracy, ii) precision, and iii) recall, as well as the iv) F1-score [32–34]. These parameters are based on the results of true positives, true negatives, false positives and false negatives.

- True Positive (TP): correctly classified positive instances
- True Negative (TN): correctly classified negative instances
- False Positive (FP): incorrectly classified as positive
- False Negative (FN): correctly classified as negative

Accuracy

The Accuracy measures the rate of True Negatives and True Positives on all classified instances, being generically represented for binary classification by Equation 1. This result may induce in error or can hide important details since it does not distinguish between the number of correct labels of different classes. It can be understood as the number of correct predictions on top of the total number of prediction. The problems of misclassification may arise even though the accuracy results are high. In the medical field, the misdiagnose of an unhealthy subject may cost its life. When dealing with multi-classification, this formula reverts to the number of well predicted samples in relation to the total number of samples.

$$Accuracy = \frac{TN + TP}{TP + TN + FN + FP} \quad (1)$$

Precision

Precision (Equation 2) equalizes to the rate of true positive instances in the correctly classified instances.

$$\boldsymbol{Precision = \frac{TP}{TP + FP}} \quad (2)$$

Recall

Recall or sensitivity (Equation 3) gives higher scores when a high number of true positives is achieved while avoiding false negatives, this defines the true positive rate.

$$\boldsymbol{Recall = \frac{TP}{TP + FN}} \quad (3)$$

F1-Score

The F1-score is another general metric that is broadly used for evaluating these systems, the Equation 4 combines the precision and recall into a single number and is seen as one of the most reliable metrics for evaluating machine learning results.

$$F1_{score} = \frac{2 * (Precision * Recall)}{Precision + Recall} \quad (4)$$

Experimental Results

The tests performed for training the model were optimized with SGD and Adam, both with a learning rate of 0.1. Other optimisers could have been used, however, we relied on SGD and Adam based on the related work and their broad use[35]. To understand the evolution of the models with the number of epochs, both systems were tested with 10, 25, 50, 100 and 150 epochs, the maximum number of epochs was defined after the first tests, where any test over 150 epochs demonstrated that the model stopped learning. As seen in Figure 3, the first dataset was randomly sliced in 80% for training and 20% for testing, with the training set being further separated into train and validation (65/35%).

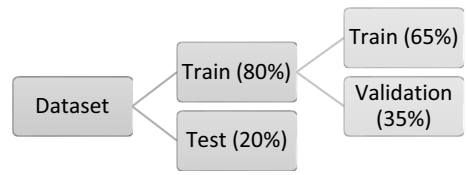

Figure 3 – Modeling the First Dataset for Training and Testing the Model

Several tests were performed for tuning the hyperparameters and adapting the learning rates to the behavior the model was exhibiting. Since this is a multi-classification task, the metrics for each class are calculated.

Figure 4 presents the overall accuracy of the models with a different number of epochs, a batch size of 2000 beats and as we are dealing with multi-classification, it used the categorical cross-entropy as loss function. The accuracy of the model reached 96% for the SGD optimizer with 150 epochs

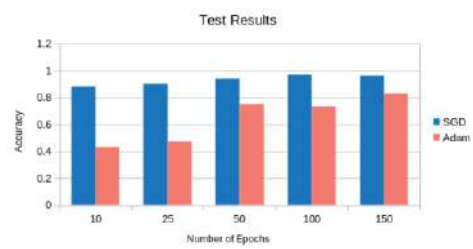

Figure 4 – Testing Results Regarding the Accuracy of the Model using Stochastic Gradient Descent and Adaptive Moment Estimation as Optimizers.

On the other hand, Figures 5 and 6 rely on the F1-score regarding the test results with the 20% of the dataset created.

The model behaves accordingly to what was expected, presenting good results for classifying all the instances initially defined. However, it can be noticed the higher results of the model optimized with stochastic gradient descent. These results are an effect of how both these optimizers work.

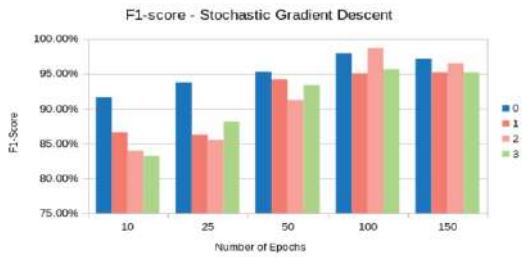

Figure 5 – Testing Results Regarding the F1-Score of the Model using Stochastic Gradient Descent as Optimizer

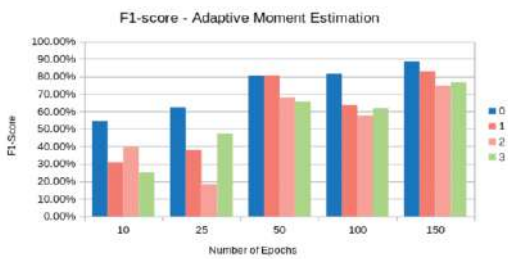

Figure 6 – Testing Results Regarding the F1-Score of the Model Using Adaptive Moment Estimation as Optimizer

The results obtained did not present overfitting, the error was minimal, and the test set obtained good results both in accuracy and F1-score. The model was able to classify all four classes and these results increased with the number of epochs.

When scrutinizing the two types of arrhythmia classified it is possible to disclose the reasons why atrial premature contractions (class 2) is the least accurate arrhythmia when using the Adam optimizer. This results can be due to the computation of gradients using this optimiser, as so, the gradient may reach a local minima but not the lowest point. In this case, it may be because of the small number of beats of this class on the test dataset. On the other side, SGD is able to find better gradients for the classification of all the classes. However, it can be seen that when the model was trained with 100 epochs it was able to reach better results when classifying the atrial premature contractions (class 2).

After the best model was trained and evaluated, the new dataset, with unforeseen data for the model, was tested. These tests were performed record by record, where 21 records achieved more than 90% of accuracy. The only problem detected was when the model tried to predict class 2 where there was no class 2 in any of those records. Tacking this into account, a new model was trained, comprising the 11 least accurate records for training and the remaining 5 records with an accuracy below 30% for testing, we decide not to use all the records due to the lack of computational power. Table 2 presents the precision, recall, and F1-score values of the last evaluation of the new model.

This model was able to accurately classify the arrhythmias with an accuracy of 81% while the F1-scores for the normal class (class 0) reached 89.9%, the other two classes performed poorly, reminding the need to perform data augmentation to balance the data to train the model.

On the other hand, several limitations raised during the development of this project, such as, the lack of computational power to diminish the training time, which took over 15 hours for the subset of only 11 records from the second dataset as well as the imbalanced dataset. These issues present a hindrance in the success of these approaches, nevertheless it is important to emphasise it presents an advance in relation to typical systems were the annotations have to be carefully reviewed 100% of the time.

Table 2 – Results Obtained for the New Dataset Based on 11 Records from the Hospital for Training and the Five Worst Records from the Hospital for Testing

Labels	Precision	Recall	F1 Score
Class 0	98.9%	82.3%	89.8%
Class 1	8.8%	47%	14.9%
Class 3	4.1%	35.3%	7.4%

In comparison with the related work, namely the work performed by [16], where the authors performed a beat-to-beat classification using the MIT-BIH arrhythmia database and obtained an accuracy of 83.4% in classifying the signal as normal or abnormal (arrhythmic), we were able to outperform their approach in 10% while classifying into four different classes.

Conclusions

In this paper, we developed a deep learning model that was able to accurately classify the heartbeat into four different classes. Focusing on two types of arrhythmia, the results obtained for this classification task were promising showing that this path for beat classification should be further investigated and providing a basis for future studies. Researchers have been dealing with beat classification using deep learning, however, the results were slowly reaching 90% of accuracy and many of these results were based on two-dimensional layers. This paper presents a ResNet with one-dimensional convolutional layers and was able to reach over 90% of accuracy and F1-scores for the four classes proposed, without falling on the rabbit-hole of overfitting.

A new dataset was created, having records 48 times bigger than the records from the MIT-BIH Arrhythmia Database. This allowed us to further explore these results, increasing our training data to create a new and better model, able to classify these 24-hour record accurately and also to try to balance the data available. Since deep learning is a methodology data-driven, the larger the dataset, the better the results. With this in min, this dataset will allow us to increase the spectrum of classified types of arrhythmia in order to create a fully automatic system without neglecting the precision and the importance of the outcome.

Abstract

We report initial experiments for analyzing social media through an NLP annotation tool on web posts about medications of current interests (baclofen, levothyroxine and vaccines) and summaries of product characteristics (SPCs). We conducted supervised experiments on a subset of messages annotated by experts according to positive or negative misuse; results ranged from 0.62 to 0.91 of F-score. We also annotated both SPCs and another set of posts to compare MedDRA annotations in each source. A pharmacovigilance expert checked the output and confirmed that entities not found in SCPs might express drug misuse or unknown ADRs.

Keywords:
Natural Language Processing; Pharmacovigilance; Social media

Introduction

According to the World Health Organization (WHO), pharmacovigilance is "the science and activities relating to the detection, assessment, understanding and preventing of adverse effects or any other drug-related problem".[1] The drug development process has several steps, from discovery in a laboratory, to preclinical research and clinical development involving patients. Nonetheless, after approval, complete and definitive information about drug safety is not available. Moreover, the drug use may change, the benefit/risk may evolve and health authorities need any information available.

Self-reports of adverse drug reactions (ADRs) are scarce: the French National Agency for Drug Safety (ANSM) evaluated that only 5% are reported by patients. Because ADRs are known late, except in case of highly publicized events (e.g., H1N1 flu), social media is used to improve pharmacovigilance efficiency [1,2]. However, web-based data generally contain colloquial jargon that is hard to process with common Natural Language Processing (NLP) tools, calling for dedicated approaches [3]. Pharmacovigilance also addresses abuse and drugs misuse, which involves "situations where a medicinal product is intentionally and inappropriately used not in accordance with the terms of the marketing authorization" [4].

We present an ongoing work on pharmacovigilance analyses in health fora written in French, with a special focus on drug misuse. We present the experiments we made based on a comparison of the Medical Dictionary for Regulatory Activities (MedDRA) codes annotated in web messages and the codes identified in Summaries of Product Characteristics (SPCs). As far as we know, this source has not been commonly used for NLP in health social media; this is our main contribution. We annotated pathological conditions in social media and SPCs using an NLP pipeline designed to identify such entities [5]. This tool was improved for normalizing annotations based on codes from MedDRA [6] and the Anatomical Therapeutic Classification (ATC) [7]. These methods identify potential drug misuse and unknown ADRs.

Background

Social media are useful to identify both adverse effects and drug misuse [1,2,8]. Different types of drug misuse may occur; Bigeard and colleagues report a comprehensive typology [9]. Misuse may be related to whether the drug is prescribed by a practitioner, or taken as self-medication. In case of a prescription drug, misuse may involve interaction with other drugs, an incorrect frequency, duration or dose of medication intake. Other situations involve not respecting the drug intake (e.g., if levothyroxine is not taken on an empty stomach), or problems of conservation (e.g., to keep an eye drop solution open for more than 2 weeks). Indication misuse involves the intake of a medication for an unrelated pathology (e.g., using baclofen for alcohol addiction). Another situation of interest is drug abuse, which occurs when users take drugs without any pathology but searching for a specific effect (e.g., a psychotropic effect, as is the case with the *purple drank* cocktail based on codeine cough syrup with soda).

Detection of drug misuse in social media is hard to identify automatically, since knowledge on a given medical drug indications or posology are needed to infer *unexpected* user's intake behaviors. The few works undertaken to detect drug misuse have applied supervised methods and annotated data by pharmacovigilance experts [10].

In the absence of enough available annotated data, we resorted to methods for generating training data over unlabeled samples. Distant supervision approaches [11] are close to that paradigm and have been applied in the medical domain [12]. Our method, however, relies on the annotation of knowledge

[1] https://bit.ly/2FtIYX5 [Accessed March 2019]

sources (SPCs in our context of pharmacovigilance) and then compares the output to annotations in web fora.

Methods

We conducted two types of experiments. First, we conducted a *supervised experiment* with a small set of messages annotated by pharmacovigilance experts regarding positive or negative misuse. Second, we tested to which extend comparing MedDRA codes found in messages from web fora and in SPCs provide cues of drug misuse and unknown side effects.

Corpus for Supervised Experiments

Corpus 1 contains posts written in French by consumers, extracted from several public fora from the health domain: AlloDocteurs,[2] Atoute,[3] Baclofène,[4] Doctisimo Médicaments,[5] eSanté,[6] Journal des Femmes,[7] and Vulgaris.[8] In these posts, different drugs and pharmacological substances are discussed:

Agomelatine (Valdoxan®): an antidepressant, which may be misused for insomnia, panic and anxiety attacks.

Baclofen: a muscle relaxant, used to treat addictions (especially alcoholism) out of any marketing authorization.

Duloxetine (Cymbalta®): an antidepressant drug.

Exenatide (Bietta®): an antidiabetic injection; a dose misuse (i.e., users took more injections than what is prescribed) has been detected by pharmacovigilance experts.

Myolastan (Tetrazepam®): a muscle relaxant; both misuse (indication and posology) and drug abuse has been reported.

Messages were collected with a framework for extracting data from web fora [13] and then processed using an NLP pipeline to annotate pathological and medical drug entities. Pharmacovigilance experts—pharmacists, or physicians qualified in Pharmacology—revised a selection of 1178 posts and manually annotated them as expressing misuse or not.

Corpus for Comparing Internet Posts and SPCs

Corpus 2 gathers posts from similar kind of consumers' web. We chose three specific and actual drug topics (regarding the media coverage and patients' interest), each in different fora:

1. Baclofen: data come from the Atoute website and were used in semi-automatic methods to detect drug misuse.
2. Levothyroxine: this drug replaces or provides more thyroid hormone, and a new formulation was marketed in August 2017. Messages come from the Vivre sans thyroïde forum.9
3. Vaccines: in France, only 3 vaccines (diphtheria, tetanus, poliomyelitis) were mandatory until January 1st, 2018. Since that date, 11 vaccines are compulsory: tetanus, diphtheria, poliomyelitis, and 8 additional ones: pertussis, polio, measles, mumps, rubella, hepatitis B, haemophilus influenza bacteria, pneumococcus, and meningococcus C. We used posts from the Doctissimo website.10

For each topic, we extracted 100 messages according to two inclusion criteria: presence of drug name and pathology names, and a limit of words (we avoided long generic discussions). In case of lack of messages with drug names and pathology entities, we extracted new messages to gather up to 100 messages per topic. We also used SPCs available from the French authorities[11] for baclofen, levothyroxine, and the twenty marketed products to perform the newborns immunization for the eleven vaccines: ACT-HIB®, Boostrix Tetra®, Engerix B®, Fendrix®, HBVaxPro®, Hexyon®, Imovax Polio®, Infanrix Tetra®, Infanrix Quinta®, Infanrix Hexa®, M-M-RVaxPro®, Menjugate®, Neisvac®, Pentavac®, Pneumovax®, Prevenar®, Priorix®, Repevax®, Revaxis®, and Tetravac®. We focused on sections describing indications, counter-indications or adverse drug reactions.

Annotation of Messages with an NLP Pipeline

We applied an NLP pipeline on both corpus: 1178 posts annotated by pharmacovigilance experts, and 300 concerning levothyroxine, baclofen and vaccines. As previously explained [5], the pipeline has modules for normalization, tokenization, Part-of-Speech tagging and concept annotation based on machine learning, namely Conditional Random Fields (CRF) [14]. Because the tool was improved since the first evaluation made on the first set of web fora [5], we evaluated the annotations of the 300 posts. We manually checked those annotations to build a gold standard, using BRAT (Figure 1) [15]. We evaluated the annotations through pre-cision, recall and F1-score (F1) metrics using BRATeval [16].

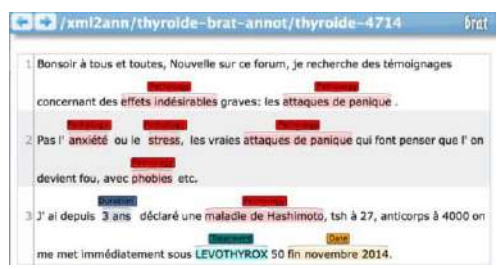

Figure 1 - Sample of forum message annotated with BRAT

We also applied the annotation tool on the summary of product characteristics (SPCs) detailed before. Thus, pathological entities in indications covered by those selected drugs are annotated and labeled with MedDRA codes. We also revised the annotations of sections Indications and Side effects in SPCs, using the same methodology to revise annotated posts.

Experiments in a Supervised Context

We followed the procedures applied by Bigeard and colleagues [10]. We tested Naïve Bayes (NB) and

Multinomial Naïve Bayes (MBN) algorithms on the 1178 posts annotated as expressing misuse or not by pharmacovigilance experts. We tested different features:

Word tokens in message

Word roots in message

Anatomical Therapeutic Classification (ATC) codes of medical drugs in each message

MedDRA codes of pathologic entities in message

3-grams

3-character-grams

We used ScikitLearn Software for this set of experiments [17]. In all contexts, we applied 10-fold cross-validation and used an 80% and 20% ratio of training and test sets, respectively.

We also tested different subsets of messages with regard to the number of messages annotated as misuse. In real-life contexts, most posts will not contain any misuse behavior or ADR. The datasets will suffer from *class imbalance* (i.e., most samples will not express misuse nor ADRs), a common problem with supervised machine-learning algorithms [18]. In a context where most posts bear a negative class, a random classifier or a classifier labeling all samples as negative will certainly have good accuracy, even though it does not make use of any linguistic or knowledge-based feature. We thus tested different ratios of messages annotated as positive or negative misuse:

The full corpus of messages (1178 posts), 111 messages annotated as positive misuse (~10:1 ratio)

A subset of 336 messages: 111 classified as positive misuse and 225 as negative misuse (~2:1 ratio)

A subset of 246 messages: 111 classified as positive misuse and 135 as negative misuse (~1:1 ratio)

Comparing Messages in Social Media and SPCs

Once we applied the NLP tool to annotate the pathological entities in the SPCs, we assumed these coded pathologies set up the list of correct uses to be found in messages over the Internet. Conversely, all pathologies related to one of those drugs found in a message (missing in that list of *expected* pathologies) may be a drug misuse or unexpected ADR. Because we used the same annotation schema and tool, we could compare MedDRA codes in both sets and extracted a list of candidate terms. Finally, a pharmacovigilance expert and coauthor of this work (ALL)—a physician, qualified in Pharmacology, with 20 years of expertise—checked the selected entities to confirm misuse behavior or unknown ADRs.

Normalization

We used MedDRA for coding terms of pathological entities. Following Bousquet *et al*. [19], we coded Lower-level terms (LLT) for expressions of pathologies (*verbatim terms*), but also mapped these LLTs to preferred terms (PT) for pharmacovigilance analyses. We used the UMLS® [20] Concept Unique Identifiers (CUIs) to map term variants referring to the same concept. Normalization rules were applied considering inflection (singular/plural, diacritics, syntactic variants of multiwords); and Levenshtein distances were used to get the candidate term with closer string distance from a term variant.

Results

Evaluation of the NLP Pipeline

We annotated a total of 2249 pathologies and medications in forums, and 6772 in the SPCs (Table 1; we report the count of both annotations and types, i.e., different annotated items). Table 2 shows the evaluation results of each subset of posts.

Table 1 - Number of annotated entities (total items and types)

	# words	# annotations (types)	
		Pathologies	**Medical drugs**
Levothyroxine	18274	511 (230)	314 (67)
Baclofen	12941	259 (133)	386 (52)
Vaccines	10336	390 (185)	389 (83)
Total posts	41551	1160 (480)	1089 (192)
[avg per post]	[138.5]	[3.87 (1.6)]	**[**3.63 (0.6)**]**
Total in SPCs	88919	3687 (815)	3085 (320)
[avg per SPC]	[4041.8]	[167.6 (37.1)]	[140.2 (14.5)]

Table 2 - Evaluation of the NLP annotation pipeline (P: Precision; R: Recall ; F1: F-score; Avg: average)

	Pathologies			**Medical drugs**		
	P	**R**	**F1**	**P**	**R**	**F1**
Levothyroxine	0.80	0.68	0.74	0.98	0.85	0.91
Baclofen	0.84	0.70	0.76	0.89	0.80	0.84
Vaccines	0.84	0.72	0.77	0.82	0.78	0.80
Avg (posts)	0.83	0.70	0.76	0.93	0.83	0.88
SPCs	0.92	0.90	0.91	0.76	0.90	0.82

In web posts, higher F1 scores were obtained when annotating medications rather than pathological entities. This is mainly due to the higher number of different pathological entities (480) and also to the difficulty in annotating expressions of pathological conditions in *patient language* (e.g., *crevé,* 'worn out' stands for *fatigue*). Annotation results of messages concerning the baclofen and levothyroxine show higher F1 scores; this might be due to the fact that messages discussing newborns vaccination contain more different drug names (83). Results of pathological entities in posts regarding the levothyroxine might also be due to a higher number of different pathological entities in this forum (230). Because SPCs feature a lower degree of *patient language,* annotation of pathologies achieved a higher F1 score than in web fora.

Results of Supervised Experiments

As expected, the best results were obtained on the full corpus, either using Naïve Bayes or Multinomial Naïve Bayes (Table 3; we only report the results of the best features on the test set). The experiments on the other corpora configurations helped us better understand the features that *really* helped the classifier to learn and distinguish positive and negative

misuse. The best results were mainly obtained with these features: ATC codes, MedDRA codes and word roots. We had similar results as those reported by Bigeard *et al*. [10].

Table 3 - Results of classifiers in supervised context: Naïve Bayes (NB, above) and Multinomial Naïve Bayes (MNB, below). The label ratio is the proportion of posts annotated as positive or negative misuse. 2:1 stands for 2 negative posts per 1 positive; P: Precision; R: Recall; F1: F-score

	Label ratio	Features	P	R	F1
NB	~ 10:1 (all data)	ATC codes + MedDRA codes + word roots + 3-grams	0.94	0.93	**0.91**
	~ 2:1	ATC codes + MedDRA codes + word roots	0.63	0.67	0.62
	~ 1:1	Tokens + 3-grams + ATC codes; or Tokens + 3-grams	0.88	0.88	0.88
MNB	~ 10:1 (all data)	ATC codes + MedDRA codes + word roots	0.93	0.92	**0.89**
	~ 2:1	ATC codes + MedDRA codes + word roots	0.71	0.70	0.62
	~ 1:1	Tokens + 3-grams + ATC codes ; or Tokens + 3-grams	0.82	0.82	0.82

Results of comparing messages in social media and SPCs

We extracted from posts 301 pathological entities that were not documented in SPCs. Most were related to Levothyroxine (166) and Baclofen (103). Pathologic conditions related to vaccines (32) concerned Boostrix®, Engerix®, Infanrix®, Neisvac®, Pentavac®, Prevenar®, Priorix®, Repevax® and Revaxis®. We observed that some vaccines did not appear in the selected posts (ACT-HIB®, Fendrix®, HBVaxPro®, Hexyon®, Imovax Polio®, Infanrix Tetra®, M-M-RVaxPro®, Pneumovax® and Tetravac®). The pharmacovigilance expert considered that only 3 cases might be misuse related to Baclofen (1.3% of candidate items). However, one case is ambiguous: we cannot state if, when the user mentioned the unexpected pathology, he/she meant to link it to an indication related to the intake of Baclofen. No other misuse cue was confirmed with regard to other drugs. The expert identified 68 undocumented ADRs (22.6% of selected items; 28 need more context to be confirmed). Unknown ADRs mostly involved levothyroxine (52 cases), baclofen (6), Engerix® (2), Infanrix® (2), Pentavac® (3), Priorix® (1) and Repevax® (2).

Qualitative Evaluation

We analyzed messages to detect linguistic cues expressing drug indication or misuse (Table 4). Misuse due to incorrect dose might be expressed with specific verbs. However, in the Corpus 1, we observed that experts did not always annotate as misuse some contexts with those cues. Exact validation of drug doses reported by web users might indeed be within the range of correct doses that could be a *user-perceived misuse*. We estimate a linguistic analysis needs to be complemented by knowledge-driven approaches; e.g., analyses of doses in posts may be compared with ranges of doses approved by authorities. Likewise, we noticed that possible adverse drug reactions or misuse events were not detected due to the lack of MedDRA terms, especially when users write narrative descriptions of events or use non-technical expressions.

Table 4 – Samples of linguistic cues of indication, misuse or unknown adverse drug reactions (ADRs)

Misuse	*surdosé* (‘overdosed’) *mauvais dosage* (‘bad dose’) *tu ingurgites le triple de ce qui est recommandé,* ‘you take 3 times more than what is recommended’ *prendre des doses de cheval de X* (‘take a raging / strong dose of X’)
Indication	*je prends X pour …* (‘I take X for’) *X utilisé comme / pour* (‘X used as / for’)
ADRs	*X m’empechait de dormir* (‘X keeps me awake’)

Results of the Normalization Step

Applying the normalization rules on Corpus 2, we mapped to CUIs 263 out of the 344 different types of pathologies (76.4% of types), and 199 to MedDRA codes (57.8% of types). Errors were due to spelling, syntactic variation (*treatment failure* vs. *failure of treatment*), inflection (*panic attack* vs. *panic attacks*), derivation (*depressive* vs. *depression*), abbreviations (*rgo* vs. *reflux gastroesophagique*) or errors in CUI mappings.

Discussion

Communication in Internet fora is asynchronous and asymmetric, without specific interlocutors. This impacts the way medical information is expressed: incomplete, informal and creative expressions for health conditions abound, which make it difficult concept normalization and automatic analyses through NLP. Comparing pathological entities documented in SPCs medical drugs and unexpected pathologies in social media needs quality term detection and normalization. Our work is thus preliminary and suffers from the limitation that terms in patient language remained still unannotated, or entities were not normalized to accurate terms or CUIs. Moreover, we did not check the quality and correctness of the normalization step. We would like to explore normalization techniques based on word-embeddings and deep-learning. The comparison method was weak for detecting misuse, but helped in finding new ADRs; this opens the door to future work.

Regarding our supervised experiment, we lack enough data for training our model and generalizing our predictions on drug misuse to new datasets. We want to annotate SPCs of more medical drugs to gather a database of annotations to be

used in future work, especially for distant supervision approaches.

Using social media brings up other limitations related to: 1) the fact that users may not necessarily post their misuse behavior or ADRs; and 2) privacy concerns: despite users post contents to be publicly available, careful anonymization protocols are required, as we applied in the project [13].

Conclusions

We presented a method and initial experiments on pharmacovigilance analyses on social media based on NLP annotations of web fora. Through a supervised experiment with a minimal set of data, we showed that classification models might perform adequately. However, lacking of enough data to address current medications of interest, we resorted to Summary of Product Characteristics (SPCs) to overcome the data bottleneck. This approach, as far as we know, has not commonly being used and might be a source of knowledge for contrasting data reported in SPCs and unexpected users' health or conditions. A pharmacovigilance expert confirmed possible cases of misuse and some unknown ADRs. We make available the annotated data of SPCs.[12]

We highlight that our methods do not aim at replacing human decisions concerning users' behavior that could be drug misuse. These need pharmacovigilance experts to be validated; luckily, automated methods supporting these tasks make this validation faster and easier to be conducted.

Acknowledgements

The Agence Nationale de Sécurité du Médicament funded this work (grant ANSM-2016-S-076, PHARES project). We greatly thank the LIMICS team (U. Paris 13) for the data, and the pharmacovigilance team for annotating those posts.

Expanding Evolutionary Terminology Auditing with Historic Formal and Linguistic Intensions: A Case Study in SNOMED CT

Werner Ceusters[a] and Sarah Mullin[a]

[a] Department of Biomedical Informatics, University at Buffalo, Buffalo NY, USA

Abstract

A method is described to use SNOMED CT's history mechanism as a means to compute how the formal and linguistic intensions of its concepts change over versions. As a result of this, it is demonstrated that the intended principle of concept permanence is not always adhered to. It is shown that the evolution of formal intensions can be monitored fully automatically and that the proposed procedure includes a method to suggest missing subsumers in a concept's transitive closure set by identifying mistakes that have been made in the past. Changes in linguistic intensions were found to be much more labor-intensive to identify. It is suggested that this could be improved if the history mechanism would come with more detailed motivations for change than the current and insufficiently used annotation to the effect that a fully specified name 'fails to comply with the current editorial guidance'.

Keywords:

Systematized Nomenclature of Medicine; Algorithms; Semantics

Introduction

SNOMED CT is a biomedical terminology which is anchored in an ontology of 'concepts' which are defined and related to each other using a combination of formal logic and editorial rules as specified in SNOMED CT's concept model [10, p24]. Fundamental in SNOMED CT is that each of its concepts comes with a unique identifier (SCTID) and is intended to have a unique meaning. What this meaning is intended to be, is conveyed formally by means of description logic-based assertions and informally by means of human-readable 'terms' which are called '*fully specified names*' (FSN) and which are connected to the concepts by means of '*descriptions'* [10, p12]. Each FSN is since 2003 formed by what we henceforth call a '*term proper'* and a '*semantic tag*' which indicates to which subhierarchy of SNOMED CT the concept belongs. For example, the concept with SCTID '87612001' has the FSN 'Blood (substance)' where 'Blood' is the term proper and 'substance' is the semantic tag. Concept 87612001 is an example of a concept for which the term leaves not much room for misinterpretation of the intended meaning. Its formal definition, however, specifies the intended meaning only partially: blood is a subtype of 'Body fluid (substance)' and of 'Blood material (substance)'. Semantic tags also disambiguate concepts for which the term proper is homonymous. This is for instance the case for the term 'hematoma' which comes in two flavors: 'Hematoma (morphologic abnormality)' (SCTID: 35566002) and 'Hematoma (disorder)' (SCTID: 385494008) which is formally defined in terms of the former.

SNOMED CT is since its inception in 2002 updated twice annually, for instance to include missing relevant content [7] or to remove content that was erroneous because of editorial mistakes [9] or because of mismatches in intended meaning between formal definitions and terms [11]. Also changes in the concept model itself require updating which impacts both the formal components and the FSNs. A unique feature of SNOMED CT is that it comes with a history mechanism involving certain formal metadata components that – to some degree – describe what and when changes have been made, what the reasons for these changes were (for example inconsistency with editorial rules), and how impacted components relate to each other after the change (for example what concepts, if any, replace inactivated concepts) [5].

One central principle that is intended to be maintained over versions is code or concept permanence [6]: '*Once assigned a meaning, a code must not change its meaning. Refinements, due to changes in the state of knowledge, may lead to inactivation of codes from SNOMED CT. An inactivated code may be replaced by a new, more precisely defined code*' [9, p203]. The objectives of the work presented here are twofold. The first one is to assess the extent to which the principle of concept permanence is adhered to and whether adherence to this principle can be quantified by resorting to SNOMED CT's history mechanism. The 2nd one is to find methods using this quantification to improve on prior efforts in Evolutionary Terminology Auditing which attempts to find mistakes in the last version of an ontology on the basis of errors made in the past [2]. Our hypothesis is that the stability of a concept's position in the hierarchy over distinct versions and the formal representation of reasons for change [3] contribute positively to quantification while changes in the concept model and in the FSNs contribute negatively [1].

Methods

Since SNOMED CT is an ontology that does not explicitly adhere to a view based on Ontological Realism [12], the meaning of a SNOMED CT concept can be thought of as what is conveyed by means of three aspects: (1) a *linguistic intension* as conveyed through its *label(s)*, (2) a *formal intension*, i.e. the properties implied by it as exhibited, for instance, by means of the formal relations it holds with other concepts and (3) an *extension*, i.e. the collection of data elements in, for instance, electronic medical record systems annotated with the concept [13]. Whether two concepts have the same meaning can then be determined by applying appropriate similarity functions to each of the three aspects followed by an assessment of whether the similarities are sufficiently high. For systems like SNOMED CT that maintain explicit identity over versions, concept permanence – or the opposite: *concept drift* [13] – can then be

'**S**': Semantic similarity function result ('0' = not considered semantically equivalent, '1' = 'semantically equivalent').

evaluated by determining (1) whether changes in the concept's labels lead to different interpretations, (2) whether the formal intension is kept constant, and (3) whether the same sorts of data elements are annotated irrespective of version.

In absence of data annotated by means of different versions of SNOMED CT, we focused our efforts on linguistic and formal intensions. Using the history information from the July 2018 version of SNOMED CT International, we computed for all concepts, all descriptions specifying an FSN containing any semantic tag introduced since 2003 and all relations a *historic signature* as a 34-character string, using one character for each version since January 2002. A character '1' in position *n* indicates the presence of that component in version *Vn* (*n* ranging from 1 to 34), '-' absence of the component prior to its introduction, and '0' absence of the component because of its deactivation. For relationships between two concepts, the extra character '!' was used to indicate that a relationship does not hold anymore because of deactivation of the target concept.

For the formal intension aspect of a concept's meaning, we followed a suggestion from [13] and defined the *formal intension of a concept in Vn* (FIn) as the collection of all subsumers in its transitive closure in *Vn* and *the historic formal intension of a concept* (HFI) as the union of any subsumer ever encountered in some version. We further defined the *rigid formal properties set of a concept* (RFP) as the subset of transitive closure subsumers that is present in all versions in which the concept is active. Finally, we defined a *stable history segment of a concept* (SHSC) as a segment of the concept's history during which the FIn remains constant over successive versions.

Consistent with our proposal advanced in [4], we identified two types of *suspicious events* for historic signatures of concept-subsumer pairs. Concepts C1 and C2 form a concept-subsumer pair if and only if C2 is in the historic transitive closure set of C1. A historic signature for a concept-subsumer pair is *suspiciously gapped* for any transitive closure subsumer which becomes reactivated after having been deactivated: during the gap, the subsumer was thus unjustifiably absent ('missing'). A concept-subsumer pair is *suspiciously annulled in S* whenever there is a stable history segment S for which (1) the historic signature of that concept-subsumer pair contains only '0's and (2) when there is at least one other concept-subsumer pair for that concept of which the historic signature contains only '!' in S: this might be an indication that the subsumers marked by '0' are missing from the transitive closure set because of the removal of any property marked by '!'. To clarify these definitions, Table 1 provides an example of a concept with a HFI of 15, and an RFP of 4. Its HFI has 5 stable segments of which S5 is suspicious; this is because the historic signature of the properties (7) … (13) are suspiciously annulled in S5 due to the historic signature of property (5) in S5 containing '!'. This suggests that the subsumers marked by '0' are missing, i.e. unjustifiably absent, because of the – most likely justified – removal of the duplicate concept 'septicemia' (marked by '!') which was subsumed by these concepts.

Variables used in the analyses thereafter are the sizes of HFI and RFP as well as their ratio, the lifetime of a concept, and its number of suspicious events. A random number generator was used to select two random samples of each 100 concepts that were active since the first version. The samples were manually inspected for possible missing subsumers. The 1st sample was drawn from concepts which were marked as having a suspiciously gapped subsumer but not as having a suspiciously annulled subsumer. The 2nd sample consists of concepts which have at least one suspiciously annulled subsumer but are not marked as having a suspiciously gapped subsumer. Decisions for whether a subsumer is truly missing were based on SNOMED CT's editorial guidelines [9].

For the linguistic intension of a concept's meaning, we collected the historic signatures of all its FSNs over time and indicated for each change from one FSN to the next one whether a reason for the change was specified in one or other reference set distributed as part of SNOMED CT's metadata components (Table 2). Changes were syntactically qualified as having occurred in the term proper, in the semantic tag (ST), or in both. Changes from one ST to another were semantically qualified as being different, thus suggesting a distinct linguistic intension for the concept under scrutiny. To identify whether syntactic changes in the term proper for FSNs with the same ST would qualify as constituting a semantic change as well, we implemented a simple rule-based string transformation algorithm based on 99 rules. This algorithm processes each FSN in the history of a concept by iterating over a manually constructed knowledgebase sanctioning the substitution of certain character sequences (case insensitive). If at the end of the process an identical string is obtained for some FSNs, then these FSNs are considered semantically equivalent. It takes advantage of the fact that FSNs and subsequent changes thereof follow certain patterns. The example in Table 3 works for any HLA-*X*, e.g. HLA-Cw2, HLA-DQw8. Possible non-intended changes as in 'Chlamydia' → 'Cmydia' are innocent for our purposes as they would happen in each FSN of that concept. But obviously, it renders this algorithm inappropriate for computing the semantic similarity of distinct concepts on the basis of their linguistic intensions. A random sample of 200 concepts exhibiting at least one FSN change for which the algorithm failed to conclude semantic similarity was manually inspected for verification.

Changes in semantic tags (ST) were further analyzed by computing transition probabilities from one ST to another ST, and by performing agglomerative hierarchical clustering on larger trajectories and including activation and deactivation, for example finding → event → inactive, or substance →product → medicinal product. The result was assessed using the Ward (minimization of residual variance), average (averages of distances), and complete (minimization of diameter of each new group) methods from R cluster.

Table 3 – String transformation algorithm example

Search string	**Replacement**	**Rule**
"human leukocyte antigen"	→ " "	R1
"antigen"	→ " "	R2
"hla"	→ " "	R3
"-"	→ ""	R4
" "	→ ""	R5
String transformation sequence		**Rule**
'hla-dr8 antigen'		
'hla-dr8 '		R2
'-dr8 "		R3
'dr8 '		R4
'dr8'		R5
'human leukocyte antigen hla-dr8 antigen'		
' hla-dr8 antigen'		R1
' hla-dr8 '		R2
' -dr8 '		R3
' dr8 '		R4
'dr8'		R5
'human leukocyte antigen dr8'		
' dr8'		R1
'dr8'		R5

Results

Our analysis involved 403,360 concepts that were active for at least one version, 340,639 (84.45%) of which are still active in the July 2018 version (Table 4).

The size of the historic formal intensions of concepts ranged from 2 (204 concepts) to maximally 152 (1 concept, most likely not the one most frequently found in an EHR: SCTID:35057008 - *Nonvenomous insect bite of penis with infection (disorder)*). The number of stable history segments ranged from 1 (7,961 concepts) to 25 (15 concepts). Only 61,001 concepts of all concepts (15.13%) exemplified a rigid formal property set (RFP) constituting 100% of its historic formal intension, while 51,936 concepts (15.25%) do so for all currently active concepts. 39,771 (=340,639-300,868, 11.68%) active concepts have at least one suspiciously annulled formal property. 7,583 concepts (403,360-395,777) have at least one suspiciously gapped subsumer. 2,706 concepts exhibited both.

Manual inspection of the samples for possible missing subsumers revealed that 83 of the 100 concepts with the suspicious gap criterium and 91 of those selected on the basis of suspicious annulment of a subsumer did, in our opinion, miss at least one subsumer. Some examples are provided in Table 5.

The number of concepts involved in changes in linguistic intensions, separated in semantic tag changes and term proper changes, are displayed in Table 6. Only 19% of these changes were found to be documented by means of a reference set. Of the remaining 81%, 91% could be eliminated through our term transformation algorithm, thereby still leaving over 48,000 term changes to be manually inspected.

Table 6 – Changes in Fully Specified Names

		Concepts with Semantic Tag changes				
		0	**1**	**2**	**3**	**Total**
Concepts with Term Proper changes	**0**	333,712	33,697	3,833	56	371,298
	1	23,631	3,026	468	19	27,144
	2	1,748	1,704	1,186	0	4,638
	3	46	145	82	0	273
	4	1	1	5	0	7
Total		359,138	38,573	5,574	75	403,360

Table 7 – Examples of changes in linguistic intension without concept deactivation

SCTID: 374142001
1 Product containing miglitol 25 mg/1 each oral tablet (clinical drug)
2 Product containing only miglitol 25 mg/1 each oral tablet (clinical drug)
3 Product containing precisely miglitol 25 milligram/1 each conventional release oral tablet (clinical drug)
SCTID: 100191000119105
1 Acquired asymmetry of prostate (finding)
2 Asymmetry of prostate (finding)
SCTID: 102549009
1 Night cramps (finding)
2 Cramp in lower leg associated with rest (finding)
SCTID: 106109006
1 Number of previous abortions (finding)
2 Number of previous induced termination of pregnancy (finding)
SCTID: 302828001
1 Syringoma (disorder)
2 Syringoma of skin (disorder)

In our sample of 200 concepts with at least one such non-documented change, we discovered 15 concepts with an FSN change exhibiting a clear shift in meaning. Some examples are shown in Table 7. Hierarchical clustering revealed statistically significant (1) that findings typically transition to events, (2) that multiple semantic tags (context dependent category, finding, procedure, regime/therapy, and disorder) transition to situation semantic tags, and (3) that substance and product have transitioned to medicinal product form, clinical drug, or became significantly more inactive.

Discussion

Computing the historic formal intension of all concepts in SNOMED CT requires a thorough understanding of the meta-components, but is algorithmically straightforward. As to the question of what formal properties should be included in it – direct subsumers only, stated relationships separate from inferred ones, the complete transitive closure with or without all associative relationships – there is no agreed upon answer [13]. Our preference for using the full transitive closure set made it possible to identify for those concepts whose formal intension changes under that criterion, subsumers that were possibly inadvertently removed as a consequence of rightfully removing some subsumed concept. While many assessments are straightforward, a problem for the evaluation, however, is that not enough textual definitions are provided for terms and concepts. What is, for instance, the scope of 'partial' in a subsumer? A 'resection of stomach fundus' (Table 5), whether complete or partial to the fundus is for sure partial for the stomach. Also the use of 'and' and 'or' is problematic. SNOMED CT's editorial guide comes in here handy, but it seems that the application thereof by SNOMED CT's authors is not rigorously followed.

The same holds for evaluating FSN changes that are suspicious for changes in the linguistic intension (Table 7). We can't imagine that clinicians who used in an earlier version a concept of the form 'Product containing X', would consider that equivalent to 'Product containing *only* X' and 'Product containing *precisely* X'. Over 300 change-sequences of this sort have been made in 2018 despite deactivation of the concepts involved seems to have been the more logical choice in light of concept permanence. Finding such meaning changes turned out not to be straightforward precisely because the reason for change mechanism is insufficiently used. Our algorithm for comparing linguistic intensions can for sure be improved, but more practical would it be if SNOMED CT would include a much more detailed list of reasons for change, and why not, a formal representation of all those conditions which make a component follow – or not – the 'current editorial guidelines'. This includes changes related to the concept model itself. Our findings related to the transitions involving semantic tags are consistent with those obtained via another methodology in [1]. It is in the first place an incomplete anchoring of the semantic tags into the formal hierarchy that poses a problem.

A limitation of the work presented here is that more manual analysis of discrepancies found is required in order to produce clear cut precision and recall values for our proposed algorithm. Also more experimenting with alternatives for historic formal intension computation is needed. Finally, it is worth exploring which missing subsumption relations detected through our effort are found as well through other methods [7; 8; 14].

Conclusions

Our results demonstrate that SNOMED CT's intended adherence to the criterion of concept permanence can be quantified but that, unfortunately, this criterion is not sufficiently applied. That changes in the concept model as expressed through changes in semantic tags have a negative effect on the automatic interpretation is re-confirmed: it cannot be formally computed whether for any given concept a semantic tag is changed because of a *local* mistake in the interpretation of that concept or a *global* change at the level of the concept model. Changes in linguistic intensions quantified on the basis of changes in the term proper of FSNs are detectable as well, but currently only with low estimated recall and precision.

Without doubt, our work demonstrates that SNOMED CT's history mechanism is a formidable resource from which valuable knowledge can be extracted to prevent mistakes in the future. It is our opinion that a mechanism like this should be standardly available in any ontology worth the name.

Abstract

Unstructured electronic health records are valuable resources for research. Before they are shared with researchers, protected health information needs to be removed from these unstructured documents to protect patient privacy. The main steps involved in removing protected health information are accurately identifying sensitive information in the documents and removing the identified information. To keep the documents as realistic as possible, the step of omitting sensitive information is often followed by replacement of identified sensitive information with surrogates. In this study, we present an algorithm to generate surrogates for unstructured electronic health records. We used this algorithm to generate realistic surrogates on a Health Science Alliance corpus, which is constructed specifically for the use of development of automated de-identification systems.

Keywords:

Algorithms, data anonymization, electronic health records

Introduction

Unstructured electronic health records (EHR) such as discharge summaries, encounter notes, pathology reports and radiology are valuable source of information for basic, clinical and translational researchers [1-4]. These documents are often shared with researchers for clinical and biomedical research purposes. However, these documents may contain sensitive protected health information (PHI) such as patient name and unique patient identifiers. When private information is removed, patients are willing to share their medical records for research use [5]. To protect the privacy of patients, researchers need to share or access these documents in de-identified manner. Traditionally, the PHI was manually identified and removed before they are shared. However, with large number of documents, the manual process is tedious and not feasible to scale. In a study by Dorr et al [6], it was reported that average time required to manually de-identify one document (7.9 types of PHI per document) is 87.3 seconds. Various studies have shown that it is possible to automatically de-identify unstructured EHRs with acceptable accuracy [7-10].

Automated de-identification can be employed to replace traditional manual process. The process often consists of two main stages: identifying PHI and replacing identified PHI with surrogate information. Surrogates are realistic replacements of PHI that are close to real PHI but do not contain any private information. There are a few challenges in surrogate generation.

First, surrogates are supposed to be as realistic as possible. Since the documents are mostly intended to be shared for research, readability of the text need to be maintained. Researchers need to understand the text and ineffective surrogates can be distracting. Additionally, natural language processing systems also need the documents to be realistic so that the documents can be used to train the models to detect PHI in unseen documents. Second, the context of the document needs to be preserved. Some words, especially names and locations, can appear in different forms in one piece of text. For example, a name 'John Smith' can appear in the text as 'Smith, John', 'JS', 'Mr. Smith' or just 'Smith', they refer to one person and failing to maintain these complexities can lead to biased training during the development of de-identification systems.

Third, the temporal information also needs to be preserved well so that the order of occurrence of the clinical events is maintained. Lastly, PHI can carry not only private information, but also information that could be useful in research. For example, a person's name could imply one's gender, which might be useful when no structured gender information is not available.

Some datasets use placeholders or other forms of obfuscation to remove PHI [11, 12]. Stubbs & Uzuner [13] discussed the challenges of generating realistic surrogates and described their algorithm to generate surrogates. Multiple strategies were applied to PHI of different categories in doing this algorithm. Alphabet and date shift were introduced to maintain the consistency of the context in the document. However, these methods were specific to the US and not directly translatable to Australian setting. As a result, the readability of the surrogated documents is low, and the performance of automated de-identification systems trained using this surrogated data might not perform well on Australian EHR. In this study, we improved previous strategies for surrogate generation to make it more relevant to Australian setting. Several matching strategies for different kinds of PHI were developed to match PHI with same meaning expressed in different formats. We have used the Health Science Alliance (HSA) biobank de-identification corpus. HSA biobank is an institutional biobank at UNSW Sydney for translational research.

Methods

HSA Biobank Corpus

We constructed a large corpus of pathology reports that was annotated specifically for the use of development of automated de-identification systems for unstructured EHRs. The corpus consisted of 2100 pathology reports from 1833 patients. There were 38414 pieces of PHI identified in the corpus. Most of the PHI was tagged as names, locations, dates and IDs. Only few of

the PHI were related to PHI categories: contact and age. There was no category of profession or other information observed in the HSA corpus. EHRs and their annotations were stored in the format of XML files as shown in the Figure 1.

Figure 1— Annotated Sample Document from the HAS Corpus in XML Format

PHI Categories

The definition of PHI categories was the same as it was in the i2b2 2014 de-identification shared task [14]. This in turn was developed based on the HIPAA (Health Insurance Portability and Accountability Act) established by the USA which defines 18 categories of PHI. The guideline expanded the original 18 categories to include more information. All patients' ages were included despite that only ages above 89 years were considered PHI in the HIPAA. These categories had been grouped into 8 main categories and 25 sub-categories. Detailed categories and sub-categories along with examples of each categories are presented in Table 1.

Table 1 – Detailed PHI Categories and Sub-Categories

PHI category	Sub-category	Example
Name	patient, doctor, username	John Doe, Dr. Max, Mr. Smith
Profession	none	lawyer, teacher
Location	room, department, hospital, organization, street, city, state, country, zip, other	peri-operative unit-pow, macquarie ward – rhw, 12 abc street
Age	none	23, 98
Date	none	24/12/1987, September 26th
Contact	phone, fax, email, url, ipaddress	+61-421123456 abc@gmail.com 194.223.1.1
IDs	social security number, medical record number, health plan number, account number, license number, vehicle id, device id, biometric id, id number	mrn: 9174338 id number: 12r1500257
Other	none	finger print, company logo

HSA Biobank Surrogate Algorithm

Names were collected from the Internet for the use of surrogate generation so that the surrogates can be closer to reality. Names are stored in separate files by categories. Names collected were names of individuals and locations. Names included first names and surnames. Location names included Australian states, cities, streets, organizations and hospital names. These files were loaded into the memory as lists and were later used to generate surrogates. The names and location information were specific to Australia. When a PHI entity was not found in the existing constructed surrogates map, PHI was considered as first-time occurrence, and a new surrogate was generated in various ways according to the PHI's category. In many cases, such as IDs, phone numbers, URLs and emails, it was easier to generate surrogates since they were merely combination of strings of digits and letters and sometimes some special characters such as commas, periods, parentheses. We simply replace them with randomly generated strings with the original format kept. There were some other PHI categories such as individual names, locations names lists were used so that the surrogates can appear more realistic. We formulated some rules to pick surrogates from these lists for some categories to improve the performance, which is discussed in later sections. The HSA biobank surrogate algorithm is available at https://github.com/TCRNBioinformatics/PHISurrogates/.

Name and Location

Surrogate generation for names turned out to be the most challenging part. Mapping names that could appear in different forms and preserving as much information as possible were the key challenges.

A name can appear in many different forms in one given document. For example, if a comma existed in the name, we considered the name included both first and last name. Accordingly, the algorithm removed the comma and replaced original information with surrogate names from the lists we constructed. After this replacement, names could appear as a full name, or combination of initials, or a combination of the initial of one name and another name as full. In the algorithm, we took the first two letters from both parts of the name as the key in the map. For example, "JOSM" in the case of "John Smith". If an abbreviation was observed in the text, a space character was used. For example, "J(space)SM" for "J Smith" and "JO (space)(space)" for "John". The reason for not using only the first initial letter was that different names might have identical initials and it could cause mistake in mapping. For example, "John Smith" and "Jack Scott" had the same initials "JS". On the other hand, "John" and "Johnny" could stand for the same person if "Johnny" was used as a nickname for "John". So, taking the whole name as a key could also cause mismatching in the map. With the two initials as key, a simple rule can be applied: if more than half of the letters in the key are same, they are considered as same name. For example, "JOSM", "J(space)S(space)", "JOS(space)", "J(SPACE)SM" and "J(space)S(space)" were all considered one name. As for the names as initials, we did not look up in the map but proceeded to the surrogate generation directly as the algorithm was able to map a full name's initials to the initials of its possible surrogate with the method describe above. For example, "JS" can be directly mapped to "LU" without looking up in the map or the name table so it is faster. The titles (i.e., "Dr.", "Mr.", "Miss.", "Mrs.") were extracted out initially. These titles were then added back to the surrogate names generated later.

In order to preserve context, two rules were applied when generating surrogates. Firstly, to preserve the gender information, we constructed and split the names dictionary into three types; male first names, female first names, and surnames. A first name was first searched in both male and female first names list to determine its gender. For those that belonged to both, or not found in both, a random gender was given. Then a surrogate was picked from the dictionary according to the name's gender. Then alphabet shift of fixed length was applied. With

this shift, the initial letter of a name was mapped to another letter in the alphabet, then a name starting with this letter was picked from the names dictionary lists as surrogate. We maintained various dictionaries for different sub-categories of locations, including countries, states, cities, streets, hospitals and organizations. Surrogates of locations were randomly picked from dictionaries accordingly.

Date and Age

A randomly generated date shift in the range of 1 to 730 days was applied. Dates and ages in records from same patient were shifted with the same length to maintain temporality. Similar to the names PHI category, dates could appear in various forms. For example, '18/12/2017' could appear as '18.12.2017' or '2017-12-18'. Similarly, a date '18/12' could be written as "December 18" or "Dec 18". Another challenge was the ambiguity of date strings caused by different date notation styles. For example, a date string "03/04/05" could possibly in the format of "DD/MM/YY" or "YY/MM/DD" or "MM/DD/YY". Since all the reports were retrieved from Australian hospital, we considered all the date strings are of either "DD/MM/YY" or "DD/MM/YYYY" format. We normalized all the non-standard date variations into ISO-8061 standard, "YYYY-MM-DD". The parsed dates were then shifted by adding a time shift in the format. As for the age information, applying a date shift was relatively easier. The date shift in days was converted into years and added.

ID and Contact

Surrogates for IDs were relatively easier to generate. For BIOID and IDNUM, surrogates started with two digits from 10-99, followed by an "N" and an "R" respectively, then seven digits from 1000000-9999999, as similar format was observed in our documents. Medical record numbers with seven digits varied between 1000000 and 9999999, followed by three alphabets. As for fax and phones, all surrogate numbers were generated in the Australian format: two digits from 01-08, followed by seven digits from 0000000 to 9999999. For emails, the format was a random string of length 32 plus "@gmail.com". Surrogates found from the list map or newly generated information was then used to replace the original PHI.

Results

We presented an algorithm for surrogate generation for de-identification of unstructured EHRs. This algorithm can be used either during the de-identification corpus construction or during the development of automated de-identification systems for unstructured EHRs. We tested our algorithm on 2100 annotated pathology reports from the HSA corpus. The algorithm took a total time of 2.94 seconds to process the 2100 documents and 0.0014 seconds per document on average. There was 38,414 pieces of annotated PHI in the corpus, 18.29 in each file on average. Most of the surrogates generated were names and locations (Table 2). Among all PHI entities in the HSA corpus, a total number of 1085 pieces of PHI were replaced with the previously generated surrogates found in the existing map before a new surrogate was generated (Table 2). Though it is not feasible to validate every surrogate generated, two authors have manually verified 5% of the documents from the HSA corpus to assess the readability and contextual information of the documents after surrogate generation. Our algorithm has generated surrogates as intended but few issues were observed, as we discuss in the next section.

Table 2— Count of Surrogates Generated by Categories and Found in the Lists Developed

Category	Count of surrogates	Count of surrogates from lists developed
Name	11789	284
Age	141	0
Contact	7	0
Location	9861	104
Date	7665	321
ID	8951	376
Professions	0	0
Other	0	0
Total No. of documents	2100	1085

Discussion

We discussed in detail strategies applied to tackle the key challenges in surrogate generation. Lists of names and locations were collected and used to make the surrogates as realistic as possible. Maps of existing surrogates were used to make sure that same surrogates were used to replace the same objects so that the context could be maintained. Formats of dates, IDs and contacts were saved according to the Australian standards since the EHRs were all retrieved from Australian hospitals. For names, a key of first two letters of both part of names was designed to deal with co-reference and ambiguity. Also, a date shift was applied for the generation of dates and ages so that the progress of date in the context can be preserved. The information of names was preserved by determining the possible gender of name by searching in the real name lists.

Alphabet shift was applied on names to maintain the context. There are advantages mapping the letters with a fixed alphabet shift. We could easily replace the initials with the shifted letters without concerning about the ambiguity of initials, such as "JS" for either "John Smith" or "Jack Scott" would both be replaced by "LU" with a shift of length 2. Additionally, mistakes in, mapping initials to names could be reduced too. A consistent shift of initials could make sure that the surrogates are distributed more evenly so that the surrogated documents can have a better performance when training automated de-identification systems. It is possible that the shift of initial letters in names can be inferred according to the frequency of letters in the context. It is possible that an initial can be used to identify a person, but since there are a limited number of names that appear in the documents, and the alphabet shift is generated randomly per document, it is almost impossible to deduct the original initials from the surrogate names. Even if the alphabet shift pattern is identified, only the initials of the names can be obtained, so the risk of re-identification is still negligible.

The findings in this study are subjected to several limitations. There was no profession observed in the corpus, the surrogate generation process on professions was not applied and tested. Patients' health status might be related to their profession and a surrogate need to preserve such information so that the potential relationship could be used for research. Also, as these documents are generated by clinicians, there is a possibility of spelling errors which could impact surrogate generation process. Our algorithm doesn't consider this and as a result it is possible that a misspelt PHI entity could be replaced with a non-contextual based surrogate. Date shift was applied to dates and ages in the algorithm. However, some date information remained in the documents such as holiday names, like Christmas and New

Year's Eve. This information can be used along together with the generated surrogates to infer the date shift and therefore get the original date and age. In future, we would like to address these limitations by improving our surrogate generation algorithm in turn reducing the risk of re-identification.

Conclusion

In summary, we presented an algorithm to generate realistic contextual surrogates for unstructured EHRs de-identification systems. The algorithm can also be used to construct a corpus for the development of de-identification systems. In the algorithm, replaced the PHI with realistic surrogates in order to maintain the quality and context of the documents. Australian names and date formats were used in this study. Our findings suggest that the algorithm presented in this study is capable of processing large number of documents within few seconds. However, the documents need to have PHI information already identified. Different strategies were applied to tackle different challenges. An existing surrogate map is maintained to make sure that same PHI, or PHI with the same meaning are replaced with the same surrogate so that the context is preserved. However, professions and PHI annotated as 'other', which can possibly be an important source for research use, and a critical risk of identification leak, are not observed in our HSA corpus. This study suffers from various limitations such as failure to handle misspellings and holiday information. Future work in this area is required, especially to reduce the risk of re-identification.

Abstract

Personalized medicine implies reducing invasiveness of therapeutic procedures. Although interventional radiology proved a very interesting alternative to surgical procedures, it still raises concerns due to the irradiation dose received by the medical team (and by the patient). We propose a novel concept allowing to reduce very significantly the irradiation dose during the phases where tools inserted in the patient have to be tracked with respect to previously acquired images. This implies inserting a miniaturized X-ray detector in the tip of the tools, and reducing the dose by a "rotating collimator". We demonstrate that real-time processing of the signals allows accurate localization of the tip of the tools, with a dose reduction of at least ten times.

Image Processing, Computer-Assisted; Radiology, Interventional; Catheterization

Introduction

Interventional radiology is nowadays widely used in many medical fields such as cardiology, neurology, vascular surgery, gastroenterology, urology, gynaecology and orthopedics. In 2010, 545,000 interventional radiology (IR) procedures were reported in France for both diagnoses and treatments [1]. The benefits of interventional radiology are numerous and well established.

Among these procedures, catheterization consists in introducing a catheter in the patient's body through arteries or vessels to a certain region of the body for diagnostic or therapeutic purposes. Catheterization is a delicate procedure and it is most often performed under continuous 2D X-ray imaging, i.e. fluoroscopy guidance, to help the physician localize the catheter tip in the vascular system.

However, since fluoroscopy is performed each time the catheter moves, the staff (mostly the operating physician) and the patient can be significantly exposed to ionizing radiations, particularly in long procedures. Deterministic effects threshold due to high doses may be reached in such long procedures [2].

To follow the guidelines of the ALARA principle (As Low As Reasonably Achievable) [3], there has been a proposed approach for fluoroscopy guidance to reduce the dose received by staff and patients during IR procedures [4]. As compared to conventional fluoroscopy guidance which implements an X-ray cone beam, this approach suggests Virtual Fluoroscopy (VF) guidance based on a rapid scanning of the imaging field by an X-ray fan beam.

In this paper, we report the implementation of this approach as a proof of concept. Firstly, the operating principle of the method and its implementation are described. Then, the in-vitro exprimentation carried out in clinical conditions is presented. Finally, measured results are analyzed and discussed before conclusion.

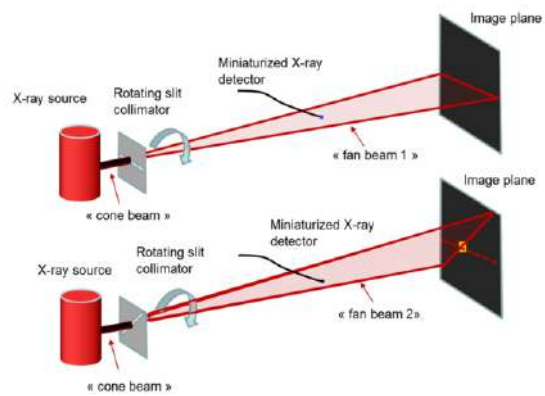

Figure 1 – Principle of the Proposed Virtual Fluoroscopy Method Based on X-Ray Fan Beam Scanning of the Imaging Field

Methods

Operating Principle

The proposed VF approach makes use of an X-Ray fan-beam to scan the image field during each fluoroscopy pulse. A rotating-slit collimator is positioned at the cone beam output of the X-ray tube. This allows the obtaining of a rotating fan beam, as illustrated in Figure 1. A miniaturized real-time X-ray detector in a guidewire is placed between the slit collimator and the image panel. The rotation speed of the collimator disk is set to be equal to the fluoroscope pulse rate. During the fan beam scan of the image field, the detector probe is irradiated two times at two specific brief moments corresponding to two projected slit positions on the image plane, $l_1(t_1)$ and $l_2(t_2)$. By detecting the detector-irradiated moments t_1 and t_2, one can determine the detector position projected in the image plane. Figure 1.a and b illustrates the two detected moments t_1 and t_2,

with corresponding slit projections l_1 and l_2 in the image plane. By calculating intersection of l_1 and l_2, the detector position projected in the collimator plane, x, is first determined and then, the corresponding position in the image plane, x', is obtained by projection along the line defined by x and the X-ray source focus. Thus, during the IR procedure, the detector position can be real-time displayed at the fluoroscopy pulse rate.

Implementation

Figure 2 implements this VF approach using several major parts presented as follows.

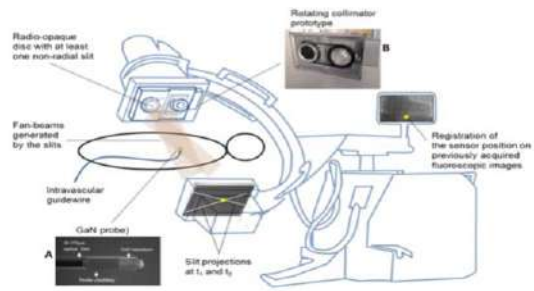

Figure 2 – Implementation of Virtual Fluoroscopy Guidance

Rotating Slit Collimator

The collimator is a 1mm-thick disk, made of Cadmium Tungstate (CdWO4), a high-density material (2'' wafer from Saint Gobain Cristal). It is noted that 1mm-thick CdWO4 absorbs more than 95% of the photon fluency at 100 keV. Moreover, CdWO4 is a scintillator with relatively high light yield, and its prompt luminescence can be detected for the synchronization of the collimator rotation on the fluoroscopy pulse rate.

The disc has a single off-axis straigth-line slit positioned at a distance *R*=2mm from its axis, as shown in Figure 3. The slit has a width of 220µm. The collimator is driven using a brushless motor (80280007, Crouzet, France) for a rotation speed up to 3000rpm (which corresponds to a fluoroscopy pulse duration down to 20 ms).

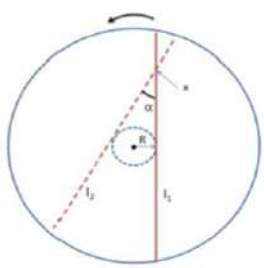

Figure 3 – Design of a Collimator with a Single Off-Axis Slit

Miniaturized Detector Probe

The detector probe is made of a small-volume Gallium Nitride (GaN) radioluminescent (RL) transducer and a coupled optical fiber to collect RL signal and to transmit it to a photodetection module. The GaN transducer has a very high RL yield with a response time in the order of ns [5]. The use of a small volume GaN transducer can produce detectable RL signal, which is suitable for designing a miniaturized detector probe.

The designed detector probe has an outer diameter smaller than 400µm, incorporating at its tip end a Si-doped GaN crystal of ~0.1mm^3 (Saint Gobain Cristals, France).

The detector probe is connected to a photodetection module for its operation. The associated photodetection module mainly consists of a photon counting head (H10682-210, Hamamatsu photonics Corp., Japan). It outputs a pulse of 10ns-width per photon and provides a pulse-pair resolution of 20ns. This signal is processed in real time by an FPGA-based processing unit.

This unit is designed to perform differents tasks: i) synchronous real-time processing of detected signal (sliding counting window of 100µs with a 10 µs resolution), ii) motor speed control and iii) instantaneous collimator position tracking.

System for In-Vitro Testing

Figure 4 illustrates a VF testing system making use of different designed parts presented above. It employs a cylindrical Plexiglas Phantom of 12cm in diameter. The detector probe is placed on the axis of this phantom. The X-ray cone beam comes from the kV On-Board-Imager (OBI) embedded on the radiotherapy system (Truebeam, Varian, Inc) installed at Centre Hospitalier Lyon Sud. This clinical equipment allows accurate positioning and alignment of the collimator and the phantom. OSL dosimeters are also employed at the top surface of the phantom for absolute dose measurements.

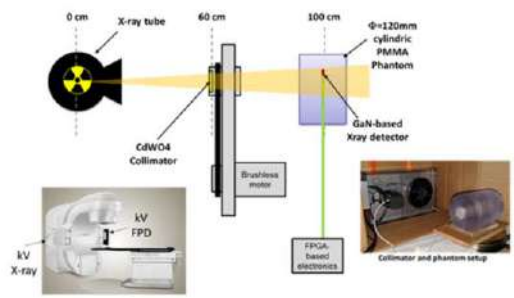

Figure 4 – System for In-Vitro Testing

Results

Dose Reduction

The proposed VF approach allows dose reduction by the ratio between the fan-beam field and the cone-beam field. By assuming an homogeneous dose in the cone beam field (i.e. $D_{CB}{\sim}constant$), the dose at a given Point of Interest (POI) in the fan beam field can be expressed in function of the cone-beam dose as:

$$\begin{cases} \boldsymbol{D_{FB}(r){\sim}D_{CB}\frac{cos^{-1}\left(\frac{R-0.5w}{r}\right)-cos^{-1}\left(\frac{R+0.5w}{r}\right)}{\pi}\ for\ r>R} \\ \boldsymbol{D_{FB}(r)=0\ for\ r{\leq}R} \end{cases} \quad (1)$$

where w is the width of the slit.

Figure 5 shows the virtual fluoroscopy dose evaluated according to equation 1.

Due to the off-axis position of the slit in the collimator, central area of the field is never exposed (blind area). For any POI positioned at an off-axis distance larger 2.5mm, the calculated dose behind the collimator is more than 20 times smaller than the one in front of the collimator.

Experimentally, we acquired images with the OBI X-ray imaging system while the collimator was in rotation at 1000rpm. We used a high dose setting of the tube to obtain a signal strong enough on the imager (i.e. 70kV, 155mA, 644ms). An X-ray image is shown in Figure 5 as well as the grey level profile along the yellow line. The central black disk of 4mm in diameter corresponds to the blind area. The bright white ring surrounding this area is due to the quasi-tangential position of the slit for these positions. The measured grey level profile is very consistent with the calculated profile shown in Figure 6.

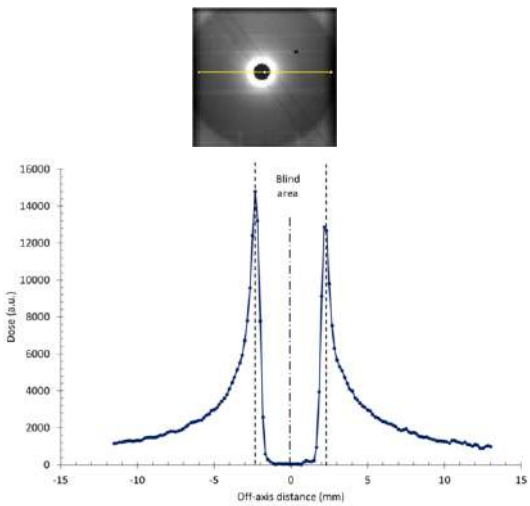

Figure 5 – Off-Axis Dose Variation Evaluated on the Rotating Collimator Image with the Gray Levels Profile Measured Along the Yellow Line

The absolute doses were measured by using the nanoDot OSL dosimeters (Landauer Inc, USA). Each consists of a 5mm diameter, 200µm thick Al2O3:C disk. The dosimeters were placed at distances D1=8mm and D2=18mm from the collimator rotation axis, on the top surface of the phantom. Each dosimeter was exposed for 10 images (70kV, 100mAs per image). The doses measured without the collimator were of 64mSv and of 62mSv for D1 and D2 positions, respectively. The dose with the collimator in operation (at 1000 rpm) decreased down to 984µSv and 681µSv, respectively. It corresponds to a dose reduction by a factor of 66 and 94 for D1 and D2, respectively.

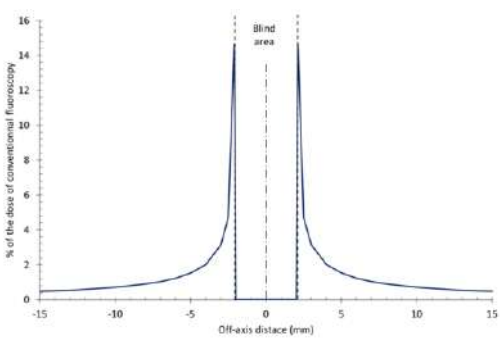

Figure 6 – Evaluated Fan-Beam Dose Versus the Off-Axis Distance of the POI (expressed as percentage of the cone beam dose)

Detection of the X-Ray Detector Probe Exposure

We placed the X-ray detector probe at a depth of 60 mm in the PMMA phantom and successively at 4mm, 7mm, and 12mm from the rotation axis (projected positions in the collimator plane). The obtained images and results are shown in Figure 7. The collimator rotation speed was set at 1000rpm and 1500rpm, respectively.

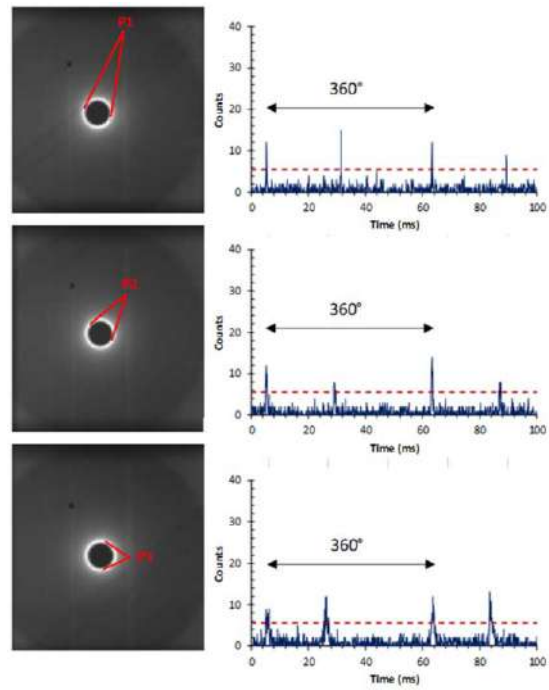

Figure 7 – X-ray Detector Probe Signal for Probes Placed at 60mm Depth in the PMMA Phantom and at Distances of a) 4mm, b) 7mm and c) 12mm from the Rotation Axis.

Figure 7 shows the signal acquired for the 3 detector probe positions. The noise floor is much higher than the dark count noise of the detector but remains sufficiently low to identify the signal peaks resulting from the detector irradiation. The slit rotation speed can be measured as the time between the i^{th} and $(i+2)^{th}$ peaks. It was measured at ~58ms/turn (i.e. 1035rpm) and ~38ms/turn (i.e. 1569rpm) for 1000rpm and 1500rpm setups, respectively.

The time between two successive peaks linearly depends on the collimator rotation angle, β required to move from slit position l_1 to the l_2 position. The angle between these two slits positions is given by $\alpha = \pi - \beta$. The radial distance of the detector from the rotation axis is given by $r = \frac{R}{\sin(\alpha)}$. We also extracted the value of α from the images shown in Figure 7. Results are shown in Table 1. For the different tests (3 probe positions and 2 collimator rotation speeds), the α values obtained by signal and image processing are consistent.

Discussion

Collimator Optimization

The testing results confirm significant dose reduction (from one to two orders of magnitudes). However, with the proposed slit

Table 1 – Results Summary

	Time /rotation (ms)	Rotation speed (rpm)	Time between consecutive probe exposures (ms)		Signal processing			Image analysis	
			Mean	Standard deviation	Rotation Angle	Alpha	Estimated radial position (mm)	Alpha	Estimated radial position (mm)
Position P1	57.9	1035	261.1	0.8	162.2°	17.8°	12.9	18.7°	12.3
	38.4	1561	171.4	4.1	160.5°	19.5°	11.8		
Position P2	57.9	1036	237.4	2.3	147.5°	32.5°	7.2	32.0°	7.3
	38.2	1571	156.8	4.8	147.8°	32.2°	7.2		
Position P3	58.1	1034	203.0	2.5	125.9°	54.1°	4.4	58.6°	4.1
	38.1	1575	132.8	7.9	125.5°	54.5°	4.4		

geometry, the dose reduction factor strongly depends on the distance of the POI from the collimator rotation axis. Thus, the dose profile versus the distance from the rotation axis (see Figures 5 and 6), show two asymptotic trends, a steep dose gradient for distances close to the slit off-axis distance and low slope for larger distances. One possible improvement may be to propose two slits as shown in Figure 8, to prevent significant dose exposure at POI close to the off_axis position of the slits. For instance, for an off-axis distance of $R = 2mm$, it could be suitable to use slits without any aperture closer than 3mm from the rotation axis. This geometry will increase the blind area (6mm in diameter instead of 4mm with the single slit geometry) but will guarantee a more homogeneous dose over the imaging field.

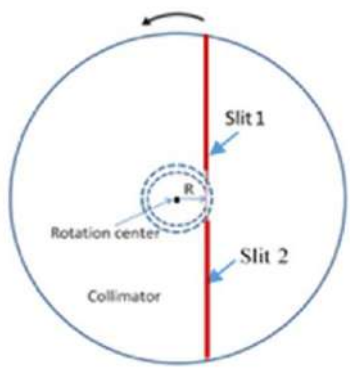

Figure 8 – Optimized Collimator Geometry with Two Off-Axis Slits

Miniaturized X-ray Detector Sensitivity

The GaN-based detector probe was operated in photon counting mode over a 100µs window. With the OSL dosimeter, we measured at the surface of the phantom a dose of 681µSv for an X-ray irradiation lasting 6440ms (10 images), i.e. a dose of ~10nSv over the counting window of 100µs. Moreover, the GaN transducer was placed at 60mm depth in the phantom where the X-ray fluence was only 19% of the fluence at the phantom surface (for the considered 70kV X-ray beam). Thus, a dose of less than 2nSv at the level of the GaN-transducer was sufficient to give more than 6 counts at the output of the detector as shown in Figure 7. This shows that the GaN-based miniaturized X-ray detector has a suitable sensitivity and a bandwidth well adapted to the VF application. Some optimizations remain to be done for contrast enhancement since the signal baseline was much higher than the dark count rate of the detector: this could be due to an insufficient shielding against radiations or parasitic scintillation light. It is worth mentioning that the corresponding dose behind the phantom, i.e. at 120mm depth was ~0.4nSv for 100µs and was not suffficient to activate the flat panel detector at this time resolution.

Conclusions

The VF method for IR procedures has been implemented and tested. The experimental results have shown that the dose can be reduced by one or two order of magnitudes by the use of a rotating slit collimator. Further studies need to be carried out on fluoroscopy clinical systems to assess dose reduction and localization resolution achieved by VF guidance as compared to conventional fluoroscopy guidance. Moreover, this study also confirms that the GaN-based miniaturized detector probe allows sufficient IN/OUT field contrast and bandwidth for this application (activated within 100µs by a dose smaller than 2nSv). These results establishes the proof of concept for the proposed VF approach. This novel method will be used for interventions such as embolization interventions, coronary angioplasty procedures, cryotherapy or radiofrequency ablations, biventricular cardioverter-defibrillator implantations. These instances represent several millions of interventions per year world-wide, so that we expect a major impact on Public Health.

Abstract

The W3C project, "Linking Open Drug Data" (LODD), linked several publicly available sources of drug data together. So far, French data, like marketed drugs and their summary of product characteristics, were not integrated and remained difficult to query. In this paper, we present Romedi (Référentiel Ouvert du Médicament), an open dataset that links French data on drugs to international resources. The principles and standard recommendations created by the W3C for sharing information were adopted. Romedi was connected to the Unified Medical Language System and DrugBank, two central resources of the LODD project. A SPARQL endpoint is available to query Romedi and services are provided to annotate textual content with Romedi terms. This paper describes its content, its services, its links to external resources, and expected future developments.

Keywords:

Pharmaceutical Preparations
Semantics
Vocabulary, Controlled

Introduction

Drug information is spread over multiples sites on the Internet. Summary of Product Characteristics (SPCs) are documents produced by pharmaceutical companies and approved by public health agencies. In France, ANSM (Agence Nationale de Sécurité du Médicament et des Produits de Santé), the French Medicines Agency, publishes SPCs approved by itself or the European Medicines Agency (EMA) on a website. An SPC contains key information about a marketed drug like the therapeutic indication(s), the posology, dosage adjustment, drug-drug interactions, and contraindications [1,2].

However, other additional knowledge related to marketed drugs can be found on the Internet and is not clearly connected. For example, the French thesaurus of drug-drug interaction (DDI), edited by ANSM, is the official reference document on this topic. This document, available as a PDF file, describes potential DDI (PDDI) between molecules. The links between molecules in the SPC and molecules in the reference document are not explicit and cannot be linked automatically due to semantic and syntactic interoperability issues. Another example is information about drugs' safety during pregnancy. The CRAT [3] (Centre de référence sur les agents tératogènes) is a French public organization especially involved in this public health issue. It provides free access to information about risks of drug intake during pregnancy that often disagrees with the SPC documents [2]. Still, connections and comparisons between these two sources can only be made by humans.

Furthermore, specific or general international sources, like DrugBank [4] and DBpedia [5], deliver supplementary information about drugs marketed abroad or about characteristics of molecules. DrugBank is a comprehensive, freely accessible, online database containing a large amount of information on molecules (e.g., chemical structure, half-life). DBpedia provides structured, machine-understandable knowledge extracted from Wikipedia articles. Many drugs and molecules are described by DBpedia contributors. The Unified Medical Language System [6] (UMLS) is a compendium of a large number of national and international vocabularies. In particular, UMLS contains RxNorm [7], a standard nomenclature developed by the United States National Library of Medicine (NLM) in the field of medications and the MeSH [8], a comprehensive controlled vocabulary for the purpose of indexing scientific articles.

The scattering of information is a significant issue for information retrieval which hampers the reusability of up-to-date knowledge on the web. Tim Berners-Lee, the inventor of the World Wide Web, suggested a 5-star deployment scheme for sharing information on the web (figure 1).

Figure 1– 5-star deployment scheme for Open Data [1].

The idea is to use W3C standards when publishing data in order to create a semantic graph that is capable of interlinking information of various datasets distributed over the web.

The W3C project, "Linking Open Drug Data" (LODD), focuses specifically on linking various sources of drug data together [9]. Participants of the LODD project have already made dozens of datasets relevant to pharmaceutical research and development available as linked data. In this paper we present Romedi, a new open dataset on French drugs linked to other related resources on the semantic web. In the methods section we discuss the Romedi data model and how it was linked to external resources. In the results section, examples of use cases are described.

[1] Source : https://5stardata.info/en/

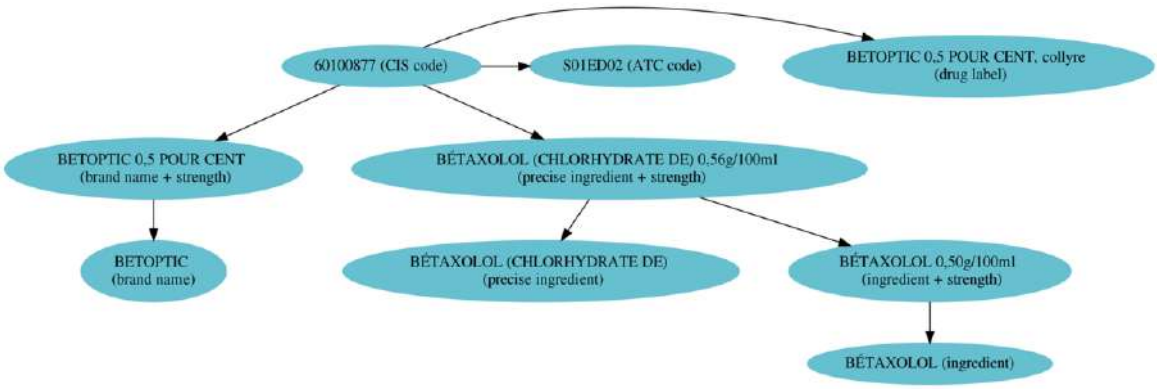

Figure 2– The Romedi data model instantiated with the drug "BETOPTIC 0.5 POUR CENT, collyre". The normalization step extracted the brand name (BETOPTIC) and the strength from the drug label. The ingredient was also normalized and linked to its corresponding UMLS concept C0005320 and DrugBank concept DB00195

Methods

Data Model

The Romedi data model is close to the RxNorm terminology [7]. It contains similar classes like the brand name (BN), ingredient (IN), and precise ingredient (PIN). The CIS code is an identifier of a marketed drug in France, and the URL (Uniform Resource Locator) to access the SPC depends on this code. For example, "BETOPTIC 0.5 POUR CENT, collyre" (Figure 2), is the label of a drug identified by the CIS code 60100877. The SPC of this drug is accessible at http://base-donnees-publique.medicaments.gouv.fr/affichageDoc.php?specid=60100877&typedoc=R. Each marketed drug has one or several ATC codes. The Anatomical Therapeutic Chemical (ATC) is a widely used system of alphanumeric codes developed by the World Health Organization (WHO)[2] for the classification of drugs.

In France, the main data source for marketed drugs is the "base de données publique des médicaments", a freely accessible database available in a text file format[3] which is updated every month by national health authorities. It contains all currently marketed drugs and drugs withdrawn from market in the last three years. The database contains details on marketed drugs like CIS codes, drug labels, and molecules. A normalization and transformation process is needed to instantiate the Romedi model as the concept of brand name is not present in this database. For example, "INEXIUM 20mg, comprimé gastro-résistant" is a drug label but the brand name "INEXIUM" is not present and must be extracted. In addition, only the precise ingredient is present for some drugs. For example, "pravastatine sodique" appears but the term "pravastatine", the ingredient, is missing. This normalization step was done by using regular expressions algorithms and an interface for manual validation by a pharmacist. This step was fully described elsewhere [10].

After model instantiation, ingredient instances were linked to UMLS [6] (Unified Medical Language System) and DrugBank [11]. The mapping between the French and international reseources was done as follows: the mapping is automatic if two terms have a perfect match, semi-automatic with a validation interface when a partial match is found, and manual when a French term cannot be found.

Ingredients were also linked to the French thesaurus of DDI. The automatic extraction and transformation of the PDF document to a CSV file was done with an R package[4]. The first use case to exploit external resources links was to compare French reference document on DDI with international ones. Ayvaz et al. [12] managed to gather information about DDI from publicly available sources, and the authors used DrugBank identifiers to describe couples of DDI interaction from different sources. The authors made a merged-PDDI database that can be downloaded online. The external links to DrugBank were used to integrate French knowledge to the merge PDDI database and to automatically compare the French national reference with other sources.

Medication Extraction Module

Automated identification of drugs in unstructured data, like social media or clinical notes, is essential for post-marketing drug safety surveillance that aims to detect signals of drug misuse or adverse event effects [13,14]. The natural language processing goal is not only to identify the terms in a corpus that correspond to drug entities, but also to map these entities to a well-established knowledge base. 'Semantic annotation' is the name given to this task by Jovanovic et al. [15].

IAMsystem, a general semantic annotation tool, was developed to facilitate the identification of Romedi terms in textual content. It was initially developed for the DoMINO project (Drug Misuses In Networks) that aims to detect drug misuse in fora [16]. The program performances were evaluated on a shared task for disease detection using death certificates [17], and the program was described in-detail at this occasion [18]. IAMsystem is open-source and available on GitHub[5]. It takes a set of terms as inputs, normalizes them, and stores them in a tree data structure for fast dictionary look-up. It handles abbreviations, a set of which were manually added for drug detection (e.g., "ac" for "acide", "vit" for "vitamine"). The typo module for drug detection is a logistic regression trained on a manually created gold standard of 3,438 potential spelling errors of brand names and molecules. Three explanatory variables are used:

[2] https://www.whocc.no/atc_ddd_index

[3] http://base-donnees-publique.medicaments.gouv.fr

[4] https://github.com/scossin/IMthesaurusANSM

[5] https://github.com/scossin/IAMsystem

1. The length of the potentially misspelled word
2. The similitude of the first letter between the potential misspelled word and the dictionary word
3. Levenshtein's distance between the phonetic transformation of two words

This last variable is computed with the French "phonetic" algorithm of the Talisman program[6]. The model is able to predict a typo of a brand name or an ingredient with a specificity of 0.93 and a sensitivity of 0.60. The performances of the annotator were evaluated in clinical texts, and the results are presented in the following section.

Romedi terms can be used to detect French drugs in textual content. Links to the CRAT website were established by detecting brand names in the alphabetic index of the web page. The graph model permits easy retrieval of information about the detected drug , such as the ATC code(s) or external resources links.

Results

Romedi Content

The first version of the Romedi terminology contains 13,661 French marketed drugs, 4,277 brand names, and 2,109 ingredients after the normalization step. Among the ingredients, 1,918 (91%) were linked to a UMLS concept and 1,434 (71%) to a DrugBank concept. 954 (95%) of the molecules in the French DDI thesaurus were mapped to a Romedi ingredient or precise ingredient. Since DrugBank contains French synonyms of ingredients and the French version of MeSH is integrated in the UMLS, most of the mappings were done automatically.

A web interface that makes the Romedi content available is accessible at https://www.romedi.fr. Like RxNav [19], the interface displays links between clinical drugs, active ingredients, brand names, ATC code(s), and external resources. Drug information from external resources is retrieved using SPARQL queries or application programming interfaces (API). For example, the DBpedia definition of a molecule is retrieved by a SPARQL query to its endpoint[7] and by using DrugBank links to DBpedia. Romedi resources are identified by their Uniform Resource Identifiers (URIs). For example, https://www.romedi.fr/romedi/CIS60100877 is the URI of the Romedi drug "BETOPTIC 0.5 POUR CENT, collyre", and is also a valid URL. Retrieving a representation of a resource identified by a URI is known as dereferencing a URI, and it can be used to obtain a representation that can be perceived by a user.

A SPARQL endpoint[8] is also available to query Romedi content. In addition, the terminology is freely downloadable as an RDF file and can be reused under an open license.

Automatic Comparison of the French DDI Reference Document with International

Mapping national ingredient concepts to international ones allows users to automatically compare drug-drug interaction information. Applied on more than 7 million drugs deliveries in France, the main discrepancy between the French thesaurus and international sources was with the couple "escitalopram – flecainide." This drug pair was considered contraindicated by an international source, and no risk of interaction is described in the French thesaurus although it contains four levels of severity. Full results of this work are available elsewhere [20]. The French thesaurus was integrated in the merged-PDDI dataset[9] in a linked open format.

Medication Extraction Module

Brand names and molecule identification performances were evaluated using the 'current medication' section in electronic health records (EHR) form from Bordeaux Hospital's emergency department. Among the 6,070 drugs detected (brand names or molecules), the specificity/sensitivity were 0.99/0.92 and 0.99/0.96 without and with the typo module respectively [10]. The performance of these models can be explained by the grocery list type of the input data and disregarding medication attributes (e.g., dosage, strength, and route). Further evaluation is required in narrative clinical notes. The programs can be installed locally[10] and the annotator is also available in an R package[11].

Discussion

Open Data has the potential to provide significant benefits to society. The Link Data movement aims to share and integrate knowledge on the Web. Still, many resources containing important information on drugs remain inaccessible to machine and hampers automatic comparison of knowledge.

Romedi is a French open dataset that connects French and international information resources about drugs.

First, the French dataset on marketed drugs (base de données publique des médicaments) was normalized and integrated in an RxNorm-like data model. Then, national and international sources were linked, including the French thesaurus of PDDI, the French reference for evaluating drugs safety during pregnancy (CRAT), DrugBank, and UMLS. An interface was developed to navigate Romedi terminology, and a SPARQL endpoint is accessible to query its content.

Developers can use Romedi API to retrieve information about French drugs for their website. Researchers can use Romedi services to extract drugs in textual content for post-marketing drug safety surveillance. Using the same terminology, data can be shared with other researchers to promote collaboration and enhance pharmacovigilance discovery.

Romedi URIs are currently used to index drugs in clinical notes in Bordeaux Hospital's i2b2 [21] data warehouse and to ease information retrieval. Searches can be performed by brand name, molecule, or ATC code. Medication extraction and indexation helps patient phenotyping and cohort identification tasks.

Future Developments

The current version of Romedi is 2.2 and the updating process is not fully automated. The biggest challenge will be maintainance of this terminology, especially correcting errors identified by users and managing updates of French-marketed drugs and external resources. Our aim is to build an engaged community of users and developers around Romedi.

So far, the Romedi data model contains no description logics. It would be feasible to infer logical equivalences between Romedi and RxNorm drugs by using a formal model. A mapping between Romedi and RxNorm beyond the ingredient level would facilitate French drug data integration in the Observational Health Data Sciences and Informatics (OHDSI) common data model that uses RxNorm as an international standard [22]. This mapping will be important to involve French researchers in international collaborations and research

projects on drugs, and it may help our national agency to exchange information about post-marketing surveillance.

Conclusions

In this paper we have presented Romedi, an open dataset about French drugs linked to multiple resources on the semantic web. Web services are provided to annotate textual documents and query Romedi content to retrieve additional information about detected drugs.

Acknowledgements

This project is part of the Drugs Systematized Assessment in real-liFe Environment (DRUGS-SAFE) research platform, funded by the French Medicines Agency (Agence Nationale de Sécurité du Médicament et des Produits de Santé, ANSM). This platform aims to provide an integrated system allowing the concomitant monitoring of drug use and safety in France.

Abstract

Semantic standards and human language technologies are key enablers for semantic interoperability across heterogeneous document and data collections in clinical information systems. Data provenance is awarded increasing attention, and it is especially critical where clinical data are automatically extracted from original documents, e.g. by text mining. This paper demonstrates how the output of a commercial clinical text-mining tool can be harmonised with FHIR, the leading clinical information model standard. Character ranges that indicate the origin of an annotation and machine generates confidence values were identified as crucial elements of data provenance in order to enrich text-mining results. We have specified and requested necessary extensions to the FHIR standard and demonstrated how, as a result, important meta-data describing processes generating FHIR instances from clinical narratives can be embedded.

Keywords:

Electronic Health Records, Natural Language Processing, Semantics

Introduction

Semantic Interoperability was defined in 2000 as "…integrating resources that were developed using different vocabularies and different perspectives on the data". Semantic interoperability requires that "systems must be able to exchange data in such a way that the precise meaning of the data is readily accessible and the data itself can be translated by any system into a form that it understands" [1].

Nearly twenty years later, the lack of semantic interoperability continues being an obstacle to a more rational and effective data and information management in healthcare and biomedical research. The authors of [1] had already distinguished between vocabularies and perspectives, highlighting the division between ontology ("what there is") [2] and epistemology ("what we can know") [3]. On the level of current health informatics standards, this has driven the evolution of two genres of semantic resources:

- Terminology systems (vocabularies, thesauri, formal ontologies, classifications), which attach meaning to domain terms and elaborate on necessary and sufficient properties of (classes of) domain entities;
- Information models, which are artefacts that provide standardized structure (section, entry, grouping, etc.) and context (diagnosis, past medical history, medication order) for clinical recording scenarios.

In this paper, we will focus on the latter, particularly on HL7 FHIR [4], a standard for healthcare information exchange and sharing, characterized by its straightforward approach to implement interfaces between Electronic Health Record (EHR) data and data consuming applications.

FHIR is based on interoperable building blocks named *Resources*, small data model components defining sets of properties that describe and provide structure for domain data acquisition. Currently there are approximately 150 resources, uniquely identified with Uniform Resource Identifiers (URIs).

Examples are *MedicationRequest* (prescription), *AdverseEvent*, *Procedure* and *Condition* (problem). They constitute a graph of clinical data by explicit inter-resource references [5]. For instance, a *MedicationRequest* resource explicitly references its prescriber (a FHIR *Practitioner* resource), its patient (*Patient* resource), and the drug prescribed (*Medication* resource). A built-in extensibility mechanism can enrich existing resource definitions.

Semantic interoperability within FHIR is provided by explicit, detail-oriented, prescriptive guidance, with its interoperable meaning anchored in external terminology standards, e.g. SNOMED CT, LOINC, or ICD-10. FHIR provides a granular way to exchange data using a RESTful style approach [6]. Its focus is on providing models for frequently occurring documentation and information exchange tasks. FHIR resources can be serialized in JSON and XML.

Looking at EHR systems in use, there is still a persisting gap between structured and coded information on the one hand and a much larger amount of semi- or unstructured narratives on the other hand. It is unrealistic that this textual documentation will be largely substituted by structured documentation [7]. This is where natural language processing (NLP), in particular text mining, comes in.

This paper addresses the issue how the output of clinical text mining systems can be harmonized in FHIR. We identify gaps in the current FHIR specification related to content essential for text mining. We introduce and discuss specific FHIR extensions that allow text-mining results to be represented in FHIR without loss.

Materials and Methods

The Text Mining System *Health Discovery*

The clinical text mining technology under scrutiny is *Health Discovery* [8] by Averbis GmbH. *Health Discovery* contains over fifty different text-mining annotators for the recognition of diagnostic statements, medical procedures, lab values, drugs, anatomy, morphology, scores and others. It is available for several languages, including English and German. *Health Discovery* bundles annotators in predefined text mining pipelines to facilitate the analysis of text genres such as discharge summaries or pathology reports. It has been successfully used for various use cases, e.g., data driven patient recruitment for clinical trials [9], automated coding and billing [10], filling of tumour registries, rare disease identification [11], antibiotic resistance monitoring [12], radiology report analysis [13] and health data de-identification [14].

UIMA

Health Discovery is based on the *Unstructured Information Management Architecture* (UIMA) [15], a flexible and extensible text-mining framework for the analysis and processing of unstructured text. UIMA allows defining text-mining pipelines consisting of a set of annotators called analysis engines. The analysis engines communicate in a pipeline by adding or modifying meta-information stored in the Common Analysis System (CAS), which, in addition to the metadata, also contains the currently processed document.

In UIMA, all elements to be extracted from texts must be predefined. This is done in a so-called *Type System*, where types and their attributes (features) are defined. The most common type is *Annotation*. It comes with the attributes *begin* and *end*, which specify the text position to which an annotation relates. These attributes are inherited by all subtypes of *Annotation*.

UIMA is only a framework and does not ship a rich selection of components. There are, however, component repositories like DKPro [16], which provide analysis engines of well-known text mining components. Prominent applications in Healthcare built upon UIMA are the DeepQA system Watson [15], the clinical Text Analysis and Knowledge Extraction System (cTAKES) [17], the medication entity and attribute extraction and normalisation tool MedXN [18], and MedTime [19], a software to extract and normalize TIMEX3-based temporal expressions from clinical text.

Making a Text Mining System FHIR Compatible

Currently, no standardized UIMA-based type systems for healthcare have found worldwide acceptance. Each text-mining provider usually defines its own type system. Interoperability is created by exchanging type systems between text mining systems – in UIMA, several type systems can be used simultaneously as long as their namespaces are unique – and mappings between type systems.

To make a text mining system FHIR-compatible, two basic procedures can be chosen:

- Defining a FHIR-compatible type system [20], or
- Exposing a FHIR compatible interface.

We pursue the second approach for the following reason: Healthcare data models continue to be the subject of intensive development. In the last 2-3 decades, different versions of the FHIR standard like Version 2, Version 3, Clinical Document Architecture (CDA) and FHIR have been published. There are also other healthcare standards like OpenEHR [21]. In order to support different standards and their versions in parallel, it is not feasible to create and maintain different versions of the text mining system with a different data model for each standard. Instead, it is sufficient and more effective to provide external interfaces to these standards and versions while keeping the data model of the underlying text mining system stable.

In this paper we describe how a FHIR-compatible interface looks like and how FHIR needs to be extended to meet the requirements of Text Mining. In particular, we will answer the following questions:

1. Which are the right FHIR resources and containers to return a text mining result?
2. How can the document text and text-mining annotations such as conditions and observations be linked together?
3. How can typical text mining features, particularly (i) text span of an annotation and (ii) its confidence score be specified in FHIR?
4. How can the types of our text mining system be mapped to FHIR resources and which challenges occur?

Results

FHIR Resources and Container for Text Mining Results

Typically, a text-mining result consists of the document text and associated text-mining annotations. The document text is usually returned back by the text mining system, mainly for the following reason: Text mining annotations contain a *begin* and an *end* attribute, which specify their exact position in the text at character level. Instead of pure text files, the sender often wants to analyse text-based documents such as PDF or MS Word. The text is then extracted during the text mining analysis. The *begin* and *end* attributes always refer to the text returned by the text mining system, not to the original document. The appropriate resource for the document text is a *Binary* resource. A *Binary* can contain any content, whether text, image, pdf, zip archive, etc.

Text Mining annotations can be represented in a corresponding clinical *FHIR Resource*, such as *Condition*, *MedicationStatement*, *Observation* etc. These resources are used to record detailed information about conditions, diagnoses, consumed drugs or any other observation that has direct or indirect impact on the patient's health.

In order to return a *Binary* together with its clinical *Resources* in a single artefact, it has to be grouped into a *Bundle*. A *Bundle* is a collection of resources useful for a variety of different reasons, e.g. returning search results or sending messages. Accordingly, different types of *Bundle*s exist, e.g., *document*, *searchset* or *collection*. In our case, we need a *Bundle* of type *collection*. A *collection Bundle* is a set of resources collected into a single package for ease of distribution.

It is important to understand that a text mining result is not a *document Bundle* in the FHIR sense. FHIR *document Bundles* represent solely structured documents that are authored and assembled in FHIR.

Linking Document Text and Text Mining Annotations: FHIR Provenance

In FHIR, resources in a *Bundle* have an independent existence – they can, e.g., also be accessed using the RESTful API. If the *Binary* was not linked to the clinical resources, it would not be possible to identify the origin of a text-mining determined resource in subsequent processing steps. Therefore, we need another FHIR resource to link both resources, the *Provenance*. *Provenance* contains, among others, three attributes: *entity* gives details about the source of the data (like a PDF, text…),

agent gives details about the algorithm that extracted the data (software name, vendor, version...) and *target* points at the created resource (e.g. *Condition*, *Observation*, *MedicationStatement*...). For each clinical resource, we also specify a *Provenance* resource. Figure 1 illustrates the resulting *collection Bundle* including clinical and associated *Provenance* resources.

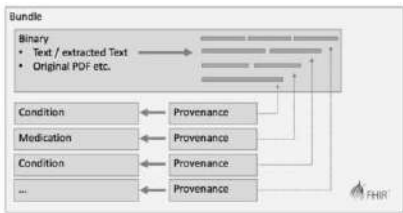

Figure 1– Simplified View of the Provenance Information Conveyed in a FHIR Bundle of Type Collection. The Result Is Conveyed in a FHIR Bundle of Type Collection. A Binary Resource Holds the Source Text (Character Stream) And/or the Extracted Text with the Original PDF Where the Text Was Extracted. Subsequently All Clinical Resources That Come out of the NLP Analysis Are listed. Each of these Resources Is Accompanied by a Provenance Resource.

Specification of Text Spans and Confidence in FHIR

As mentioned above, text mining annotations usually contain begin and end attributes that specify the exact position of an annotation in the text. Since there is no FHIR representation for these attributes yet, we specified two FHIR extensions, currently under approval by the international HL7/FHIR committee.

Extension *Character Range*

The rationale for this extension is to specify, within a source text, the place in which an annotation was found. Thus, the origin of a text mining annotation can be specified not only at document level, but also at word and character level. Traceability is an important feature of text mining systems to help users gain confidence in text mining applications and clinical research based upon text mining results.

The extension is named *character-range*. It contains an attribute named *valueRange* of type *Range*. *valueRange* itself contains the attributes *low* and *high* of type *SimpleQuantity* with the purpose to specify begin and end of annotations in text. *SimpleQuantities* always need a unit. Since characters are countable, their unit in FHIR is "1":

```
"extension": [{
  "url": "http://example.com/StructureDefinition/character-range/0.9",
  "valueRange": [{
    "low": {"value": 201,
  "unit": 1},
    "high": {"value": 219,
   "unit": 1}}]}]
```

Extension Confidence

Text mining results may be biased, incomplete or erroneous, their enrichment with a confidence score is therefore crucial. Especially text-mining systems based on machine learning, often provide a confidence value, which estimates the probability for the correctness of the annotation. Thus, the requested extension (ii) is *confidence*, specialising the type *Quantity*, stating the accuracy of annotations. The value range of a confidence is often, but not necessarily, between 0 and 1:

```
"extension": [{
  "url": "http://example.com/StructureDefinition/confidence/0.9",
  "valueQuantity": {"value": 0.1}}]
```

Mapping Text Mining Types to FHIR Resources

Now that the container, the resources and the necessary extensions have been defined, the mapping of text mining annotations to FHIR resources can be performed in a straightforward way. Both *Health Discovery* and *FHIR* know the notation of a *Concept* or *CodeableConcept*. Concepts exist to encode a medical statement with a term from a terminology. They typically consist of a code, a preferred term, a code system and the version of the code system. In *Health Discovery*, the synonym that is responsible for a match in a text (=matchedTerm) is also an attribute of *Concept*. Table 1 shows the mapping between *HealthDiscovery.Concepts* and *FHIR.CodeableConcepts*. Table 2 gives an overview of the terminology bindings used by *Health Discovery* for different *Concept* types in US English and German. In this work, we focus on the mapping of diagnoses, medications and laboratory values. Table 3 gives an overview of the mappings between *Health Discovery* and *FHIR*.

Table 1 – Mappings between HealthDiscovery.Concept and FHIR.CodeableConcept

Health Discovery	FHIR Resource
Concept	**CodeableConcept**
.conceptid	.code.coding.code
.dictCanon	.code.coding.display
.matchedTerm	.code.text
.source.split('_')[0]	.code.coding.system
.source.split('_')[1]	.code.coding.version

Table 2 – Terminology Binding in Health Discovery for US-English and German

Type	US English	German
Diagnosis	ICD-10 Clinical Modification [22]	ICD-10 German Modification [23]
Drugs	RxNorm [24]	ABDAMed [25]
Ingredients	WHO ATC [26]	German ATC [27]
Lab Values	LOINC [28]	LOINC [28]

Table 3 – HealthDiscovery Types Mapped to FHIR. Instances of (Codeable) Concept Are Marked with an Asterisk (*). The Mapping Between Medication.doseFrequency and MedicationStatement.dosage.timing (**) Is Not Further Specified, as It Is Rather Complex and Beyond this Paper

Averbis Health Discovery	FHIR Resource
Diagnosis	**Condition**
.concept*	.code*
.clinicalStatus	.clinicalStatus
.verificationStatus	.verificationStatus
.belongsTo	.subject.display
.side	.bodySite.text
Medication	**Medication**
.drug.ingredientConcept*	.ingredient*
.doseForm*	.form*
	MedicationStatement
.status	.status
.drug.strength.value	.dosage.doseQuantity.value
.drug.strength.unit	.dosage.doseQuantity.unit
.doseFrequency**	.dosage.timing**
.administrations*	.dosage.method*
LaboratoryValue	**Observation**
.parameter*	.code*
.fact.value	.valueQuantity.value
.fact.unit	.valueQuantity.unit
.interpretation	.interpretation.text

.upperLimit.normalizedValue	.referenceRange.high.value
.upperLimit.normalizedUnit	.referenceRange.high.unit
.lowerLimit.normalizedValue	.referenceRange.low.value
.lowerLimit.normalizedUnit	.referenceRange.low.unit

Assembling the JSON Response

Figure 2 shows an excerpt of a text mining response for the text "The patient had a cold". "Cold" is recognized as entity of the type *Condition* and annotated with the ICD-10 code "*J00 Acute nasopharyngitis* [common cold]".

Discussion

Provenance aspects of clinical data have been awarded major emphasis in recent years. The growing amount of EHRs provides unprecedented opportunity for its re-use in many tasks. However, there are various caveats to the use of such data, including inaccuracy, incompleteness and unknown provenance [29]. This is even more the case when EHR content is furthermore processed, such as by text mining systems. A dataset in FHIR created by structured data entry done by physicians requires a different interpretation compared to a seemingly identical dataset produced by text mining analysis of an unstructured narrative. For instance, the former one might meet the quality level required for triggering clinical decision support algorithms, whereas the latter one might not, although it may be perfectly suited for supporting cohort selection or outcome analyses. *Confidence* values that qualify each text mining generated data element can here be used as a valuable filter.

Quality assurance of text mining systems also requires formative assessment cycles in which human experts iteratively check extracted data elements against the source in order to assess their accuracy. If FHIR-based resources were not able to preserve this link between source and extract, this gap would have to be bridged outside the FHIR standard. The new *character-range* specification allows embedding text mining quality assurance completely within FHIR.

Our work is original in the sense that it extends FHIR to incorporate provenance and quality information. With the two extensions for *confidence* and *character-range*, FHIR now contains all specifications to represent text mining generated EHR extracts. Apart from this, two recent publications are worth mentioning, that combined FHIR with text mining. In [30], a FHIR data model automatically structures prostate pathology reports in several natural languages. In [18], the FHIR data model was also used to automatically structure free text and, in addition, to integrate structured data. In contrast to these systems, we argue that – due to different HL7 dialects and other standards – it is not necessary to base the underlying text mining system internally on FHIR, but to ensure that its external interface provides FHIR compatibility, as we have demonstrated. Thus, different text mining systems can operate in parallel or in combination on different HL7 dialects, feeding their results in a standardised information model.

Conclusions

FHIR is increasingly accepted as a universal clinical information model. It supports provenance assertions of data as a critical foundation for authenticity, trust and reproducibility. Provenance is especially relevant if datasets are created by machines, e.g. by text mining and machine learning. We have demonstrated how the output of a commercial clinical text mining tool can be harmonised with FHIR, preserving important provenance information like character span and confidence value. Necessary extensions to

the FHIR standard are currently being processed by the international HL7/FHIR committee.

MDRCupid: A Configurable Metadata Matching Toolbox

Noemi Deppenwiese[a], Petra Duhm-Harbeck[a], Josef Ingenerf[a,b], Hannes Ulrich[a]

[a] *IT Center for Clinical Research, Lübeck (ITCR-L), University of Lübeck, Germany*
[b] *Institute of Medical Informatics, University of Lübeck, Germany*

Abstract

Metadata matching is an important step towards integrating heterogeneous healthcare data and facilitating secondary use. MDRCupid supports this step by providing a configurable metadata matching toolbox incorporating lexical and statistical matching approaches. The matching configuration can be adapted to different purposes by manually selecting algorithms and their weights or by using the optimization module with corresponding training data. The toolbox can be accessed as a web service via programming or user interface. For every selected metadata element, the metadata elements with the highest similarity scores are presented to the user and can be manually confirmed via the user interface, while the programming interface uses a similarity threshold to select corresponding elements. An HL7 FHIR ConceptMap is used to save the matches. Manually confirmed matches may be used as new training data for the optimizer to improve the matching parameters further.

Keywords:
Metadata, Data Curation, Health Information Interoperability

Introduction

Modern healthcare produces large amounts of medical data, from routine documentation to data from clinical trials to hospital bills [1]. This data is captured using a wide variety of input systems, from hospital information systems to clinical trial management systems to laboratory systems to accounting software. The secondary use of such data for research purposes is aimed for, but complicated to establish due to the variety of different data formats [2]. However, even if the data is converted into a common format, the same bit of information may still be represented differently. For example, one system may choose to store systolic and diastolic blood pressure in two separate fields, another system may use a single field just called blood pressure. So, while the data may have the same format, it still differs semantically.

Therefore, when pooling data from different sources, e.g., for conducting meta-studies or collecting data from different healthcare providers a shared data format is needed (syntactic interoperability) first, but it alone does not guarantee that the provided data can be used together because different systems may choose different synonyms for their data (no semantic interoperability). Systems may define how they capture data by defining metadata elements which contain information about single units of data, e.g., the datatype or the unit of measure. These metadata elements can be used to identify corresponding fields in the datasets.

Then, generating a mapping including transformation rules allows converting the collected data from one system to be compatible with the data semantics of another system. In order to develop such mappings, in a first step corresponding metadata elements must be identified. This process is referred to as matching in this work.

Metadata elements need to be in a common format to be processed. The ISO 11179-3 standard [3] defines metadata elements and is supported by some metadata repositories. Metadata repositories are used to collect, store and administer metadata elements.

Multiple tools are providing an automated or semi-automated matching or mapping functionality. CUPID [4] is a popular schema matching algorithm that takes the label, datatype, permissible values, and overall structure into account but does not support all information contained in ISO 11179 data elements. Another example is the COMA++ software for schema matching which allows the usage and parametrization of multiple string-matching algorithms and accepts SQL, XML, and OWLs input files [5]. However, existing tools are not incoporating information from value sets, which is essential in the field of clinical trials.

Other systems like the MDM-Portal work by annotating metadata elements with semantic codes (in this case UMLS) and using this information to detect correspondences [6].

The objective of the developed software is to provide a highly configurable matching tool that can process ISO 11179 conformant metadata elements. The toolbox contains several string-matching algorithms as well as implementing the statistical bag-of-words method. The service can be accessed either via an application programming (API) or a graphical user interface (GUI). The toolbox includes an optimization module which processes already matched training data, to ease finding a suitable configuration.

Methods

Toolbox

Figure 1 shows the basic structure of the toolbox. To find the best match for a given data element from a set of candidate elements, a similarity score is calculated for every possible match. This score is calculated as the sum of weighted similarity scores for single data element attributes. These attributes can be regarded as metadata of the metadata and include, for example, name and datatype. Their values (e.g., *birthday* or *date of birth* for name and *string* or *date* for datatype, as seen in the left part of figure 1) are regarded as simple string values, to which processing pipes, consisting of any number of preprocessors and a lexical matching algorithm, can be applied.

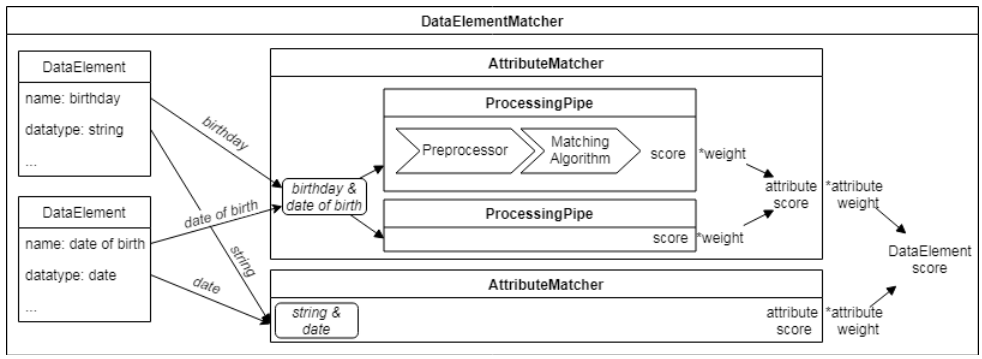

Figure 1- MDRCupid structure overview. For each metadata element attribute like name *or* datatype*, an AttributeMatcher calculates the similarity score for this attribute's values. In addition to the standard AttributeMatchers, three other calculations are performed that use information from more than one attribute (not shown).*

The toolbox provides several common lexical string matching algorithms like Levenshtein or n-gram based methods. Other string matching algorithms can be easily added provided that they fulfill two conditions:

- The algorithm needs to be normalized, and its results shall be in the range between zero and one regardless of the compared strings length.
- Higher scores shall indicate better matches. For algorithms calculating distances, this may be easily achieved by subtracting the calculated distance from one.

These conditions are necessary to ensure the optimization process works correctly. The similarity score for two string values from two data elements for the same attribute is then calculated as the sum of weighted results for all applied processing pipes. The weights for the processing pipes can be configured, as can the attribute weights mentioned before.

In addition to the comparison of simple string attributes (e.g., *name* values), similarity scores for other data element properties are calculated and contribute to the overall data element score. Since a data element may contain a list of permissible values (answer options), a similarity measure for two such lists is needed to include them in the overall score.

To calculate this measure, the similarity between every single option in data element *A* and every option in data element *B* is calculated using a configurable combination of the aforementioned lexical string matching algorithms. These scores are collected in a similarity matrix. Then, at most one number from every column and line is chosen so that the sum of these values is maximized. Every chosen value represents a match between two answer options, and the maximized combination represents the overall best matching.

Furthermore, the group elements containing a data element may hold information essential to its understanding, e.g., *inclusion* vs. *exclusion criteria*. Therefore, the similarity score between the surrounding groups influences the overall score, too.

To calculate the structural similarity between two data elements *A* and *B*, all parent group labels of *A* (a_i) are compared to all parent group labels of *B* (b_j) as well as the label of *B* itself. For every group label in *A*, the best match (highest score) is selected. These scores are then summed up and divided by the number of labels in *A* (n_a), resulting in the structure similarity score.

$$sim_{struct}(A,B) = \frac{\sum_{i=1}^{n_a} \max_{j=0}^{n_b}(sim(a_i,b_j))}{n_a}$$

The similarity between two labels is calculated analogously to the similarity between attribute values. The number of considered labels can be limited by setting the depth parameter, e.g., a search depth of one would result in only the group elements directly above the data elements being compared as formally described by (($n_{a|b} > d$) *then* ($n_{a|b} := d$)).

Finally, besides the lexical matching approaches used for the attributes, the toolbox also includes the statistical bag-of-words method [7]. Here, all values contained in one data element are treated as the text body for the data element. A dictionary-based lemmatizer is used to reduce each word to its basic form prior to generating the word count vector for every data element. The bag-of-words similarity is then calculated as the cosine distance between two data element vectors and also considered while calculating the overall data element similarity score.

A similarity threshold may be used to select valid matches. All elements with similarity scores exceeding the threshold will be considered matches, while all elements with lower scores will not.

Optimizer

Since the toolbox allows the configuration of many parameters as describes in the previous section, it also includes an optimization module to ease the process of finding the best configuration for a particular matching problem. Since the optimal configuration of attribute weights depends on the algorithms used to calculate attribute similarities, the parameters are calculated in two steps. First, the best processing pipes and their weights are determined for every attribute separately. Second, the attribute weights are calculated using the algorithm configuration from step one. A set of namespaces with at least some matching data elements needs to be provided as training data, and the correct matches need to be specified, e.g., as annotations or via an external file.

For the algorithm optimization, all possible combinations of currently implemented preprocessors and matching algorithms are built as processing pipes. To find the best combinations for a particular attribute, for every combination of two namespaces, data element similarity scores for this attribute

are calculated for each pipe separately. Then, the best three pipes are chosen per data element and rewarded three, two and one points respectively. These score points are summed up for each pipe over all training data, normalized and then used as this pipes weight.

To decide which pipes yielded the best results, one out of two different measures may be applied. Both receive a list of possible matches ranked in descending order by their similarity score to the target data element.

1. The *score distance* is calculated as the score of the first matching element (as defined by the ground truth) minus the score of the highest ranking element.
2. The *position distance* is calculated as one divided by the position of the first matching element.

Thus, larger values here imply better rankings.

To calculate how the attributes should be weighted, scores and rankings for two namespaces are calculated for each attribute separately using the pipes and weights determined in the first optimization step. Then, the attribute weights are calculated analogously to the processing pipes during the algorithm optimization. The optimization module can also be used to calculate a similarity threshold for a particular dataset. Two kinds of thresholds may be determined:

1. A *lower threshold* is calculated by summing up the similarity scores of the last correct element in the ranked result list for each training data element and dividing it by the number of training data elements. This value may be used to avoid losing correct matches.
2. Alternatively, a more *aggressive threshold* can be determined by summing up the similarity scores of the elements directly above the first incorrect match in the ranked result list. The sum is again divided by the number of training data elements and may be used to avoid false positive matches.

Interfaces

The toolbox is wrapped in a web service and can be accessed via an API or a GUI. The programming interface accepts the URLs of two Samply.MDR [8] namespaces. This open-source software is used as a source metadata repository, even though with minor adaptions other ISO 11179-3 conformant source systems should be compatible as well. Optionally, a toolbox configuration defining the pipes and weights to be used can be submitted as well. If no configuration is specified, the toolbox uses a default configuration, e.g., the result of an optimizer run. For each data element in the source namespace, the data element in the target namespace with the highest similarity score is selected as a match. Alternatively, a threshold may be used as described before. The generated matchings are returned as HL7 FHIR ConceptMaps. The ConceptMap resource provides a standardized way to represent relationships between concepts or data elements by referencing their codes, in this case, URNs assigned by Samply.MDR. ConceptMaps provide the possibility to specify the type of the relationship between the matched concepts, but since our automated matching process does not differentiate between, e.g., broader and narrower meanings, it always uses the *relatedTo* code.

Like the API, the GUI first requests the URLs of the two Samply.MDR namespaces to be matched. Then, the default mapping configuration may be edited or used as-is. In the next step, the matching is executed, and the results are displayed: For every source data element, a list of possible matches from the target namespace is shown, ranked by their similarity scores. The number of possible matches may be limited via a similarity score threshold, as described in the optimization section. The matching candidates can then be reviewed manually, and correct matches may be selected while incorrect hits may be de-selected. After confirmation, a ConceptMap containing the selected results is generated and displayed. It is also stored in an internal database to be used as further training data for the optimizer.

Results

Optimization parameters

To identify whether the score or position distance is better suited for each optimization step, the optimizer module was executed several times with different configurations on a set of training data. The metadata set originated from a biomedical research project and was split into training and test data. Elements are annotated with numeric codes, two elements with at least some common codes are considered matches. The data set has a depth of up to two nested group elements, however two thirds of the dataset have a depth of one, with an average of 11 elements per group. To evaluate the influence of the structure information, the optimization module was configured one time to omit the group label data and the other time to use all available group information. For each of this depth configurations, four configurations were calculated using all possible combinations score or position distance for the processing pipe and the attribute optimization. The obtained configurations were subsequently tested on the training and test datasets. The results are shown in table 1.

Table 1– Results of the optimized configurations using different values for the depth parameter d, on the training and test data subsets, as specified in the data column. The four rightmost columns specify whether the position (pos) or score distance was used for pipeline (first position) and attribute optimization (second position). The values indicate in which proportion of all possible matches a correct match had received the highest similarity score (Top 1) or was among the five elements with the highest scores (Top 5). The highest values per row are in bold.

d	data	error	pos-pos	pos-score	score-score	score-pos
2	train	Top 1	**0.43**	0.37	0.39	**0.43**
2	train	Top 5	0.68	0.61	0.63	**0.69**
2	test	Top 1	0.53	0.58	**0.61**	0.55
2	test	Top 5	0.78	0.82	**0.83**	0.80
0	train	Top 1	**0.44**	0.40	0.40	**0.44**
0	train	Top 5	**0.70**	0.65	0.65	**0.70**
0	test	Top 1	**0.52**	**0.52**	0.51	**0.52**
0	test	Top 5	**0.78**	0.76	0.76	**0.78**

Overall, using the score distance for pipeline and position distance for attribute optimization yields the best results and resulted in a configuration which found a correct best match for 55% of the testing data elements, in 80% of the cases suitable matches were among the five highest ranking elements. Not using the group label information yields slightly better results on the training data. However, when comparing the absolute number of correct matches, incorporating the

structure information leads to more correct matches among both the first and first five elements.

Toolbox configuration

The toolbox configuration parameters calculated by the different optimization processes are displayed in figures 2 and 3. The first figure shows the cumulated weights for pipelines over all attributes. Some pipelines with an accumulated weight lower than 0,1 for both distance measures have been omitted, among these standard edit distance measures like Levenshtein distance. Both distance measures favor similar, n-gram-based pipelines, but the position distance assigns weights more equally distributed.

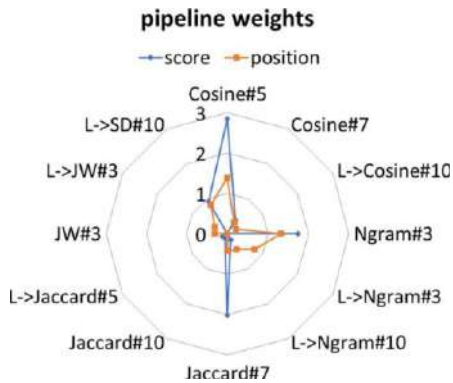

Figure 2- Pipeline weights for optimization via score and position distance, summed up over all attributes. L stands for lemmatization as preprocessing, JW for Jaro-Winkler and SD for Sorensen-Dice similarity. The numbers after the # indicate the n for n-gram-based methods.

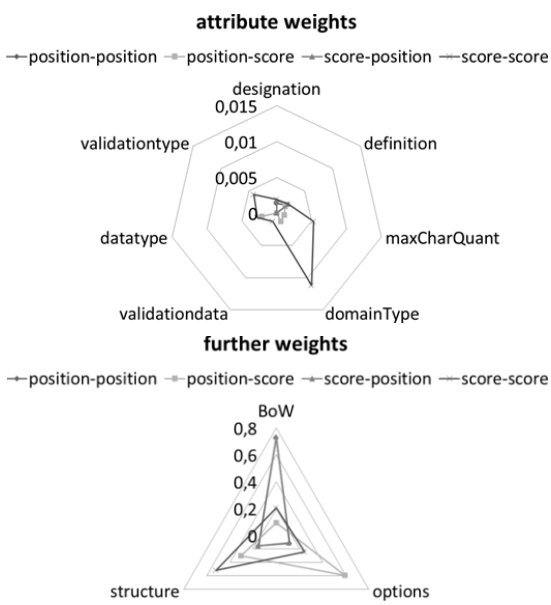

Figure 3- Calculated attribute weights by optimization method for the data element attributes (upper figure) and the computed attributes (lower figure). BoW stands for the bag-of-words score, options for the answer options similarity score and structure for the similarity score calculated from the surrounding group labels.

The weights assigned to attributes are displayed in figure 3, they are split between the data element attributes whose similarity is computed directly as string similarity (e.g., *description* or *datatype*) and the computed attributes. The computed attributes score much larger weights than the data element attributes. While both optimizers using the position distance for the attribute weight calculation step obtain similar results, the results of the optimizers using the score distance show much larger discrepancies.

Mappathon

The authors also participated in the GMDS Mappathon 2018. To comply with the competition demands, the toolbox was modified to support a Cypher-based [9] export format and external CSV files as source for ground truth. The results can be found on the corresponding website [10]. MDRCupid won the mappathon challenge in the best mapping category.

Discussion

The pipeline optimization using the score distance favors certain pipelines more clearly than the one using the position distance. This imbalance is probably due to high scores being assigned to non-matching data elements, while the three pipelines selected by the score distance tend to identify matching data elements more precise. During the attribute weight optimization, both optimizers using the position based distance for this second step calculate nearly equal weights, while the score based approach chooses very different weights. The weight that it assigns to the *domainType* attribute is remarkably high. This attribute has only two possible values . Therefore many data elements score a similarity of one and consequently a score distance of zero. The same effect occurs with option and structure similarity: here, many data elements lack an answer options list or a surrounding group and hence a similarity of zero is calculated, causing a score distance of zero if the matching element also lacks the feature in question. Thus, the score distance measure should not be used for attribute weight calculation.

Using the structure information always leads to better or equal results for the test data, but not in the training data. This effect may be caused by the lack of depth in the training and test data set. In particular, the subset of training data only contains namespaces with depths of one and zero, while the test data has depths of up to two.

While different optimization strategies like only choosing the best pipe for each attribute are feasible, trying to incorporate more matching algorithms should better avoid overfitting. In our dataset, the results of the optimized configuration were even better on test data than on training data. Still, some modifications, e.g., selecting more pipes or assigning weights directly derived from the distance measures, are conceivable and should be evaluated in further work.

One of the most common formats to represent metadata in a clinical context is the CDISC ODM widely used for clinical trials. Unlike Samply.MDR, which allows nesting as many or as little item groups as needed, CDISC ODM defines specific group layers, which additionally have an assigned meaning (e.g., *studyEvent*, *form*).

The Samply.MDR was chosen because it is open source, ISO 11179-3 conformant and allows to retrieve data elements via a RESTful API. Also, several tools exist to migrate metadata to the Samply.MDR format, e.g., from the CDISC ODM format [11].

Matching results are exported as FHIR ConceptMaps because they have multiple advantages. First, they can easily be stored, exchanged and searched by using FHIR servers. Second, multiple software libraries are supporting FHIR, easing the resource creation process. Third, ConceptMaps only store codes referring to the data elements, not the data elements themselves, avoiding problems concerning the intellectual property of the metadata elements. Fourth, they have a standardized structure and an integrated code system for metadata relationship concepts. Other formats like the Cypher-based exports required for the Mappathon challenge need to include such a code system; it is not standardized in the specification of the format.

The toolbox only supports lexical and one statistical (bag-of-words) matching methods. Another approach would include the use of semantic annotations. Although including semantic codes would allow the use of elaborate ontologies like SNOMED-CT or LOINC, annotating data elements usually requires some amount of manual work [6], while lexical and statistical methods can work with the data out of the box.

Conclusions

The secondary use of health data, e.g., using data from EHR in clinical trials, is complicated by the data models heterogeneity. Metadata matching is an essential step towards data integration because it finds correspondence in the data structure by identifying corresponding metadata elements. MDRCupid is designed to fulfill this task. It provides various lexical matching algorithms as well as the statistical bag-of-words method. The current implementation allows the user to select which combination of methods is used for each run. Preprocessing methods and string matching algorithms can be selected for each data element attribute separately. When multiple processors are applied to the same attribute, the weighting for each score can be chosen as well. Weights can be assigned to each attribute accordingly.

Besides the data element attributes per se, similarity scores are calculated for the data elements permissible values and containing item groups. Together with the attribute similarities and the bag-of-words based score, these results can be weighted and incorporated into the overall result. As an alternative to manually defining algorithms and weights, a configuration can be generated by applying the optimization module to a given set of training data. Two possible distance measures for this optimization process were evaluated on a metadata set from a biomedical research project, and the best approach resulted in a configuration which found a correct best match for 55% of the testing data elements.

While MDRCupid currently works with ISO 11179-3 conformant metadata elements, it could be adapted to support metadata with other attributes as well, e.g. the upcoming ISO 21526 standard for metadata repositories in healthcare.

The source code for MDRCupid is available on GitHub [12]. It can be deployed as a web service, including a programming and graphical user interface.

Software support for the task of metadata matching becomes more and more critical with the increase of electronically captured medical data. MDRCupid is providing this support and laying the groundwork for data integration. A set of mapped metadata elements can be used to build a comprehensive clinical repository, enabling the secondary use of healthcare data, simplifying data exchange and medical research and, ultimately, improving patient care.

A Large-Scale Analysis of Health Journalism by Reliable and Unreliable Media

Sameer Dhoju[a], Md Main Uddin Rony[a], Muhammad Ashad Kabir[b], Naeemul Hassan[a]

a Department of Computer and Information Science, University of Mississippi, USA

Abstract

Media outlets play crucial roles in disseminating health information. Previous studies have examined how health journalism is practiced by reliable and unreliable media outlets. However, most of the existing works are conducted over a relatively small set of samples. In this study, we investigate a large collection (about 30 thousand) of health-related news articles which were published by 29 reliable and 20 unreliable media outlets and identify several differences in health journalism practice. Our analysis shows that there are significant structural, topical, and semantic disparities in the way reliable and unreliable media outlets conduct health journalism. We argue, in this age of 'fake news', these findings will be useful to combat online health disinformation.

Keywords:

Health Communication

Introduction

Of the 20 most-shared articles on Facebook in 2016 with the word "cancer" in the headline, more than half the reports were discredited by doctors and health authorities [1]. The spread of health-related hoaxes is not new. However, the advent of Internet, social networking sites (SNS), and click-through-rate (CTR)-based pay policies have made it possible to create hoaxes/"fake news", publish at a larger scale and reach to a broader audience with a higher speed than ever [2]. Misleading or erroneous health news can be dangerous as it can lead to a critical situation. Houston reported a measles outbreak in Europe due to lower immunization rate which experts believed was the result of anti-vaccination campaigns caused by a false news about MMR vaccine [3]. Moreover, misinformation can spoil the credibility of the health-care providers and create a lack of trust in taking medicine, food, and vaccines. Recently, researchers have started to address the fake news problem in general [4; 5]. However, health disinformation is a relatively unexplored area. According to a report from Pew Research Center [6], 72% of adult internet users search online for information about a range of health issues. So, it is important to ensure that the health information which is available online is accurate and of good quality. There are some authoritative and reliable entities such as National Institutes of Health (NIH)[1] or Health On the Net[2] which provide high-quality health information. Also, there are some fact-checking sites such as Snopes.com[3] and Quackwatch.org[4] that regularly debunk health and medical related misinformation. Nonetheless, these sites are incapable of busting the deluge of health disinformation continuously produced by unreliable health information outlets (e.g., RealFarmacy.com, Health Nut News). Moreover, the bots in social networks significantly promote unsubstantiated health-related claims [7]. Researchers have tried developing automated health hoax detection techniques but had limited success due to several reasons such as small training data size and lack of consciousness of users [8-11].

The objective of this paper is to identify discriminating features that can potentially separate a reliable health news from an unreliable health news by investigating a large-scale dataset. We examine how reliable media and unreliable media outlets conduct health journalism. First, we prepare a large dataset of health-related news articles which were produced and published by a set of reliable media outlets and unreliable media outlets. Then, using a systematic content analysis, we identify the features which separate a reliable outlet sourced health article from an unreliable sourced one. These features incorporate the structural, topical, and semantic differences in health articles from these outlets. For instance, our structural analysis finds that the unreliable media outlets use clickbaity headlines in their health-related news significantly more than what reliable outlets do. Our topical analysis finds that while the reliable outlets discuss "cancer" along with research and studies, in the unreliable outlets "cancer" is associated with autism and vaccination. The semantic analysis shows that on average a health news from reliable media contains more reference quotes than an average unreliable sourced health news. We argue that these features can be critical in understanding health misinformation and designing systems to combat such disinformation. In future, our goal is to develop a machine learning model using these features to distinguish unreliable media sourced health news from reliable articles.

Related Work

There has been extensive research on how scientific medical research outcomes should be disseminated to general people by following health journalism protocols [12-16]. For instance, Lopes et al. suggest that it is necessary to integrate journalism studies, strategic communication concepts, and health professional knowledge to successfully disseminate professional findings. Some researchers particularly focused on the spread of health misinformation in social media [17]. For example, [8] analyzes Zika related misinformation on Twitter. In particular, it shows that tracking health misinformation in social media is not trivial, and requires some expert supervision. It exploited crowdsource to annotate a collection of Tweets and used the annotated data to build a rumor classification model. One limitation of this work is that the used dataset is too small (6 rumors) to make a general conclusion. Moreover, it didn't consider the features in the actual news articles unlike us. Ghenai and Mejova [9] examines the individuals on social media that are posting questionable health-related information,

[1] https://www.nih.gov/
[2] https://www.hon.ch/en/
[3] https://www.snopes.com/
[4] http://www.quackwatch.org/

and in particular promoting cancer treatments which have been shown to be ineffective. It develops a feature based supervised classification model to automatically identify users who are comparatively more susceptible to health misinformation. There are other works which focus on automatically identifying health misinformation. For example, Kinsora et al. [18] developed a classifier to detect misinformative posts in health forums. One of the limitations of this work is that the training data is only labeled by two individuals. Researchers have also worked on building tools that can help a user to easily consume health information. Kostkova et al. [10] developed the "VAC Medi+board", an interactive visualization platform integrating Twitter data and news coverage from a reliable source called MediSys[5]. It covers public debate related to vaccines and helps users to easily browse health information on a certain vaccine-related topic.

Our study significantly differs from these already existing researches. Instead of depending on a small sample of health hoaxes like some of the existing works, we take a different approach and focus on the source outlets. This gives us the benefit of investigating with a larger dataset. We investigate the journalistic practice of reliable and unreliable outlets, an area which has not been studied to the best of our knowledge.

Data Preparation

The results are presented here. Authors may choose a combination of text, tables, figures, and graphs to convey the results of their work to the reader. There are no set limitations on the number of tables, figures, and graphs that may be used in papers, posters, and proposals. Large figures and tables may span two columns. Please number tables and figures and reference them appropriately in the text.

Media Outlet Selection

The first challenge is to identify reliable and unreliable outlets. The matter of reliability is subjective. We decided to consider the outlets which have been cross-checked as reliable or unreliable by credible sources.

Reliable Media

We identified 29 reliable media outlets from three sources– i) 11 of them are certified by the Health On the Net [19], a non-profit organization that promotes transparent and reliable health information online. It is officially related with the World Health Organization (WHO) [20]. ii) 8 from U.S. government's health-related centers and institutions (e.g., CDC, NIH, NCBI), and iii) 10 from the most circulated broadcast [21] mainstream media outlets (e.g., CNN, NBC). Note, the mainstream outlets generally have a separate section for health information (e.g., https://www.cnn.com/health). As our goal is to collect health-related news, we restricted ourselves to their health portals only.

Unreliable Media

Dr. Melissa Zimdars, a communication and media expert, prepared a list of false, misleading, clickbaity, and satirical media outlets [22; 23]. Similar lists are also maintained by Wikipedia [24] and informationisbeautiful.net [25]. We identified 6 media outlets which primarily spread health-related misinformation and are present in these lists. Another source for identifying unreliable outlets is Snopes.com, a popular hoax-debunking website that fact-checks news of different domains including health. We followed the health or medical hoaxes debunked by Snopes.com and identified 14 media outlets which sourced those hoaxes. In total, we identified 20 unreliable outlets. Table 1 lists the Facebook page ids of all the reliable and unreliable outlets that have been used in this study.

Table 1– List of Facebook page ids of the reliable and unreliable outlets. Some of them are unavailable now

Reliable	everydayhealth, WebMD, statnews, AmericanHeart, BBCLifestyleHealth, CBSHealth, FoxNewsHealth, WellNYT, latimesscience, tampabaytimeshealth, philly.comhealth, AmericanHeart, AmericanCancerSociety, HHS, CNNHealth, cancer.gov, FDA, mplus.gov, NHLBI, kidshealthparents, ahrq.gov, healthadvocateinc, HealthCentral, eMedicineHealth, C4YWH, BabyCenter, MayoClinic, MedicineNet, healthline
Unreliable	liveahealth, healthexpertgroup, healthysolo, organichealthcorner, justhealthylifestyle1, REALfarmacy.com, thetruthaboutcancer, BookforHealthyLife, viralstories.bm, justhealthyway, thereadersfile, pinoyhomeremedies, onlygenuinehealth, greatremediesgreathealth, HealthRanger, thefoodbabe, AgeofAutism, HealthNutNews, consciouslifenews, HealthImpactNews

Data Collection

The next challenge is to gather news articles published by the selected outlets. We identified the official Facebook pages of each of the 49 media outlets and collected all the link-posts[6] shared by the outlets within January 1, 2015 and April 2, 2018 using Facebook Graph API. For each post, we gathered the corresponding news article link, the status message, and the posting date.

News Article Scraping

We used a Python package named Newspaper3k[7] to gather the news article related data. Given a news article link, this package provides the headline, body, author name (if present), and publish date of the article. It also provides the visual elements (image, video) used in an article. In total, we collected data for 29, 047 articles from reliable outlets and 15, 017 from unreliable outlets.

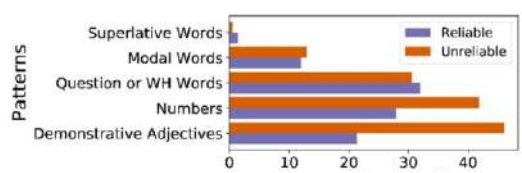

Figure 1– Distribution of clickbait patterns

Filtering non-Health News Articles

Even though we restricted ourselves to health-related outlets, we observed that the outlets also published or shared non-health (e.g., sports, entertainment, weather) news. We removed these non-health articles from our dataset and only kept *health, food & drink*, or *fitness & beauty* related articles. Specifically, for each news article, we used the document categorization service provided by Google Cloud Natural Language API to determine its topic. If an article doesn't belong to one of the three above

[5] http://medisys.newsbrief.eu

[6] Facebook allows posting status, pictures, videos, events, links, etc. We collected the link type posts only.

[7] https://newspaper.readthedocs.io/en/latest/

mentioned topics, it is filtered out. This step reduced the dataset size to 27,589; 18,436 from reliable outlets and 9,153 from unreliable outlets. We used this health-related dataset only in all the experiments of this paper. Figure 1 shows the health-related news percentage distribution for reliable outlets and unreliable outlets using box-plots. For each of the 29 reliable outlets, we measure the percentage of health news and then use these 29 percentage values to draw the box-plot for the reliable outlets; likewise, for unreliable. We observe that the reliable outlets (median 72%) publish news on health topics comparatively less than unreliable outlets (median 85%).

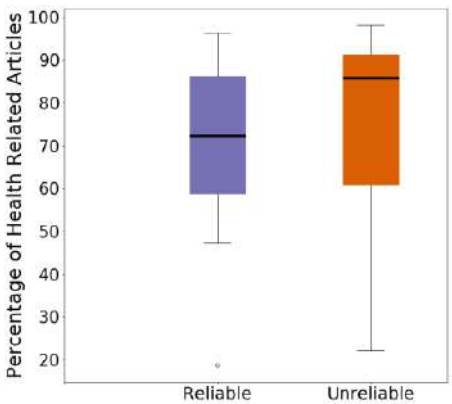

Figure 2– Comparison between reliable and unreliable outlets with respect to the presence of health-related news contents

Analysis

Using this dataset, we conduct content analysis to examine structural, topical, and semantic differences in health news from reliable and unreliable outlets.

Structural Difference

We particularly examine two structural elements- headlines and visual media of news articles.

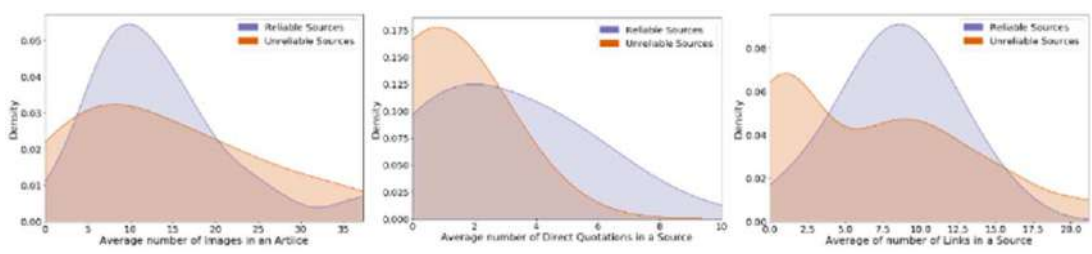
Headline

The headline is a key element of a news article. According to a study done by American Press Institute and the Associated Press [26], only 4 out of 10 Americans read beyond the headline. So, it is important to understand how reliable and short headline does. We observe that the average headline unreliable outlets construct the headlines of their health-related news. According to Breaux [27], a longer headline results in significantly higher click-through-rate (CTR) than a length of an article from reliable outlets and an article from unreliable outlets is 8.56 words and 12.13 words, respectively. So, on average, an unreliable outlet's headline has a higher chance of receiving more clicks or attention than a reliable outlet's headline. To further investigate this, we examine the *clickbaitiness* of the headlines. The term clickbait refers to a form of web content (headline, image, thumbnail, etc.) that employs writing formulas, linguistic techniques, and suspense creating visual elements to trick readers into clicking links but does not deliver on its promises [28]. Chen et al. [29] reported that clickbait usage is a common pattern in false news articles. We investigate to what extent the reliable and unreliable outlets use clickbait headlines in their health articles. For each article headline, we test whether it is a clickbait or not using two supervised clickbait detection models– a sub-word embedding based deep learning model [30] and a feature engineering based Multinomial Naive Bayes model [31]. Agreement between these models was measured as 0.44 using Cohen's κ. We mark a headline as a clickbait if both models labeled it as clickbait. We observe, 27.29% (5,031 out of 18,436) of the headlines from reliable outlets are click bait. In unreliable outlets, the percentage is significantly higher, 40.03% (3,664 out of 9,153). So, it is evident that the unreliable outlets use more clickbaits than reliable outlets.

We further investigate the linguistic patterns used in the clickbait headlines. In particular, we analyze the presence of some common patterns which are generally employed in clickbait according to [27; 32]. The patterns are- 1) Presence of demonstrative adjectives (e.g., this, these, that). 2) Presence of numbers (e.g., 10, ten). 3) Presence of modal words (e.g., must, should, could, can). 4) Presence of question or WH words (e.g., what, who, how). 5) Presence of superlative words (e.g., best, worst, never). Figure 2 shows the distribution of these patterns among the clickbait headlines of reliable and unreliable outlets. Note, one headline may contain more than one pattern. For example, this headline *"Are these the worst 9 diseases in the world?"* contains four of the above patterns. This is the reason why summation of the percentages isn't equal to one. We see that unreliable outlets use demonstrative adjective and numbers significantly more compared to the reliable outlets.

Use of visual media

We examined how often the outlets use images in the articles. Our analysis finds that on average an article from reliable outlets uses 13.83 images and an article from unreliable outlets uses 14.22 images. Figure 3a shows density plots of the average number of images per article for both outlet categories. We observe that a good portion of unreliable outlet sourced articles uses a high number of images (more than 20).



(a) Image (b) Quotation (c) Link

Figure 3–Distribution of average number of image/quotation/link per article from reliable and unreliable outlets

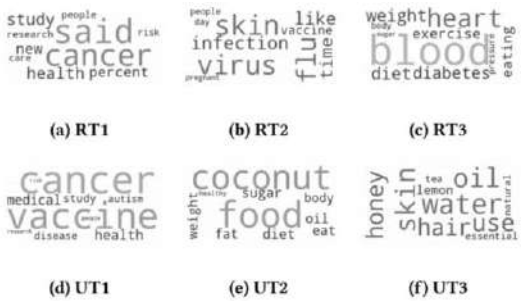


Figure 4– Topic modeling (k = 3) of articles from reliable outlets (top, denoted as RT) and from unreliable outlets (bottom, denoted as UT).

Topical Difference

The health domain is considerably broad and it covers many topics. We hypothesize that there are differences between the health topics in reliable and unreliable outlet articles. We test this hypothesis using an unsupervised & a supervised analysis.

Topic Modeling

We use *Latent Dirichlet Allocation(LDA)* algorithm to model the topics in the news articles. The number of topics, *k*, was set as 3. Figure 4 shows three topics for each of the outlet categories. Each topic is modeled by the top-10 important words in that topic. The font size of words is proportional to the importance. Figure 4a and 4d indicate that "cancer" is a common topic in reliable and unreliable outlets. Although, the words *study, said, percent, research,* and their font sizes in Figure 4a indicate that the topic "cancer" is associated with research studies, facts, and references in reliable outlets. On the contrary, unreliable outlets have the words *vaccine, autism,* and *risk* in Figure 4d which suggests the discussion regarding how vaccines put people under autism and cancer risk, an unsubstantiated claim, generally propagated by unreliable media[8,9]. Figure 4e and 4f suggest the discussions about weight loss, skin, and hair care products (e.g., essential oil, lemon). Topics in Figure 4b and 4c discuss mostly flu, virus, skin infection, exercise, diabetes and so on.

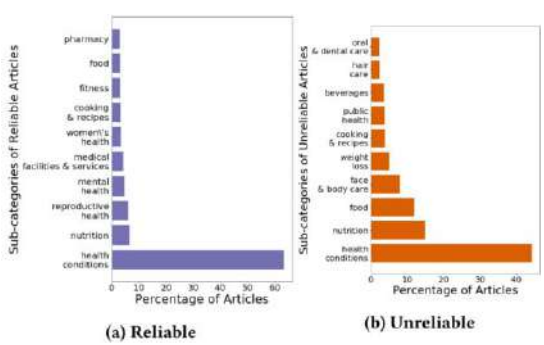

Figure 5 –Top-10 topics in reliable and unreliable outlets.

Topic Categorization

In addition to topic modeling, we categorically analyze the articles' topics using Google Cloud Natural Language API. Figure 5 shows the top-10 topics in the reliable and unreliable outlets. In the case of reliable, the distribution is significantly dominated by *health condition*. On the other hand, in the case of unreliable outlets, percentages of *nutrition* and *food* are noticeable. Only 4 of the 10 categories are common in two outlet groups. Unreliable topics have *weight loss, hair care, face & body care*. This finding supports our claim from topic modeling analysis.

Semantic Difference

We analyze what efforts the outlets make for a logical and meaningful health news. Specifically, we consider to what extent the outlets use quotations and hyperlinks. Use of quotation and hyperlinks in a news article is associated with credibility [33; 34]. Presence of quotation and hyperlinks indicates that an article is logically constructed and supported with credible factual information.

Quotation

We use the Stanford QuoteAnnotator[10] to identify the quotations from a news article. Figure 3b shows density plots of the number of quotations per article for reliable and unreliable outlets. We observe that unreliable outlets use less number of quotations compared to reliable outlets. We find that the average number of quotations per article is 1 and 3 in unreliable and reliable outlets, respectively. This suggests that the reliable outlet sources articles are more credible and unreliable outlets are less credible.

Hyperlink

We examine the use of the hyperlink in the articles. On average, a reliable outlet sourced article contains 8.4 hyperlinks and an unreliable outlet sourced article contains 6.8 hyperlinks. Figure 3c shows density plots of the number of links per article for reliable and unreliable outlets. The peaks indicate that most of the articles from reliable outlets have close to 8 (median) hyperlinks. On the other hand, most of the unreliable outlet articles have less than 2 hyperlinks. This analysis again suggests that the reliable sourced articles are more credible than unreliable outlet articles.

Conclusion and Future Work

In this paper, we closely looked at structural, topical, and semantic differences between articles from reliable and unreliable outlets. Our findings reconfirm some of the existing claims such as unreliable outlets use clickbaity headlines to catch the attention of users. In addition, this study finds new patterns that can potentially help separate health disinformation. For example, we find that less quotation and hyperlinks are more associated with unreliable outlets. However, there are some limitations to this study. For instance, we didn't consider the videos, cited experts, comments of the users, and other information. In the future, we want to overcome these limitations and leverage the findings of this study to combat health disinformation.

An Interactive Timeline Visualization for Patient Cohorts in the Oncological Routine: A Use Case on Multiple Myeloma

Julia Dieter[a], Janko Ahlbrandt[a], Alexander Knurr[a], Janine Al-Hmad[a] and Frank Ückert[a]

[a] Division of Medical Informatics for Translational Oncology, German Cancer Research Center (DKFZ), Heidelberg, Baden-Württemberg, Germany

Abstract

With the growing interdisciplinarity of cancer treatment and increasing amounts of data and patients, it is getting increasingly difficult for physicians to capture a patient's medical history as a basis for adequate treatment and to compare different medical histories of similar patients to each other. Furthermore, in order to tackle the etiological mechanisms of cancer, it is crucial to identify patients exhibiting a different disease course than their corresponding cohort. Several timeline visualizations have already been proposed. However, the functions and design of such visualizations are always use case dependent. We constructed a cohort timeline prototype mock-up for a specific oncological use case involving multiple myeloma, where the chronological monitoring of various parameters is crucial for patient diagnosis and treatment. Our proposed cohort timeline is a synthesis between elements described in the literature and our own approaches regarding function and design.

Keywords:
Clinical Decision-Making, Cohort Studies, Data Mining

Introduction

For the treatment of cancer, physicians need to consider comprehensive information about the patients, including the medical history [1] as well as current events such as examination results. The information mainly comprises basic variables such as age, gender, education, and clinical variables such as details on diagnoses, therapies, staging results, laboratory analyses, and further examinations. However, those variables are usually stored in different systems within the hospital, e.g., the laboratory information system or the hospital information system. The data then have to be chronologically realigned in a manual fashion by physicians, often under time pressure. Thus, there is a great need for tools creating a chronological overview of patient data, helping to save time, and preventing errors.

To support physicians in the compaction and comparison of salient patient information as well as in the chronological realignment of data from different sources, several approaches have been developed for integration and visualization of medical patient histories. There are tools for either single patient (e.g., LifeLines, KNAVE-II; [2–4]) or for patient cohorts (e.g., LifeLines2, VISITORS; [4–7]), and they aim to display various data types, such as numerical data (e.g., MIVA), categorical data or both (e.g., WBIVS; [4,8]).

A fundamental work for the display of a single patient medical history is the LifeLines approach of Plaisant et al. [2]. It is not restricted to oncology and aims at displaying the key information of a single patient's medical history by aligning zoomable lanes on top of each other. Depending on the task at hand, they can be opened up or closed [2,4]. It focuses on categorical data. The lanes represent different areas of the patient record such as "Problems", "Diagnoses" or "Tests", while single events are encoded within the lanes. For instance, the lane entitled "Tests" harbors examination events such as "Blood" or "ECG" etc. The separate markings within the lane are positioned according to their corresponding chronological position on the x-axis, which is located at the bottom of all lanes. Design aspects such as line thickness reflect the severity of medical problems. Detailed information on an event is given in a separate window, which can be summoned by clicking on the respective event in the main view. Further interactive features include a mouseover function (i.e., displaying information when hitting a label with the cursor), zooming, alerts and a search option for keywords such as symptoms (e.g., "migraine"). KNAVE-II is another visualization architecture for time-oriented clinical patient data and has been implemented and tested in the oncological domain [3]. Similar to Lifelines, it comprises horizontally stacked views, but in contrast to the former, KNAVE-II offers domain-specific groupings as well as temporal abstractions to enable interactive data manipulation and exploration [3,9]. However, drawbacks of Lifelines and KNAVE-II might be crowding problems, i.e., the display might become too complex due to increasing timespans and number of events [2].

Approaches to the chronological display of patient cohorts have also been developed. Bernard et al. [10] developed a network of static dashboards to visualize the medical histories of a post-operative prostate cancer cohort. Each separate dashboard represents a temporal segment of the cohort, i.e., one part of time-ordered temporal data. Each dashboard is composed of different visualizations such as bar charts, pie charts or box plots. The chronological connection, i.e., the medical history of the cohort, is represented by the network that is constructed based on the connections between the single dashboards. Unfortunately, the tool has not been validated as previous visualization approaches. Thus, its efficiency in the real world setting still remains uncertain. The tool does not support the traditional timeline display, so that physicians might need extended training. In addition, the data processing steps underlying the temporal segmentation of data might be hard to follow and only a limited number of EHR elements might be shown within the dashboard due to space issues.

The LifeLines2 approach uses a classical timeline visualization, just like its predecessor LifeLines. It enables the

display of temporal categorical data for multiple patient records. The lanes are stacked vertically and represent each single cases, with event markers color-coded on the corresponding positions at the horizontal time axis [11]. All records can be aligned by a specific event in chronological display [4]. The alignment can also be achieved according to a specific events, e.g., the second diagnosis. Furthermore, users are able to filter and search for specific event sequences; and the temporal distribution of selected event types can be displayed by histogram [4,11]. In addition, approaches such as Similian, which extended LifeLines2 with a similary measure, enable the search for similar medical patient histories [4,12]. However, LifeLines2 displays one patient record per horizontal lane, so that not all records can be viewed simultaneously in larger patient cohorts due to space issues [13]. In addition, numerical data have to be preprocessed as the approach focuses on categorical data only.

The VISITORS system by Klimov et al. [7], an extension of KNAVE-II, is a visualization and exploration tool for time-oriented, categorical as well as numerical data of multiple patients. VISITORS is also constructed of horizontal lanes that are associated with a horizontal, chronological x-axis and enables the display of raw data as well as abstracted concepts for overviews. However, the tool does not enable the display of multiple numerical parameters within one lane. When several lanes for different numerical parameters need to be applied, not all lanes might be viewed within one window.

Taken together, there exist various cohort timeline visualizations for different application scenarios and data types, also exhibiting multiple interactive features. Yet, as the literature about the cohort timelines shows, their configuration and functionalities mostly depend on a specific use case for which they are constructed or adapted. Thus, there does not exist one universal solution for all use cases.

The visualizations in clinical routine is still in high demand, as no approaches are widely deplayed yet [14]. As such, we developed a timeline for cohort in clinical oncological routine, adapted to the specific use case of multiple myeloma (MM; ICD10: C90.0) within the first-line therapeutic setting. It could become apparent for the need to monitor several parameters over time and to compare the course of one patient to a corresponding cohort by applying such tool (see below).

MM can arise from two pre-stages, i.e., the Monoclonal Gammopathy of Undetermined Significance (MGUS) or the smoldering myeloma [15]. Both conditions are lacking in treatment indication and can be differentiated from the MM and monitored by several parameters such as clonal plasma cells in the bone marrow, monoclonal protein in the serum and urine as well as end organ damage [15]. The transition from the pre-stages to an MM is marked by the fulfillment of one or more of the SLiM-CRAB criteria (an acronym standing for ">60% clonal plasma cell content in the bone marrow", "free light chain ratio in the serum >100", ">1 focal lesion >1cm in MRI imaging", "Calcium", "renal insufficiency", "anemia" and "bone lesions"; [16,17]). Those criteria comprise several laboratory parameters (e.g., calcium, creatinine and hemoglobin), bone lesions as determined by imaging, the percentage of clonal plasma cells in the bone marrow, the free light chain ratio in the serum and focal lesions as determined by MRI [15].

In addition, although the steps for treatment are given in the MM treatment guideline, it might still be necessary to decide between different treatment options. Those decisions have to be made individually, for instance, the decision in favor of or against an autologous stem cell transplantation. Especially in the cases of older patients, it becomes increasingly important to weight the burden of therapeutic side effects against the potential treatment benefit. To support decision making, it might be of help to compare one patient's medical information with treatment profiles from previous patients and their treatment outcomes.

We therefore developed the MM use case-specific prototype mock-up of an interactive cohort timeline.

Methods

The construction of our cohort timeline was based on a combination of timeline functionalities and design aspects collected from a literature review and our own approaches to these issues.

The prototype mock-up of the proposed cohort timeline was developed in iterative cycles with clinical, medical informatics as well as biological inputs. We adapted the concept of horizontal lanes from previous tools, such as LifeLines, LifeLines2 and VISITORS, for visualizing the medical history of patients [2–4,7,9]. Functionalities for interactive data visualization were designed and incorporated to meet physician's needs and suggestions of previous studies [4–7,11].

The parameters in our prototype mock-up were selected based on the MM treatment guideline for diagnosis, therapy and the monitoring of the remission status, including the laboratory values, the designations of therapy steps as well as the criteria for evaluating the treatment response. In addition, the International Myeloma Working Group (IMWG) and the revised-Myeloma Comorbidity Index (R-MCI) were also included, which have been suggested to be useful in identifying geriatric risk profiles and prognostic values for functional decline among older multiple myeloma patients [18]. They are calculated by a combination of weights among various parameters including age, comorbidities and the ability to perform activities of daily living (e.g., self-care and household) [19]. Therefore, those scores are referenced as relevant decision criteria to differentiate between treatment options documented in the MM treatment guideline, especially for older patients.

We documented our general design and planned interactive funcions in a detailed prototype mock-up by a user experience specialist.

Results

The proposed interactive cohort timeline is built up of vertically stacked lanes, each comprising one key clinical component such as information on the general patient condition (IMWG score, R-MCI), laboratory data, treatment options and information on the treatment response, which are all significant for diagnosing, treating or monitoring MM. This sequence of events during patient treatment is reflected in the vertical order of the lanes from top to bottom (see Figure 1).

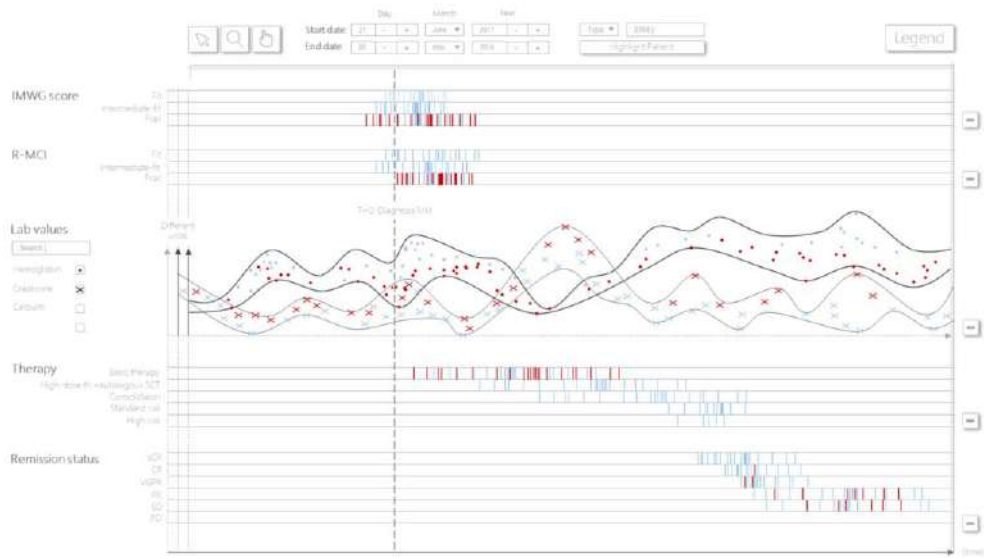

Figure 1: Prototype mock-up of the use case-specific cohort timeline

Each lane depicts all corresponding data points of the selected cohort. In case of visualizing multiple cohorts, the latter are color-coded in order to be distinguished within the same lane. The associations of laboratory values to their parameters are represented by data points, e.g., dots and crosses (see Figure 2).

The chronological reference of the visualization is given by a time-harboring x-axis at the bottom of all lanes. The vertically stacked lanes can be chronologically compared and referenced to the horizontal time axis by means of a thin vertical marker that spans all lanes (similar to the Data Point Scrubber of Faiola et al. [20]) and follows the cursor.

The visualization type for each lane is content-specific. Laboratory values are presented in an x-y-diagram-lane. Different laboratory parameters are visualized within the same lane. Upper and lower flanking lines that connect the lowest and highest values, respectively, indicating the value range. A filtering option next to the lane allows the selection of single laboratory parameters or functional parameter sets.

The occurrence of events such as treatments or evaluation of a remission status is marked in the corresponding lane by a small vertical line per patient at the corresponding time point (i.e., position on the time axis).

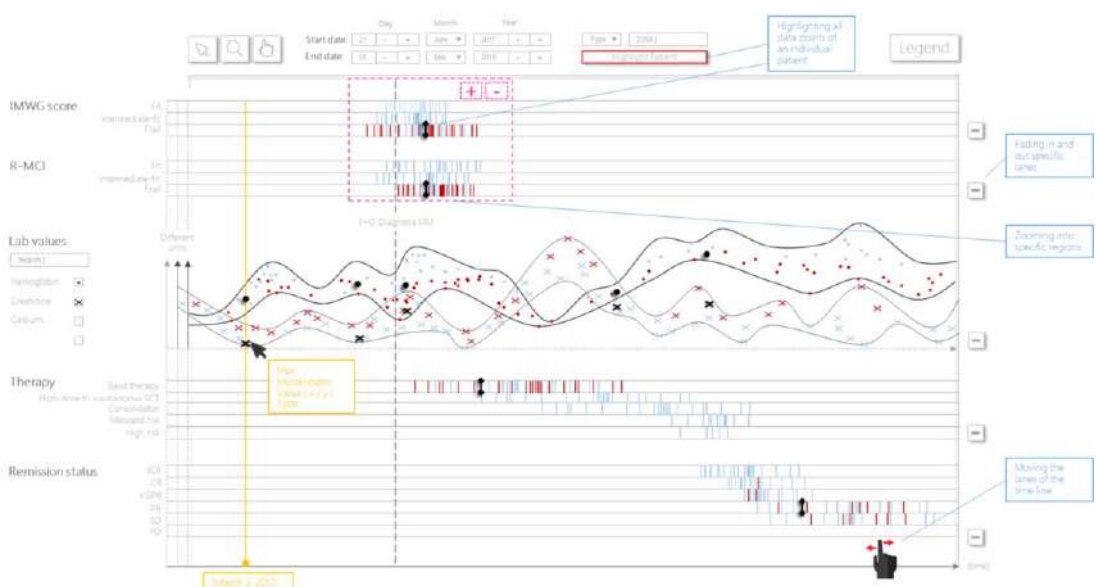

Figure 2: Proposed interactive features for the cohort timeline

Given a specific use case, a user might want to read the values in an absolute timeline or a relative one to a defined reference time point. For instance, the time of diagnosis of a specific disease might serve as reference, relative to all other events that are calculated and displayed chronologically for each individual patient. Therefore, similar to VISITORS [7], an option to choose between absolute and relative chronological display will be integrated. The options to switch between different parameters of reference [4–6] as well as the selection of a time window of interest will also be given [4,7].

Additionally, lanes can be faded in and out depending on the use case at hand [2]. Further interactive features include a hover over function (similar to Wang et al. [11]), displaying the patient-ID as well as the corresponding value when hitting a data point with the cursor. In addition, all data points from a specific patient shall be highlighted throughout the cohort timeline in order to enable the comparison to a corresponding cohort. To differentiate compact or clustered data, a zoom function will be included (e.g., [2]). In the case where a lane is too cluttered with data points or if subcohorts are to be selected, a filtering function is also added. This is enabled by checking or unchecking selection boxes on a target lane or simply by marking specific data points. In case of visualizing long time spans, a sideward scroll is included as well as an option to constrain the time window for which data are to be displayed. A retractable legend is included. Furthermore, certain users such as physicians in different specialities might have different preference on the ways to display the cohort information in timeline. And customized configurations can be saved for future use to save time. An export function for data and images will also be provided. An example of the general cohort timeline design is shown in Figure 1. The interactive functionalities are presented in Figure 2.

Discussion

The literature shows a multitude of approaches for temporal visualizations for medical histories of patient cohorts, including a variety of interactive features. However, it is also obvious that each timeline has to be adapted to a specific use case in order to see if the approach can address the specific questions in different user scenarios.

We developed a prototype mock-up for the oncological use case of diagnosing, treating and monitoring MM, as a synthesis between designs and functionalities of previous cohort timelines and our own ideas.

As described above, a physician might want to weight the burden of therapeutic side effects against the potential treatment benefit for an old MM patient. In this case, the physician plots two cohorts of previous MM patients onto the timeline: One having received stem cell transplantation as well as high-dose therapy (blue cohort in Figure 1 and Figure 2, appearing brighter in the black and white view) and another one having received basic therapy only (red cohort, appearing darker in the black and white view). Patients categorized as “frail” in the IMWG score and the R-MCI have higher creatinine and lower hemoglobin levels after therapy than fitter patients and a less optimal treatment response (e.g., remission status=stable disease).

The data points of a current patient can now be plotted, highligted and compared to the two cohorts to estimate potential treatment outcomes with and without SCT and high-dose therapy. The example patient might rather resemble the cohort not suited for SCT and high-dose therapy in our prototype mock-ups.

In a future step, the prototype mock-up presented here shall serve as a basis for an evaluation by end users. Although the prototype mock-up was constructed based on realistic data and procedures as much as possible, it has to be taken into account that the plot has not been programmed and tested with real data yet. Thus, the behavior of the plot in real live scenarios presently cannot be anticipated.

Conclusions

We present a compact, interactive cohort timeline visualization approach to display multidimensional data points of oncological cohorts in a chronological reference frame. Our prototype mock-up shall serve as a basis for a comprehensive evaluation by physicians as potential end users. Although our visualization has not been realized and tested with real data yet, it might become a promising tool for physicians to support decisions in treatment of oncological patients, hypothesis generation, and the exploration of the etiological mechanisms underlying cancer.

Acknowledgements

This work was conducted within the frame of the DataThereHouse (DTH) project in cooperation with the National Center for Tumor Diseases (NCT) Heidelberg, supported by the Federal Ministry of Education and Research (BMBF). The project is concerned with the integration of data from different sources including the Heidelberg University Hospital as well as the German Cancer Research Center (DKFZ) Heidelberg for all oncological entities.

Abstract

A significant part of medical knowledge is stored as unstructured free text. However, clinical narratives are known to contain duplicated sections due to clinicians' copy/paste parts of a former report into a new one. In this study, we aim at evaluating the duplications found within patient records in more than 650,000 French clinical narratives. We adapted a method to identify efficiently duplicated zones in a reasonable time. We evaluated the potential impact of duplications in two use cases: the presence of (i) treatments and/or (ii) relative dates. We identified an average rate of duplication of 33%. We found that 20% of the document contained drugs mentioned only in duplicated zones and that 1.45% of the document contained mentions of relative dates in duplicated zone, that could potentially lead to erroneous interpretation. We suggest the systematic identification and annotation of duplicated zones in clinical narratives for information extraction and temporal-oriented tasks.

Electronic Health Records, Natural Language Processing, Algorithms

Introduction

The use of electronic health records (EHRs) and clinical data warehouses [1] (CDWs) lead to a better collection and preservation of patient information. CDWs store all kinds of data, including laboratory results, diagnostic codes, and clinical narratives (free text medical reports). In fact, CDWs are major tools for translational research. While a large portion of the information are stored in structured ways, and virtually directly reusable, a significant part of medical knowledge is stored as unstructured free text. Some studies have even shown that free text contains up to 80% [2] of overall information. With the availability of information, new ways of exploring data have emerged. For example, high-throughput phenotyping, machine learning or statistical models (including through the use of deep learning). However, free text can be subject to different types of issues (quality, typos…), that could profoundly bias results of analysis and models. One potential problem could come from duplicated sections in clinical reports [3] (created when clinicians copy/paste parts of a former report into a new one).

Duplications are common during care; information can be replicated from one document to another because of the static nature of the family history, previous treatments, and so on. However, in the case of secondary use of clinical data and more specifically, in the context of data extractions, duplications can have a strong impact on the chronology of the information. Old information can be found duplicated in a recent document. In this study, we aim at assessing if duplications have an impact on different types of models.

This study takes place in the context of big data, and where simple naïve approaches are not compatible with the volume of data considered (i.e. several months of calculation would be needed for simple tasks). A large body of work has been developed around the detection of plagiarism and duplication in clinical narratives. The volume of duplications has been evaluated as high as 80% in Northern American Hospital [4–6]. However, the exploration of duplications in French narratives remains limited, and the potential impact of such duplications is not easy to evaluate.

State of the Art

The identification of duplicated zones or plagiarism has generated a large body of work over the years. However, no open source solutions are available and able to handle the volume of text compatible with our purpose. In medicine, several studies focus on the characterization of copy and paste redundancy.

In their publication of 2013 [6], Cohen *et al*. studied the impact of 'copy and paste' redundancy in a large corpus of text. For that purpose, they developed a character based fingerprint method. This technique is inspired by BLAST [7] a bioinformatics algorithm which aims to find similar sequences. The authors considered 22,654 notes from 1604 patients. They found that clinical text had a redundancy level of 29%.

In a preliminary French study [3], D'Hondt *et al.* extend the Cohen methods and studied duplications in French clinical notes. The algorithm allowed the use of overlapping fingerprints. They also oriented documents in time. They choose fingerprint length of 30 and overlap of 10 char as their parameters. Furthermore, they identified that in clinical notes, most of the redundancy located on the footer and header section were in administrative sections. They worked on documents from three records and 361 documents. They found a redundancy level of 33% in clinical notes. Their algorithm allows finding near-duplicated and exact redundancy (at a price of a higher complexity of the algorithm).

A recent study [8] by Gabriel *et al.* was able to scale up to 1.5 million notes in 36.3 hours, regardless of the patient vector. They developed a new method base on windows of three phases. The first step is mini-hashing generation from files. Instead of looking at the character levels they look at the word level and defined a signature. This approach will not be followed in our study because we want to find exact duplication.

Goals

In this study, we aim at evaluating the duplications found within patient records at the European Hospital Georges Pompidou, a French hospital located in Paris. We adopted a strategy to enable the treatment of large quantities of text in a reasonable time. Finally, we evaluate the potential impact of duplications in two use cases: (i) the identification of treatments present in clinical narratives and (ii) the presence of relative dates.

Materials

In this section, we introduce the European Hospital Georges Pompidou and the corpus of text used for the study.

European Hospital Georges Pompidou

The European Hospital Georges Pompidou (HEGP in French) is a 700 bed hospital located in Paris. The HEGP is specialized in oncology, cardiovascular diseases and emergency medicine. The hospital has a clinical data warehouse (HEGP CDW) based on i2b2 [9] integrating virtually all the data generated by the hospital information system, which was deployed in 2008. Among the data collected, clinical narratives (comprised of clinical reports, letters, imaging reports, and so forth) represent more than 10 million items.

Corpus of Clinical Narratives

Our dataset is a subset of the corpus of the text of the HEGP CDW. We identified all the patients who received chemotherapy since the opening of the hospital 2000 (10,393 patients). We limited the selection of patients to those who had a follow-up of at least a year (i.e. patients with at least two visits distant by 365 days). Because we are interested in duplications within the record of a patient, we selected only patients with at least two distinct documents. Starting from 666,956 documents, we conserved a total of 649,651 documents after a preprocessing step (detail in the method section).

Methods

Definition of Duplicated Zones

In this manuscript, we define a duplication as an identical zone of text found conserved in at least two different documents. We focus on intra-record duplication (i.e. we search for duplication with the record of a patient, and not between patients). The document pairs are oriented in time.

Preprocessing

All documents generated in the hospital comprised administrative information (with the phone number of the service, the names of the staff, and so forth), the clinical notes themselves and footer information regarding the possible secondary use of data. We preprocessed the documents to remove the administrative zones and the footer information section. We also normalized the documents by converting the entire text to lower cases, and transforming multiple spaces into single ones.

Efficient Detection of Duplications

We aim at developing a method able to manage a substantial number of documents. We leverage the approaches developed by Cohen et al. [6] and D' Hondt *et al.* [3] to develop a mixed approach. In a nutshell, we rely on fingerprints build from the text to identify identical zones. A fingerprint is a segment of *N* consecutive letters. Fingerprints are not overlapping, if the first fingerprint is constructed from character 1 to N, the second fingerprint starts at position N+1. Similarly to D'Hondt et al., we also leveraged the notion of overlap: we add series of fingerprints with an offset of value OFFSET (i.e. starting at the OFFSETth character). OFFSETs are very similar to Open Reading Frames in DNA. Figure 1 shows a graphical summary of the approach. We detect duplicated ones by comparing fingerprints between pairs of documents. Contiguous or overlapping pairs of fingerprints (in the source and target documents) are merged together. We evaluated different sizes of fingerprints, and values of offsets to find a good compromise between the number of duplicated zones detected and the computed time needed to perform the calculation.

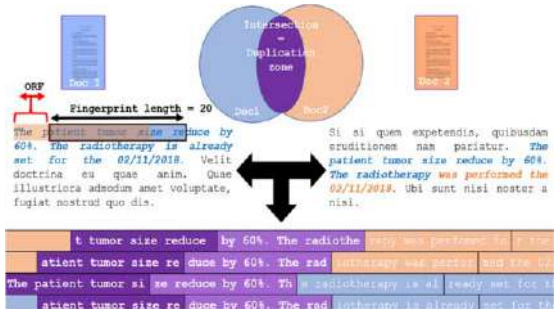

Figure 1: detection of duplicated region between two texts. The method relies on fingerprints.

Evaluating the optimal parameters: We tested combination of parameters for the values of N (size of the fingerprints), and OFFSET (value of the offset). We respectively tested the values of 30, 40 and 50 characters from the fingerprints, and 1, 5, 7, 10, 15 and 20 for offsets. In each case, we considered the offset of 1 as our baseline (fingerprints are calculated at each character position). We computed the number of common fingerprints detected, the time needed for the computation.

Computing Duplicated Zones on the Corpus of 650,000+ Documents

Using the optimal values obtained from the previous section (fingerprint length of 30, and offset of 15 characters), we computed duplicated zones on the entire corpus. Duplicated zones are detected among the documents of a single patient. We search for duplicated zones between documents oriented in time: the source document was always older than the target document. Once the pairwise duplication step has been performed, we focus on document levels, and merge all the duplicated zone detected. Figure 1 illustrates the approach.

***Filtering duplicated zones*:** After the merging steps, we identified duplicated zones with a wide variety of length, starting from 30 (the length of a fingerprint). We chose to filter out zones too small, because they likely did not correspond to copy/paste. To select a relevant threshold, we considered the number of duplications found for a given duplicated zone length.

Evaluation the volume of duplicated zones

Finally, we designed three scores to evaluate the volume of duplicated zones in the text;

Global volume of duplication in the corpus: The global duplication score

$$DupScoreGlobal = \frac{\sum_{j=0}^{Totaldocs} DuplicationLength_j}{\sum_{j=0}^{totaldocs} LengthDoc_j}$$

Average duplication score by document: The duplication score per document defined as

$$DupScoreAverageDoc = \frac{\sum_{i=0}^{Totaldocs} \frac{DuplicationLength_i}{LengthDoc_i}}{Totaldocs}$$

Average duplication score per patient: The duplication score per patient is defined as

$$DupScoreAveragePat = \frac{\sum_{k=0}^{TotalPatients} \frac{\sum_{ki=0}^{Totaldocs} DuplicationLength_{ki}}{\sum_{Ki=0}^{totaldocs} LengthDoc\ k_i}}{TotalPatients}$$

In a nutshell, the three score describe different means to measure the amount of duplications. The global duplication score ($DupScoreGlobal$) evaluate the overall amount of duplication in the corpus (in term of number of characters in duplicated zones). The average duplication score per document evaluates the impact of duplication normalized by document. Finally, the average duplication per patient measures the overall impact of duplication per patients.

Potential Impact of Duplicated Zones on Two Use-Cases

We identified two use cases that could potentially be impacted by the presence of duplicated zones:

***Detecting drugs in duplicated zones*:** We searched for occurrences of medical drugs in our corpus. We used an exact match strategy, based on a list of ingredients and brand names from the Romedi [10] resource. Romedi is a semantic web version of a French public resource of drugs made available by the French National Health Insurance. Molecules such as simple sugars (e.g., glucose), water, inorganic elements (e.g., calcium), and so forth are listed as ingredients in Romedi. However, when mentioned in the clinical narratives, these molecules rarely refer to clinical drugs. Therefore, we eliminate them from the list of drugs identified by Romedi (more precisely, we eliminated the French terms *para, olivier, alcool, sodium, potassium, calcium, glucose, magnesium, eau*). All drugs were normalized to their corresponding CUI.

We identified the number of drugs present *only* in duplicated zones, and not in the rest of the document. While the presence can be useful for the medical history and for the care of the patient, the presence in portions of text duplicated from former documents could impact machine learning models, or information retrieval processes.

***Relative dates in duplicated zones*:** Our second use case focused on temporality. One major issue when working with text is the identification of the temporality associated with the concepts identified in the text. It is always important to distinguish between events or phenotypes that occurred during or prior the encounter. We searched the duplicated zones for temporality markers using relative dates (i.e. using expressions such as yesterday, two months ago, tomorrow, today, etc.). In such cases, the reference date is assumed to be the date of the creation of the document, but because the expression is located in a duplicated zone, its actual reference date should be identified in the past. We searched the corpus for a series of 8 terms corresponding to relative dates and determined if the terms were located within a duplicated zone.

Implementation of the Pipeline of Detection

We leveraged NextFlow [11] and Docker [12]. Each portion of our pipeline uses a Docker container and Nextflow ensure the parallelization of our processes. The pipeline ran on an Ubuntu 14.04 server, with 15 cores, 64 GB of RAM, and was developed in Python 3.10. Code is accessible on our github repository: https://github.com/equipe22/duplicatedZoneInClinicalText [13].

Results

Preprocessing

A mean values of 1670 characters were eliminated in general during the preprocessing. Overall, the number of character decreased by 36%. The average length of a text before preprocessing was 4145 and 2474 characters after.

Efficient Detection of Duplications

We compared the execution time and performance with respect to the overlap for different sets of parameters of the detection duplication algorithm (see Table 1).

Table 1 – Result of parameters evaluation for 50 patients which have 30 documents in average

fingerprint length	orf size	execution time (second)	% median overlap with the baseline
20	3	653	83
	5	196	77
	7	85	69
	10	34	72
	15	**18**	**67**
	20	10	66
30	3	665	84
	5	274	82
	7	125	80
	10	46	79
	15	**22**	**78**
	20	14	75

	fingerprint generation	merge	drug annotation	time annotation
execution time	3h19	20h19	80 s	23 s

Figure 2– Distribution of the patient duplication score

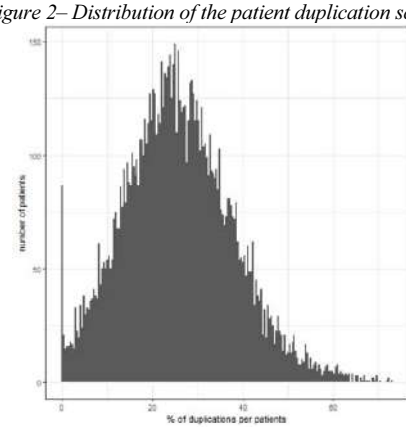

Table 3– Summary of duplication score

score	mean	Standard deviation
Global	0.33	0.33
Avg per document	0.25	0.12
Avg per patient	0.28	0.14

Potential Impact of Duplicated Zones on Two Use-Cases

***Detecting drugs in duplicated zones*:** We extracted 2,689,998 brand name and 761,611 ingredients from the corpus. 330,272 documents contain at least one drug mention. Overall, 161,067 documents had a drug detected within a duplicated region. 130,233 documents had at least one drug detected only within the duplicated zone (19.64% of our corpus).

Relative dates in duplicated zones: 45,557 documents contained at least one mention of a relative date. 9,632 documents contained a mention of a relative date within a duplicated region (21% of relative dates, 1.45% of the corpus).

Discussion

Detection of Duplication

We found that fingerprints length did not have an impact on the algorithm speed neither for the generations of fingerprints, nor the identification of duplications. The offset size did have a strong effect on both the execution time and the quality of detection. Compared to the baseline (offset of 1), the lower the offset size is, the better is the quality. However, in the spirit of a scalable approach, the processing time is incompatible with high volume of documents. We selected an offset of 15 for a fingerprint size of 30 for the reminder of our process to preserve a good quality while benefiting from a 200-fold speed improvement of the algorithm.

Filtering: We observed a large number of small-sized duplicated zones of 30 characters (more than 200 million detected duplications). 30 characters are highly unlikely to correspond to a full sentence in French. We decided to use a threshold of 1.5 fingerprints (i.e. 45 characters) to reduce the impact of artefacts that are unlikely to have been generated by a copy/paste process. Using this threshold, we found 29 million detected duplication.

Duplicated zones: Overall, the ratio of duplicated rate of duplications is 33%, in par with findings from the literature [3]. 20% of document had drugs mentioned only in duplicated zones. 1.45% of the document contained a relative data present in a duplicated zone. While the number is relatively low, the global number of documents is high: several thousands of documents for CDW with 10 million documents. The risk of misinterpretation of relative dates is high; tools such as HeidelTime [14] often used to identify mentions of temporality could provide erroneous normalization of the date since the tool would use the date of the document as a reference (instead of the data of the document source of the duplication).

Technical Significance

The performance of our heuristic allows treating a large amount of text. In this study, we managed a corpus of more than 650,000 documents within less than a day. Our CDW hosts a total of 10 million clinical narratives, some of which are the seldom report in the patient record.

The heuristic approach probably underestimates the volume of duplications. Additional fined grained approaches [3] could be applied to refine our results. We applied our approach to French, but the algorithm could be used for other languages as well.

Significance for secondary use of clinical data

The overall rate of duplicated zone (33%) is reasonable. However, we identified both drugs and relative dates were present in duplicated zones and could have a strong impact on information extractions from the text.

Duplications can have various meanings. The physician can use copy/paste to summarize the past, or to carry medical history from one document to another. Our method does not allow to identify the meaning associated with the copy/paste. However, for any application in which temporality is of importance, relative dates in duplicated zone might present an issue.

Limitation

The HEGP is specialized in oncology and cardiovascular diseases. Our selection of patients did not reflect the variety of the case present in the hospital. However, we did not filter the documents to specific sets of providers. In chronic diseases, with longer follow-ups, it would be possible for the ratio of duplication to be higher.

We used a rule based approach to clean-out the administrative sections of the document. This approach is not transposable, but proved efficient. The structure of the document is highly linked to the EHR used, the adoption of standard, etc.

We did not consider inter-patient duplications. Whereas our method could be used similarly to detect duplications among documents from different patients, it was not the purpose of our study. The detection of such zones could be interesting for quality control, or to reduce the work when annotating large corpora of texts for example.

Perspectives

Evolution of the volume of duplication over time: Because of the large variety of profiles, it is too complex to provide a good indicator of the evolution of the duplication rate over time. In our corpus, the documents were generated by many providers (medical services). We explored visually this question by representing the duplication rate over time. For comparison purpose, we normalized the time. Figure 3 provides a visualization of the duplication rate over the documents (the 0 in abscissa corresponding to the first document, and 100 to the last). A single point represents the rate of duplication of a single document for a single patient. We can see that there is visually a small trend toward an increase in the rate of duplications in the early part of the distribution, followed up by a plateau.

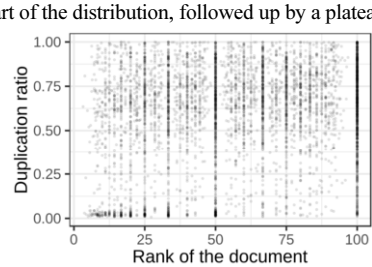

Figure 3 – Duplication representation over time per provider

We explored a visualization of the duplications within a patient records, and their organization over time in Figure 4. We leveraged the circlize [15] visualization to build a graphical summary of the duplicated zone, and their origin for a given patient. The outside circle represents the document of patients. The inner circle represents the provider of the document. Each edge represents a duplicated zone between documents. The date difference between two documents is rendered by the color; darker arcs correspond to the larger number of days than lighter arcs. In our example, Patient 1 and 2 both have 30 documents. The two patients have two distinct pathologies, and therefore two sets of distinct providers. The arcs reflect different hospitalization trajectories.

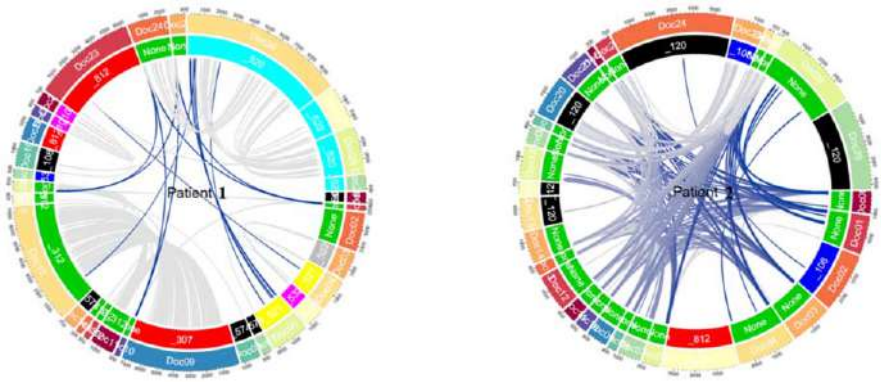

Figure 4. Duplication representation over time for two distinct patients. The length of a document reflects its number of characters, an arc between two regions translate the duplication of a portion of text.

For Patient 1, the providers reflect an oncology trajectory: digestive surgery (502, 532), imaging (312) and chemotherapy (574). For Patient 2, providers are coherent with urgent care: Internal medicine (812) and emergency medical (108) and reanimation. The systematic identification and annotation of duplicated zones are important for many aspects of data reuse. While we limited our exploration to drugs and relative dates, other semantic areas would be relevant to explore. For example, procedures and phenotypes. The annotation of duplicated zones could help identify procedures that are not relevant to the current visit

Conclusions

We developed a method to identify efficiently duplicated zones in clinical narratives. We explored a corpus of more than 650,000 documents belonging to 10376 patients. We identified an average rate of duplication of 33%, in par with value found in other studies. We evaluated the potential impact of duplications in two use-cases, the identification of drugs and the identification of relative dates. We found that 20% of the document contained drugs mentioned only in duplicated zones and that 1.45% of the document contained mentions of relative dates in duplicated zone, that could potentially lead to erroneous interpretation. We suggest the systematic identification and annotation of duplicated zones in clinical narratives for information extraction and temporal-oriented tasks.

Abstract

With the proliferation of digital communication in healthcare, the reuse of laboratory test data entails valuable insights into clinical and scientific issues, basically enabled by semantic standardization using the LOINC coding system. In order to extend the currently limited potential for analysis, which is mainly caused by structural peculiarities of LOINC, an algorithmic transformation of relevant content into an OWL ontology was performed, which includes LOINC Terms, Parts and Hierarchies. For extending analysis capabilities, the comprehensive SNOMED CT ontology is added by transferring its contents and the recently published LOINC-related mapping data into OWL ontologies.

These formalizations offer rich, computer-processable content and allow to infer additional structures and relationships, especially when used together. Consequently, various reutilizations are facilitated; an application demonstrating the dynamic visualization of fractional hierarchy structures for user-supplied laboratory data was already implemented. By providing element-wise aggregation via superclasses, an adaptable, graph representation is obtained for studying categorizations.

Keywords:

Biomedical Ontologies, LOINC, SNOMED CT

Introduction

As a prerequisite for any reuse of clinical data, it is essential to communicate in a semantic interoperable way so that the content's meaning is preserved independently from locally used terms and external influences like the applied software system. This is achieved by coding information explicit with a standardized terminology. The most widespread coding scheme in the laboratory domain is the *Logical Observation Identifier Names and Codes* (LOINC) terminology [1]. Each laboratory test is assigned a unique code representing its characteristics through the values of at least five axes. By using mapping methods, prepared and integrated laboratory data can provide valuable insights into patient care [2; 3].

However, activities to extend identifying LOINC codes by hierarchical structures or formal specifications have only recently begun, so that so far their use is limited to the unambiguous identification of laboratory tests with language-independent codes. Repeatedly it was demanded that LOINC codes should be enriched with a hierarchical structure., e.g. for aggregating reportable diseases in public health [4] or for improving semantic interoperability of LOINC-coded data [5].

So, the project aimed to transform the given LOINC terminology contents into a different, computer-processable representation subsequently enabling a larger scale of aggregation, analysis, and visualization of coded laboratory data.

Therefore, relevant LOINC components are converted into an ontology based on the well-known Web Ontology Language (OWL), i.e. a knowledge representation often defined as an "explicit specification of a conceptualization" [6], which uses formal logic to infer reasoner-based conclusions.

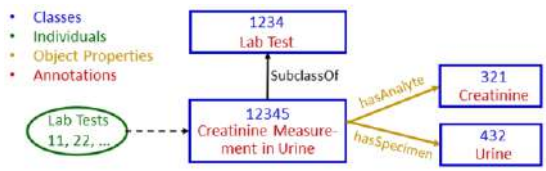

Figure 1 - Formalization of lab test classes and individuals

In order to enrich the given LOINC contents with additional information and hierarchical structures, the extensive *Systematized Nomenclature of Medicine – Clinical Terms* (SNOMED CT) shall be incorporated into the resulting ontology, as well. By using formal definitions throughout its scope, SNOMED CT is already specified as an ontology and can thus be integrated easily.

But to establish the connections between equivalent or otherwise related concepts in LOINC and SNOMED CT another source of data is needed. This is provided by the recently released official mapping between both terminologies, resulting from the publishers' cooperation agreement in 2013 [7]. Generating an OWL ontology for these mapping statements completes the first step, shown in figure 2, as a starting point for their integration and use.

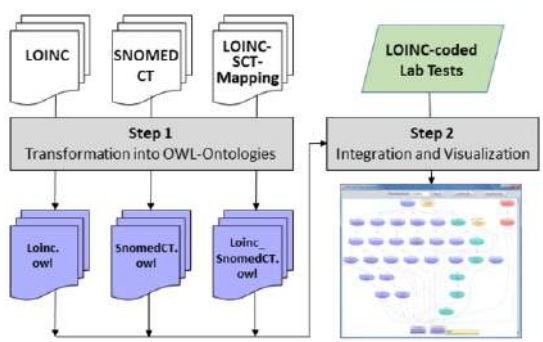

Figure 2 - LOINC aggregation and visualization tool: outline

The authors are aware that there are ontological challenges in the representation of laboratory tests, especially in connection with result values [8]. In this paper, purpose-specific LOINC

Hierarchies based on hierarchized LOINC *Part* terms (e.g. *Multi-Axial Hierarchy*), as well as logically formalized hierarchies, shall be provided via LOINC/SNOMED CT mapping in an integrated way to classify lab tests as LOINC-coded individuals per reasoner. We are convinced that LOINC- and SNOMED CT-based hierarchies serve different purposes, which complement each other but cannot replace each other [9]. This is supported by Vreeman speaking from "clinically-relevant aggregations" within LOINC by using multi-axial hierarchies and the newly introduced LOINC *Groups* [10].

Coming back to figure 2, this work concentrates on technical aspects for making use of OWL reasoners in order to integrate the three mentioned formalizations in step 2 and visualize LOINC-coded lab tests as individuals with respect to the integrated hierarchies. While there have already been attempts to build an ontology for LOINC [11; 12], this approach includes a larger scale of contents. Here, the main focus is laid onto arranging LOINC tests in hierarchical structures based on both explicit subclass relations as well as on their implicit features inferred by the LOINC/SNOMED CT-mapping.

Methods

LOINC resources

As the starting point for the project, the latest LOINC version 2.64 was utilized, published by the Regenstrief Institute in June 2018. This release contains a total of 87,863 LOINC *Terms* representing distinct laboratory tests or other clinical observations. Each *Term* is defined by a number of atomic components within. These LOINC *Parts* can be identified by their unique LP-Code and correspond to LOINC's main axes or their subcomponents describing the test's properties in detail. An example of usage is shown in figure 3. All in all, there are currently 52,000 *Parts* available which are used in about 900,000 relationships to define LOINC *Terms*.

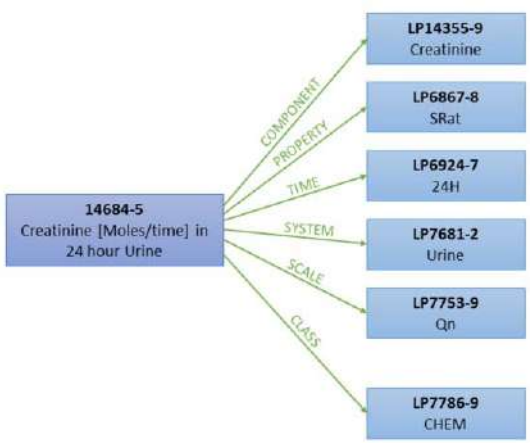

Figure 3 - Interrelation between a LOINC Term (left) and its definition by a unique combination of LOINC Parts (right).

To include even more contents into the transformation process we accessed the database containing background information within RELMA 6.23, a software offered by the Regenstrief Institute to enable searching in and mapping to LOINC. In these database tables, the information mentioned before can be found as well as more hierarchical structures. After further investigation a number of 10 so-called *Part Hierarchies* could be identified, each referencing a different aspect of laboratory tests. Even though the *Hierarchies* are built using LOINC *Parts* they are made to arrange complete LOINC *Terms* in a hierarchical structure based on their properties. As a special case the *Multi-Axial Hierarchy* is formed and made public, which uses composite LOINC *Parts* to structure *Terms* by their properties of two or more axes [13].

Converting LOINC to OWL ontology

In order to create an OWL ontology for the LOINC coding system in an automated and reusable way, an algorithmic approach was implemented using *Java*. For parsing all source files, present or previously transformed in CSV format, the Java CSV library is incorporated. Subsequent construction of OWL aspects is conducted by means of the OWL API [14].

```

     and (<.../loinc #hasSystem> some <.../loinc#LP7681-2>)
     and (<.../loinc #hasTime> some <.../loinc#LP6924-7>)
```

Figure 4 - OWL definition in Manchester Syntax for the LOINC Term shown in figure 3.

LOINC *Terms* are represented as distinct OWL classes with their code as an identifier, complemented by human-readable descriptions as label and comment. To model fully-defined LOINC *Terms* on the detailed level, they receive an equivalence statement combining all related *Parts* into one axiom. Here, an additionally defined superclass L_0, referring to LOINC Tests in general, is used as a starting point. Then, each LOINC *Part* is integrated as a specifically defined OWL class and added via an *ObjectProperty* derived from the *Part's* category. An exemplary result of this OWL translation is given in figure 4. For some LOINC *Terms,* not all required *Parts* are stated so that the combined definition is represented as subclass axiom, limiting logical inferences later on.

```
Class: <http://imi.uni-luebeck.de/loinc#LH56020>

  Annotations:
    rdfs:label "Urine Test"

  EquivalentTo:

     and (<.../loinc#hasSystem> some <.../loinc#LP7681-2>)

  SubClassOf:
    <http://imi.uni-luebeck.de/loinc#LH647>
```

Figure 5 - OWL concept of a hierarchy element describing all tests measured in the specimen "urine". The partially identical definition to figure 4 shall be noted.

For the ontological representation of LOINC *Hierarchies* each of their elements found as tree nodes in the source files is translated into a separate OWL class. The respectively specified parent node is referenced in a subclass axiom, building the hierarchy's backbone structure. In order to add its conceptual meaning, each element is furthermore defined using the LOINC *Part* associated with the hierarchy node in question. So, an equivalence axiom is constructed from the conjunction of the lab test basic class, the appropriate *Object-Property* and the *Part's* OWL class, as shown in figure 5. By using this kind of definition for hierarchy elements, the similarity to those used for LOINC *Terms* leads to logically inferred subsumptions of test terms into hierarchical classes.

But as there are some divergent structures in the LOINC *Part Hierarchies*, these implicit definitions can't be used throughout. Regarding both the *Component* and the *Multi-Axial Hierarchy* duplicate uses of the same LOINC *Part* can be found, causing equivalent definitions of hierarchy elements by the previously described approach. To avoid false inferences, the affected *Hierarchies* are therefore limited to primitive definitions. LOINC *Terms* are thereupon subsumed explicitly by the means of subclass axioms.

SNOMED CT resources

To include SNOMED CT contents, both the source files of the terminology in itself as well as those specifying the mapping to LOINC are needed. For the latter, we could obtain the latest version of the LOINC/SNOMED CT Cooperative package, published as Production Release in July 2017. According to the version used in these mapping files, we decided to utilize the International release 20170731 of SNOMED CT.

As the largest terminologies in medicine, SNOMED CT covers a much wider range of application than LOINC. Though laboratory tests and observations are mainly described by SNOMED CT *Procedure* and *Observable Entity* concepts, many other categories can be applied to define individual aspects of lab data as well, especially by combining them into *Post-coordinated Expressions*. Because of this, the complete SNOMED CT ontology shall be taken into consideration.

The cooperative package includes two main types of relations between LOINC and SNOMED CT. Firstly, entire LOINC *Terms* are mapped to combined SNOMED CT post-coordinated expressions, using the *Observable Entity* concept as a basic class. Any other components required to describe the LOINC *Term* are added as pairs of attributes and concepts, adhering to a compositional model. Secondly, the elementary LOINC *Parts* are associated with corresponding SNOMED CT components, once again built from attribute-concept-pairs.

Convert SNOMED CT to OWL ontology

For the transformation of SNOMED CT into an OWL ontology a Perl script is provided by SNOMED International. It was applied according to its instruction, converting given RF2 files into the OWL XML/RDF format.

Regarding the ontology generation for the mapping contents, the same procedure as for the LOINC terminology could be utilized. So, another Java algorithm using the OWL API was implemented.

```
Class: <http://imi.uni-luebeck.de/loinc#14684-5>

  EquivalentTo:
    <http://snomed.info/id/363787002>
    and (<http://snomed.info/id/370132008> some <http://snomed.info/id/30766002>)
    and (<http://snomed.info/id/704318007> some <http://snomed.info/id/118562009>)
    ...
```

Figure 6 - Excerpt of the equivalence definition for the previous LOINC Term mapped to SNOMED CT components.

Relationships of LOINC *Terms* to SNOMED CT post-coordinated expressions are hereby represented in the same way already used for their definition by combined LOINC *Parts*, as shown in figure 6. Where applicable, another equivalence or subclass statement is added to the OWL class of the LOINC *Term* accordingly, composed of the conjunction of all required SNOMED CT attributes and concepts.

The ontological representation of LOINC *Part* mappings turned out to be more difficult, resulting partly from the given unbalanced definitions, which refer to single LOINC *Parts* on one side but combined SNOMED CT expressions on the other. As a portion of each *Part's* meaning is implicitly included in its category, the corresponding *ObjectProperty* is used to form a combined expression for the LOINC *Part*. Additionally, both sides are complemented by the inclusion of the respective basic class (*LOINC Test* and *Observable Entity*) to ensure conformity with any other ontological components.

As a result of these adjustments, both terms needed for the part mapping transformation consist of complex class definitions, so that *General Concept Inclusions* (GCIs) have to be used for an appropriate OWL representation (see figure 7).

```
Class: "Observable Entity"
    and "Has Specimen" some "Urine specimen"

  EquivalentTo:
    "LOINC Test"
    and "hasSystem" some "Urine"
```

Figure 7 - Simplified OWL example of a SNOMED CT expression (above) mapped to a LOINC Part (below) using labels instead of identifiers.

Another problem occurred during the conversion of non-equivalent part mappings, with LOINC *Parts* being broader or narrower in content than the corresponding SNOMED CT expression. Due to the exactly specified compositional model of SNOMED CT, some LOINC *Parts* are mapped to a rather complicated composition of elements. In the given source files these relations were found to be not differentiated sufficiently, leading to imprecise definitions and thus false inferences. Because of this, only LOINC *Parts* with equivalent SNOMED CT expressions were considered for the envisioned prototype.

Visualization of created hierarchies

In order to demonstrate the resulting OWL ontologies' possibility of usage and to gain a graphical representation of the hierarchical structures inferred by them, another Java application was implemented afterward. It is based on the OWL API as well and uses an implementation (*ElkOwlApi*) of the ELK reasoner for computing inferences in addition [15]. Furthermore, the *JGraphX library* was chosen to provide graph drawing functionality. Accordingly, the complete graphical user interface was designed using Java *Swing*.

The application's input mostly consists of the three previously created OWL ontologies, each providing LOINC, SNOMED CT or mapping knowledge, which are then inferred conjointly by the ELK reasoner. Based on LOINC-coded laboratory individuals provided by the user, all relevant classes of these terminologies are determined. A recursive algorithm is hereby used to traverse the inferred hierarchies while collecting all visited superclasses. These are added as nodes to a tree-like graph structure, including their relationships as edges.

When the root element is reached, the completed graph is visualized on the GUI. A number of stylesheets are utilized to differentiate between elements by defining distinct representations according to source terminology or class type. Furthermore, some interactive functions are implemented in order to improve usability beyond basic operations. By folding and expanding subtrees, the graph's complexity can be reduced as needed and by highlighting a path's course becomes more concise. Finally, the implemented tool allows adding user-defined hierarchies that are transferred to a light-weight ontology which is as well included in the inference and visualization, shown as red elements on the right in figure 8.

Results

For the LOINC terminology, two different OWL ontologies were generated successfully: A full version and one comprised

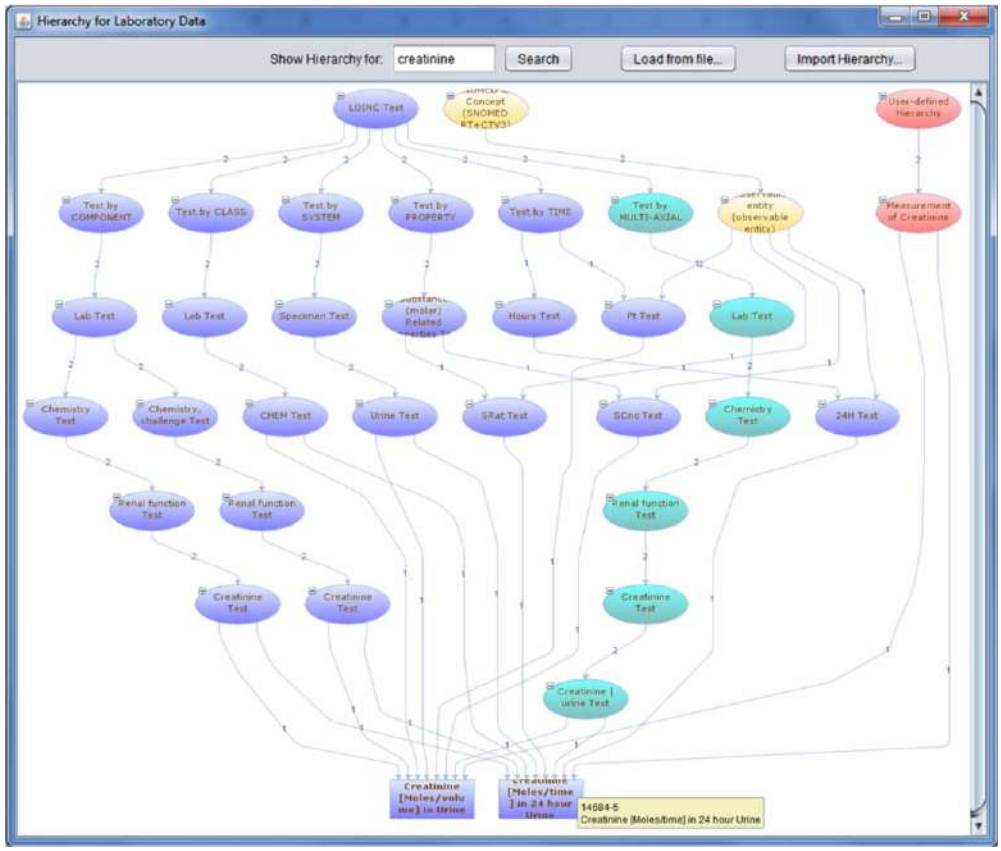

Figure 8 - Visualization of inferred hierarchies for the LOINC Terms 14684-5 and 14683-7 as leaf nodes. Each tree node represents a distinct OWL class, each edge denotes a subclass relation. The three root elements refer to the LOINC terminology (left), the SNOMED CT ontology (middle) and a user-defined hierarchy (right). The OWL ontology generated for the LOINC/SNOMED CT-Mapping does not include any named classes, so its contents is solely represented by edges.

of laboratory tests only. Both of these are divided into two main areas separating single 'LOINC Parts' from composite 'LOINC Tests'. The latter contains hereby all transformed hierarchy elements in their defined tree-structure as well as all LOINC *Terms*, which are classified into these hierarchies. A basic *Term* without subcomponents is typically included into six different hierarchies, one for each of its definitional *Parts* (except 'Scale') and the *Multi-Axial Hierarchy*.

For SNOMED CT an OWL representation could be generated easily by using the given script. The output contains the entire terminology contents keeping its extensive predefined relations and hierarchies. Another OWL ontology could be built for the cooperative package linking LOINC to SNOMED CT. Here, all of the LOINC *Term* mappings were transformed into OWL axioms using classes already defined in the other ontologies. In terms of the LOINC *Parts*, only equivalent mappings could be included as explained before, leaving one quarter of the enclosed relationships out of the result.

All of the created OWL ontologies can be applied as input in suitable software applications, either separately or combined. By importing them into the ontology editor *Protégé,* their contents and characteristics can be examined, see Table 1.

Additionally, the ELK reasoner was used to infer all ontologies, requiring about ten seconds in the case of their combined usage. Afterwards, both stated and inferred axioms were evaluated manually.

Table 1 - Extent of generated OWL ontologies

	LOINC (lab only)	**SNOMED CT**	**Mapping**
Axioms	1 004 634	1 520 034	62 155
Classes	277 159	335 225	34 272
ObjectProperties	16	97	25
AnnotationProp.	2	6	0
SubClassOf	366 292	253 406	2 355
EquivalentClasses	62 306	81 818	25 503
GCIs	0	0	5 969

No conflicts or contradictions could be found up to this point, concluding that the ontologies are consistent and valid. Regarding the inferred hierarchical order, the LOINC *Hierarchies* were found to yield a large amount of structuring information. This becomes particularly apparent through the graphs generated by the visualization application, as shown for two exemplary LOINC *Terms* in figure 8. Most of the pictured nodes refer to OWL classes generated based on LOINC contents. The same applies to the edges depicting subclass axioms, both stated and inferred.

By the inclusion of SNOMED CT knowledge and the cooperative mapping further hierarchical deductions are inferred into the arrangement of LOINC *Terms*. These are computed by the reasoner in a multi-level process, typically based on one of the *Term's Parts*, its representation in SNOMED CT and the

subclass definitions therein. Though there is more background information used in the inferred hierarchies, the graph visualization includes only two SNOMED CT elements: The root concept and the basic *Observable Entity*. All other involved SNOMED CT components are defined as post-coordinated expressions and thus not as named classes, which could be represented as tree nodes. The visualization application allows the rendering of multiple instances of LOINC *Terms*. These are displayed collectively in one hierarchy graph, taking into account their interrelations and frequencies of occurrence. As a result, an aggregated analysis in different levels of granularity is facilitated for a set of LOINC-coded laboratory tests.

Discussion

Despite the heterogeneous structure and non-formal definitions of LOINC contents, an extensive OWL ontology could be created comprised of LOINC *Terms, Parts* and *Hierarchies*. By using this formalization new insights into the terminology's hidden information are granted, whereupon the already existing hierarchies appeared to yield a particularly large potential by structuring the otherwise unsorted LOINC *Terms* according to their characteristics.

Additionally, the integration of SNOMED CT contents adds even more knowledge and relationships, enabling a wider range of application. The tree-like graphs created based on a user-supplied input of LOINC codes of interest provide a clearly arranged hierarchical structure and thus new possibilities to evaluate laboratory data. In this representation LOINC *Terms* and hierarchy elements are already displayed comprehensively, whereas contents derived from SNOMED CT or the cooperative mapping is included in a more subtle way that requires further improvement in order to present meaningful information.

For all of the generated OWL ontologies and their inferences, a profound evaluation is needed to ensure validity and to specify statistical properties. Amongst others, it is planned to use this tool within the "LOINC-300"-activities within the BMBF-funded Medical Informatics Initiative in Germany [16].

Conclusions

In this project we could develop an approach to improve the reusability of LOINC-coded laboratory data by converting relevant terminology contents into OWL ontologies, hence facilitating advanced analysis based on formally-defined representations and logical inferences.

By including the otherwise only internally used LOINC *Hierarchies* as well as SNOMED CT knowledge, extensive structures could be formed that build novel hierarchical classifications for LOINC *Terms*. For a concrete visualization, an application could be implemented that creates tree-like hierarchy graphs for LOINC-coded lab data, thereby enabling individualized and aggregated evaluations.

Acknowledgements

We thank the Regenstrief Institute for providing the structured LOINC source data and for their support.

The research was supported in part by the BMBF Medical Informatics Initiative. For using SNOMED CT source data an affiliate development license was obtained from IHTSDO.

Compatible Data Models at Design Stage of Medical Information Systems: Leveraging Related Data Elements from the MDM Portal

Martin Dugas[a], Stefan Hegselmann[a], Sarah Riepenhausen[a], Philipp Neuhaus[a], Leonard Greulich[a], Alexandra Meidt[a], Julian Varghese[a]

[a]*Institute of Medical Informatics, University of Münster, Germany*

Abstract

Compatible data models are key for data integration. Data transformation after data collection has many limitations. Therefore compatible data structures should be addressed already during the design of information systems.

The portal of Medical Data Models (MDM), which contains 20.000+ models and 495.000+ data items, was enhanced with a web service to identify data elements, which are frequently collected together in real information systems. Using Apache Solr, a fast search functionality to identify those elements with semantic annotations was implemented.

This service was integrated into the metadata registry (MDR) component of MDM to make it available to the scientific community. It can be used to build intelligent data model editors, which suggest and import frequent data element definitions according to the current medical context.

Keywords:
Health Information Interoperability, Data collection, Metadata

Introduction

Integration of medical data from different sources is a common but complicated task. There are many use cases for data integration, for instance in medical research: comparison of data from different sites, comparison of new study results with published data sources or merging of routine data with study data. In routine care, data integration is needed for quality assurance, for example to transfer a site-specific data set into a central database, or clinical decision support, for instance to apply standardized decision rules on local data sets. This list is not complete. However, there are many reports about data integration issues [1].

In many cases, collected data from different sources is similar in several aspects (e.g. regarding disease domain, patient group, assessment, therapy, outcome), but from a data analysis point of view, similar is not good enough. Instead, data shall be compatible to enable merging of data sources and joint analysis. A common approach to address this problem is data transformation after data collection. Data warehousing is a typical example for this approach: It applies extract-transform-load (ETL) to generate an integrated data set from different sources. However, the transformation step has important limitations, such as information loss during aggregation or bias due to semantic differences of data elements.

Why are there so many similar but incompatible data sources in medicine? This is caused by the semantic richness of medical terminology. SNOMED CT [2] contains more than 300.000 non-synonymous terms. Even for a small data model like a case report form with only one sheet (e.g. 40 data elements), there is an *astronomical* number of different models. As a consequence, if two medical experts design a data model for a given medical topic independently, the probability for compatible models is extremely close to zero.

Table 1 presents an example for data elements in two information systems, which are similar but incompatible: Myocardial infarction and atrial fibrillation are only a subset of heart diseases, i.e. a patient with myocardial infarction or atrial fibrillation has heart disease, but a patient with heart disease has not necessarily myocardial infarction or atrial fibrillation. The value sets of pain level are not transformable between system 1 (5 levels) and 2 (4 levels). This similarity has major drawbacks: joint data analysis of those systems is very limited and a joint algorithm for decision support is not applicable.

Table 1– Similar data are problematic for data integration: Data from systems 1 and 2 are similar, but incompatible.

System 1	System 2
heart disease yes/no	myocardial infarction yes/no atrial fibrillation yes/no
pain level 0-1-2-3-4	pain level 0-1-2-3

The similarity of medical data models is a big challenge, but also an opportunity for standardization and thereby better compatibility. Data integration would be a lot easier if data models from different sources were more compatible, i.e. had a larger proportion of compatible data elements. Overall, it would be highly desirable to foster compatible data models at the design stage, because post-hoc transformations have limitations.

The Portal of Medical Data Models (MDM-Portal) [3] addresses this problem with an open access approach to foster best practice sharing and thereby promotes re-use of existing data models. Users can search, comment, upload and download data models. An integrated metadata registry (MDR) component provides search functionality at the data element level to identify most frequent data element definitions for a medical concept such as weight or potassium.

The objective of this work is to go one step further and answer the following question: For a given data element (or a set of data elements) - what other data elements are collected most frequently together with this data element in real information systems?

This list of related data elements can contribute to the design of new information systems. It supports completeness of data models by identification of data elements, which are frequently covered in many related data sources; and, importantly, it fosters compatibility of data models by re-use of data element definitions from existing data sources wherever possible.

A concrete example: What lab values (or any other medical characteristics) are frequently collected together with "bilirubin"? And what are the precise data element definitions of these related data elements?

This type of relatedness goes beyond terminological relationship (like atrial fibrillation is a subtype of heart disease) - it is about actual data elements used in real medical data sources.

Methods

Semantic annotation of data elements

Semantic annotation is needed to identify meaningful related data elements because item names can be ambiguous [4]. Figure 1 presents an example: an attribute named "size" could refer to body height, tumor size or shoe size. By assigning a semantic code – such as a UMLS [5] or SNOMED CT code – the medical concept of an item name can be specified and a reference to a more detailed description is available.

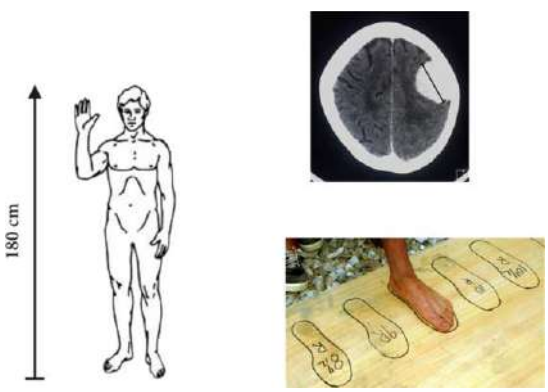

Figure 1– The need for semantic annotation: "size" is ambiguous, it can refer to body height, tumor size or shoe size.

Open access to medical data models

To identify related data elements, the MDM portal is used as a source of data models. Figure 2 presents the overall architecture of this system, which is described in more detail in [3,6]. As of March 2019, MDM contains more than 20,000 data models with approximately 495,000 semantically annotated data elements. To our knowledge, it constitutes the largest collection of medical data models in Europe. Each data element consists of name, textual description (which can be multilingual), data type, and semantic code. Optionally, a code list, value range or unit can be provided. These data elements are defined according to ISO 11179 [7], i.e. for each element, a concept domain and a value domain are specified. An MDR component provides search functionality and frequency counts based on data element name, data type, range, unit, values (code list) and semantic coding.

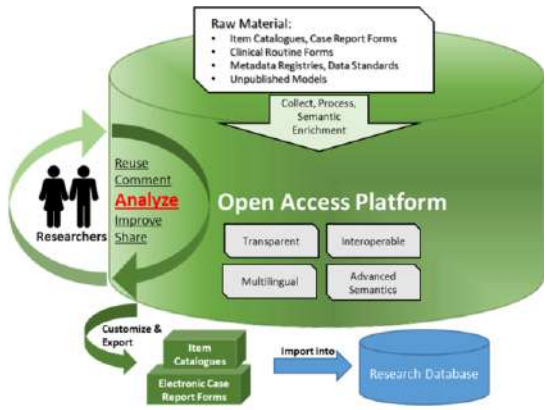

Figure 2– Overall approach of the MDM portal: an open access platform for medical data models

Relationship of data elements

Each data model consists of a list of context-specific data elements; therefore any two data elements can be defined as related, if these elements belong to the same data model. This means that these two data elements are collected together in the same documentation setting.

Results

Web service to identify related data elements

Apache Solr is used to index data elements in the MDM portal [8]. This open-source search platform is selected due to its fast full-text search and query language. A web service is implemented with the Java web framework Spring Boot. Java libraries SolrJ and JAXB are applied for the communication with Solr and to process the XML-format of ODM files within the MDM portal.

The overall architecture of the web service "related items" is depicted in figure 3. There are two variants of this service: Variant 1 identifies all data elements, which are jointly collected with a given data element (indicated by data element ID). Variant 2 identifies all data elements, which are jointly collected with a set of data elements with the same name (e.g. "age"). In both variants, results are ordered by frequency of co-occurrence.

The MDR component of MDM is enhanced with this web service using JavaScript to demonstrate the search functionality for related data elements. It is available at https://medical-data-models.org/ under actions / metadata registry (after free registration).

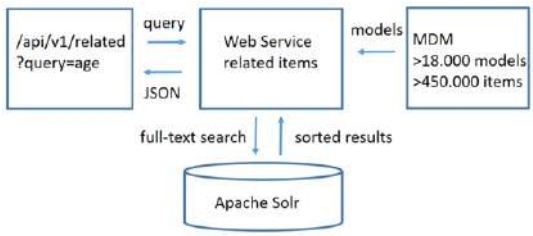

Figure 3– Architecture of the web service "related items". MDM items are indexed with Apache Solr. For a given query, jointly collected data elements are reported in JSON format, ordered by frequency of co-occurence.

Figure 4 presents the output of the MDR for search term "Bilirubin". The most frequent definition (n=30) for items named "Bilirubin" is data type float, unit mg/dl and UMLS code C0005437. By clicking on the green button "Search for related items" a list of related data elements, ordered by frequency, is displayed (figure 5). For instance, AST is on this list. This is plausible from a medical perspective, because AST and bilirubin are laboratory tests, which are frequently elevated in certain liver diseases.

Because the system architecture is web service based, this search functionality for related items can also be used by external systems.

MetaData Registry (MDR): Data Elements of MDM English

Item Name Bilirubin ↳ Search for related items

Discussion

Data from different sources should be as compatible as possible to facilitate data integration. Syntactic and semantic interoperability of Electronic Health Records (EHR) is a well-known challenge [9]. Definition of data elements is a key step in the design of medical information systems. A huge number of similar, but incompatible data models can be designed due to the semantic richness of medical terminology. For this reason, re-use of data element definitions from already existing information systems should be fostered. The MDR component of MDM supports this re-use with lists of data element definitions for a given item name.

This work goes one step beyond: It identifies data elements, which are collected frequently together with a given data element in real information systems.

The aspect of frequency is important to select most suitable elements for data collection: In a typical medical setting, data consumers want to analyze many data elements with high data quality, but data producers can provide only a limited number of data elements due to resource constraints. For example, what laboratory tests should be collected in a certain medical setting? Each additional lab value provides potentially interesting information, but is also associated with costs. The cost of data collection is a limiting factor for the number of patients, which can be documented.

With the new web service, designers of information systems can learn from already available data sources. If certain data elements were collected frequently together with a given data element, then those elements should also be considered for the new system. This facilitates joint data analysis in the future, in particular if the data element definitions from previous sources can be re-used without modifications.

Related data elements can provide a link between medical terminology and real information systems. The MDM portal provides a large collection of real data models from different sources. In contrast to terminology services, MDM contains information, which data elements are collected together. This goes beyond terminological relationships like "atrial fibrillation is a subtype of heart disease". MDM can answer the following questions: What data element definitions are available for "atrial fibrillation" and how frequent are these definitions being used? The new web service extends this functionality: What data elements are frequently collected together with the data element "atrial fibrillation"? The answer to this question provides the opportunity to harmonize and improve information systems already at the design stage.

At present, most IT frameworks for information systems provide its own data model editor. Relatively few of these editors can import external data model definitions. If it was easier to re-use data models from existing data sources, compatible data structures would be fostered and data integration would be easier. In addition, a lot of resources to maintain and use thousands of different data model editors could be saved.

A key idea of the new web service is to make data model editors more intelligent: with this web service, the editor can suggest new data elements, which are related to the current model context. For instance, suitable laboratory values for a given setting could be suggested.

There are many format options for data model definitions. In the field of clinical research, CDISC Operational Data Model (ODM) [10] is a growing standard and due to its endorsement by regulatory authorities more and more software solutions adopt it. For this reason MDM provides data models in ODM format, but also in many other formats like HL7 FHIR [11], Archetype Description Language as well as office and statistical formats.

There are many other approaches to foster compatible data models at the design stage of medical information systems. In particular, there are several initiatives to develop and consent common data elements (CDEs), such as the NIH CDE Repository [12]. Archetypes [13] are another major initiative to foster compatible data structures. Several libraries for standardized measures and instruments are being developed, such as PhenxToolkit [14] and ICHOM [15]. To our knowledge, none of these initiatives provide a service to identify related data elements from real data sources.

The current implementation of the web service for related data elements is a proof of concept and therefore has limitations, which should be addressed in future work:

1. It should be validated for a large number of data elements.
2. It relies on the contents of the MDM portal, which covers only a small subset of all medical data models.
3. It needs to be evaluated externally in the design of information systems, specifically regarding its contribution to the compatibility of data models.

Conclusions

Compatible data models should be implemented at the design stage of information systems. A novel web service to foster re-use of data element definitions is available for the scientific community. This service is based on the MDM portal and identifies data elements which are collected frequently together in real information systems.

Abstract

Structuring raw medical documents with ontology mapping is now the next step for medical intelligence. Deep learning models take as input mathematically embedded information, such as encoded texts. To do so, word embedding methods can represent every word from a text as a fixed-length vector. A formal evaluation of three word embedding methods has been performed on raw medical documents. The data corresponds to more than 12M diverse documents produced in the Rouen hospital (drug prescriptions, discharge and surgery summaries, inter-services letters, etc.). Automatic and manual validation demonstrates that Word2Vec based on the skip-gram architecture had the best rate on three out of four accuracy tests. This model will now be used as the first layer of an AI-based semantic annotator.

Keywords:

Natural language processing, word processing, data mining.

Introduction

Context

The use of clinically derived data from electronic health records and other clinical information systems can greatly facilitate clinical research as well as optimizing diagnosis related groups, operational and quality initiatives. The main approach for making this data available is to incorporate the data from different sources into a joint health data warehouse that contains different kinds of natural language documents such as prescription, letters, surgery reports, etc. All documents are written in everyday language.

A Semantic Health Data Warehouse (SHDW) was developed by the Department of Biomedical Informatics of the Rouen University Hospital (RUH), Normandy, France. It is composed of three independent layers based on a NoSQL architecture: a cross-lingual terminology server, HeTOP, which contains 75 terminologies and ontologies in 32 languages [1]. Then, a semantic annotator based on Natural Language Processing (NLP) called *Multi-Terminological Concept Extractor* (ECMT) [2]. Finally, a semantic multilingual search engine [3].

To improve the ECMT, a new strategy using deep learning techniques was defined. To implement it, a new text representation had to be designed to fit the input of neural networks algorithms.

Word embedding

In NLP, a chosen representation has to keep the semantic similarities between different words from a corpus of texts. Thus, the representation of a unique token has to show its proximity to other related meaning concepts, as illustrated in the quotation "*You shall know a word by the company it keeps"* [4], now known as the *distributional hypothesis*.

In fact, a compact and precise representation of words could bring several benefits. First, computers are way better to perform operations on low-dimensional objects. Second, probabilities calculation or mathematical operations can be done on words, such as the famous "*(king – man) + woman ~ queen*". And finally, the vectors' dimensions created to represent a word can be used to fit this word in a space and thus make distance comparisons with other tokens.

Implementations

Word2Vec

The word2vec approach was the first modern embedding released in 2013 [5]. Mikolov *et al.* implemented two kinds of architectures. The Continuous Bag of Word (CBOW) architecture treats the entire context as a single observation. A hierarchical softmax was also used to reduce computational limits [6]. The input layer accepts one-hot encoding as input (a sentence is encoded as a very sparse vector composed of 0 or 1, depending on the words found in this sentence). The Skip-Gram (SG) architecture uses a sliding window to define "*context / target*" pairs (*e.g.*, "*How / you*" is the context of the word "*are"* in the sentence "*how are you?*"). The entire corpus **V** will thus be transformed into many pairs *context / target* (*i.e., input / output* of the network). To reduce the computation of such an amount of data (in a "normal" training situation, all the weights should be updated in each passing through an example), the authors brought some new tricks. Word pairs appearing always together are treated as single tokens, frequent words subsampling and negative sampling [7].

GloVe

This model was released by the Stanford University [8]. Like Word2vec, GloVe can embed words as mathematical vectors; however, it differs on the method used to capture similarity between words, GloVe being a count-based method. The idea was to construct a huge co-occurrence matrix of shape **V×C** with **V** being the vocabulary of the corpus and **C** context examples. The probability ($Vw_1 \| Vw_2$) of a word Vw_1 being close to another Vw_2 will increase during the training. This gigantic matrix is then factorized by using the log function.

FastText

FastText is a newly released model and comes from a new idea [9]. Bojanowski *et al.* consider that a word could be the result of all of the vector decomposition of this word (sub word model). Each word V_w can be decomposed into a set of *n*-grams vectors. For example, the word "*boat*" can be seen as a set of *n*-gram with $n = 3$ as [$b + bo + boa + o + oa + oat + a + at + t$]. Thus, each word is embedded in the vector space as the sum

of all vectors composing this token, incorporating morphological information into the representation. Like Word2Vec, FastText comes with the two different architectures (SG and CBOW).

Related work

For a few years, the huge interest in word embedding led to comparison studies. Scheepers, Gavves, and Kanoulas [10] compared the three word embedding methods presented here but the three models were trained on different datasets (Word2Vec on news data, while FastText and GloVe trained on more definitional data, Wikipedia and Common Crawl respectively). Bairong *et al.* [11] also performed a comparison between these three, but focused on bilingual automatic translation comparison (BLEU score [12]) and without human evaluation for all the different models. More recently, Beam *et al.* [13] produced huge publicly available word embeddings based on medical data, however they didn't compare FastText, only Word2Vec and GloVe. Finally, Wang *et al.* [14] compared word embedding training set influence on models utilization, and its impact on different NLP tasks related to medical applications.

Moreover, many different teams or companies have released pre-trained word embedding models (*e.g.,* Google, Stanford University, etc.). However, in a clinical context, the vocabulary coverage of those embeddings is quite low regarding the words used. Indeed, many misspells, acronyms of specific abbreviations are regularly found in the documents produced in the hospital. Thus, a local training on specific data is often needed, especially with languages other than English.

Contributions

The objective here is to compare these five different methods to obtain the best possible words embedding (Word2Vec SG and CBOW, GloVe, FasText SG and CBOW). This representation will then be used as the input of deep learning models constructed to improve the annotating phase actually performed by the ECMT in the SHDW. This NER phase will be the first step toward a multilingual and multi-terminologies concept extractor. The influence of the number of documents in the training set will also be assessed.

Methods

Corpus

The corpus used in this study is composed of health documents from the SHDW of the RUH, France. All these documents are in French. They are also quite heterogeneous but their type is stored in the SHDW: discharge summaries, surgery or procedure reports, drug prescriptions and letters from a general practitioner. All these documents are written by medical staff in the RUH.

Document de-identification

These documents were then de-identified to protect each identity of every patient or doctor from the RUH. Every of the first and last name stored in the RUH main databases were replaced by non-informative tokens such as <*doctor*>, <*firstname*> or <*lastname*>. Moreover, other tokens have been used such as <*email*> or <*date*>.

Pre-processing

Texts have been split into token lists, the data has been lowered (meaningless to make distinction), the punctuation was removed, and the numerical values were replaced by a meta-token <number>. We chose to not remove stop words, due to their negligible impact on the context. Indeed, their multiple apparitions in many different contexts will just create a cluster of stop words in the middle of the VSM.

Training

Models have been trained on a server powered by four XEON E7-8890 v3 and 1To of RAM located on the RUH. We based the tuning of the models' hyper-parameters on the literature and on our own experience [15]. All chosen values are listed on Table 1. The *minimum count* parameter was set higher than usual settings due to the large quantity of data in the training set.

Table 1— Hyperparameters Used to Train the Five Word Embedding Models

Parameter	Model	Value
epochs	All	100
Min. count	All	20
Window size	All	7
Learning rate	All	2.5×10^{-2}
Embedding size	All	80
Alpha rate	All	0.05
Negative sampling	Word2vec/FastText	12
Subsampling	GloVe	$1e^{-6}$

Evaluation

Cosine similarity

We compare how similar the embeddings for a pair of concepts are by computing the cosine similarity of their corresponding vectors, and then using this similarity to assess whether or not the two concepts are related.

We used two well-known validations set UMNSRS-Similarity and UMNSRS-Relatedness, containing 566 and 588 manually rated pairs of concepts respectively [16]. However, since our corpus was in French, we used the translated and aligned version of the MeSH (Medical Sub-Heading) terminology stored in the ECMT to translate these two sets. The result provides a number of 308 pairs for the UMNSRS-Sim and 317 for the UMNSRS-Rel.

Mathematical operations

Mikolov's paper presenting Word2Vec showed that mathematical operation on vectors such as additions or subtractions are possible. Mathematical operations covering a wide range of possible subjects found in the selected documents (hospital departments, human tissues, biology, drugs) were defined.

Odd one out

The odd one out similarity task tries to measure the model's accuracy by giving three different words to the model. Two of them are known as linked, not the third one. Then, the model has to output the word vector which does not cluster with the two others [17]. To create such a validation corpus, 53 pairs of concepts potentially linked in a medical text have been defined from the MeSH terminology. Then, 53 words appearing more than 1,000 times in the corpus have been randomly selected to be used as odd terms.

Human evaluation

A formal evaluation of the five methods was performed by a medical doctor (SJD). A list of 112 terms has been extracted from the Medical Sub Heading (MeSH) terminology, covering every possible branch. SJD then assessed the relevance of the top five closest word vectors returned for each of the 112 concepts by the five created models. Retrieved citations were assessed for relevance according to a three-point modality scale

used in other standard information retrieval test sets: bad (0), partial (1) or full relevance (2).

Training set influence

To go further, models are going to be trained twice. First by randomly selecting 5% of the total amount of available documents in the RUH (~600K) and all evaluation tasks were performed against the five models. Then, the entire corpus (~12M) was used as a training set, and those evaluation tasks were assigned to these newly trained models.

Results

Corpus

In total, 641,279 documents for the first phase and 11,762,100 for the second one had been extracted from the RUH. They had been de-identified and pre-processed. Regarding the vocabulary, 355,597 unique tokens are found in those 12M of documents. However, this number can be pondered with 170,433 words appearing less than 5 times in the entire corpus (mainly misspells, but also geographic locations or biological entities like genes, proteins, etc). In total, 50,066 distinct words are found more than 20 times in the corpus, thus present in the models (minimum count parameter set to 20). On average, each document contains 281.26 words (*sd* = 207.42).
These documents were decomposed using the Term-Frequency Inverse-Document-Frequency (TF-IDF) algorithm, results in a frequency matrix. Vectors have been used to clusterize those documents with a kMeans algorithm (number of classes **K = 5**). To visualize their distribution on two dimensions, the t-SNE algorithm has been used (figure 1).

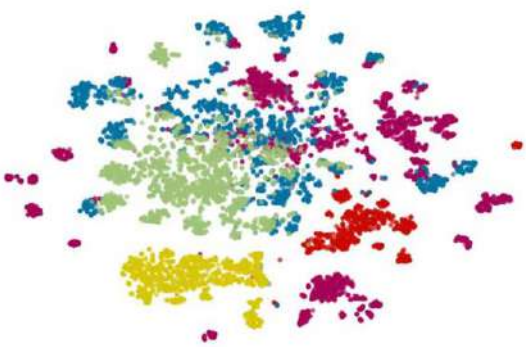

Figure 1— Two-Dimensional t-SNE Projection of 10,000 documents Randomly Selected Among Main Classes in the HDW

The five different colors correspond to the five types of documents selected (discharge summaries (green), surgery (blue) or procedure (purple) reports, drug prescriptions (yellow), letters from a general practitioner (red)).

Those main classes are well separated, the vocabulary itself contained in the documents from the HDW being sufficient to clusterize each type of text. However, discharge summaries, surgery or procedure reports are a bit more mixed because of the words used in these kind of contexts (short sentences, acronyms and abbreviations, highly technical vocabulary...). Regarding drug prescriptions and letters to a colleague or from a general practitioner, they present more specific vocabulary (drugs and chemicals, and current/sustained language respectively), involving more defined clusters for these two groups.

Training

Regarding the training time, models are very different. GloVe is the fastest algorithm to train with 18 min to process the entire corpus of 600K documents (Table 2).

Table 2— Algorithms Training Time (minutes) Regarding the Number of Documents

All time are given in minutes. GloVe is the fastest algorithm to train.

Algorithm	600K documents	12M documents
Word2Vec SG	182.0	497.9
Word2Vec CBOW	33.4	308.8
GloVe	**17.5**	**65.9**
FastText SG	1678.1	5573.8
FastText CBOW	1577.0	4974.0

GloVe performs much better in terms of computational time due to the way it handles the vocabulary. GloVe is stored as a huge co-occurrence matrix and thanks to its count-based method, which is not computationally heavy, it can be highly parallelized. It was expected that FastText would take a lot of time to train, due to the high number of word sub-vectors it creates. However, for Word2Vec, the difference between the two available sub-architectures is highly significant (33 min to 3h02 for 600K documents). This difference could come from the hierarchical soft-max and one-hot vector used by the CBOW architecture, which reduces the usage of the CPU. With SG, the minibatch parsing of all the context / target pairs highly increases the time to go through all possibilities.

Evaluation

Cosine similarity

The percentages of validated pairs from the UMNSRS datasets are presented in Table 3. FastText SG performed this task with the highest score (3.89% and 5.04% of valid pairs found for UMNSRS-Sim and UMNSRS-Rel respectively with 600K documents, 6.43% and 7.13% with 12M documents). The very low scores indicate that this kind of published dataset is useful to validate models trained on more academic texts, not those written in natural language. Some words will never be found because of the use of an acronym by health practitioners ("*HTA*" instead of "*HyperTension Artérielle*") or because of the informal form, mainly used in these kinds of documents.

Table 3— Percentage of Pairs Validated by the Five Trained Models on Two UMNSRS Evaluation Sets

	600K documents		12M documents	
	U-Sim	U-Rel	U-Sim	U-Rel
W_SG	2.92	4.10	4.73	6.92
W_CBOW	3.57	4.10	5.12	6.92
GloVe	1.29	0.94	1.35	0.94
F_SG	**3.89**	**5.04**	**6.43**	**7.13**
F_CBOW	**3.89**	3.79	**6.43**	6.65

Mathematical operations

A list of six mathematical operations has been defined with the help of a medical doctor and a university pharmacist (listed in Table 5). Each operation consists in verifying if *(term_1 – term_2) + term_3 ~ term_4* is true.

Table 4— Logical Operations on Words Having to be Retrieved with the Different Trained Models

Each is listed in English but has been performed against models in French.

1	(cardiology - heart) + lung ~ pneumology
2	(melanoma - skin) + gland ~ adenoma
3	(corpuscle - blood) + immune ~ immunoglobulin
4	(furosemide - kidney) + heart ~ fosinopril
5	(limb - lower) + upper ~ arm
6	(morphine - opioid) + antalgic ~ perfalgan

The number of validated operations performed by each model is presented on Table 4. Word2Vec SG gets the highest score on this task (5/6, regardless of the number of documents in the training set), while GloVe gets the lowest one (2/6).
Interestingly, no operation has been failed by the five models, indicating that none of them is simply not logical or just too hard to perform.

Table 5— Score for Mathematical Operation Tasks on Six Point Maximum for Each of the Five Trained Models

Algorithm	600K documents	12M documents
Word2Vec SG	**5**	**5**
Word2Vec CBOW	3	3
GloVe	2	3
FastText SG	3	4
FastText CBOW	3	3

Odd one similarity

Regarding the odd one similarity task, Word2Vec SG is the best so far with 65.38% (600K documents) and 75.5% (12M documents) of odd-one terms correctly found (Table 6).
Regarding the sub-architectures presented by both Word2Vec and FastText, the SG always performed better than the CBOW, possibly due to the negative sampling. In fact, the studied corpus is quite heterogeneous, and a word can be listed as items (*e.g.,* drugs in prescriptions) instead of being used in correct sentences. Sometimes, the complete update of vectors' dimensions generates non-sense in the models.

Table 6— Percentage of Odd One Tasks Performed by Each of the Five Trained Models

Algorithm	600K documents	12M documents
Word2Vec SG	**65.4**	**75.5**
Word2Vec CBOW	63.5	69.8
GloVe	18.5	39.6
FastText SG	44.4	45.8
FastText CBOW	40.7	41.3

Human Evaluation

The evaluation focused on 2800 terms (5 vectors × 112 MeSH concepts × 5 models), and was performed by two evaluators, CM and SJD, on models trained with 600K and 12M documents. First, the accordance between CM and SJD was assessed with a weighted kappa test (k = 0.6133). According to the literature, the agreement between the two evaluators can be considered as substantial [17]. This agreement can be retrieved in figure 2. The accord is stronger for the extreme scores (0 and 2) while the agreement about the middle score of 1 is least pronounced.
Moreover, to assess if human evaluators remained consistent regarding the cosine score computed by each model, we compared the average note given by the two evaluators with the average of the cosine distance computed for each model (table 7). Word2Vec with the SG architecture performed the highest score, regardless of the evaluator (1.469 with 600K documents and 1.420 with 12M). Interestingly, GloVe computes the shortest cosine distance in averages (0.884 on the 112 given concepts), while both evaluators gave it the lowest grade.

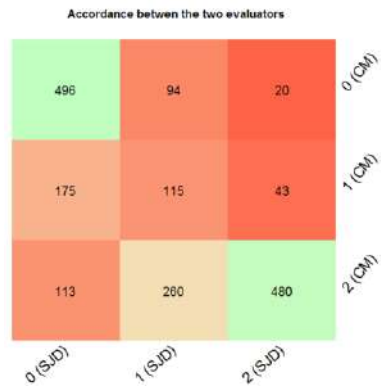

Figure 2— Global Representation of the Notation Accordance between the Two Evaluators (CM and SJD).

Notes attributed to a model output are going from 0 (bad matching) to 2 (good matching). Colors are ranging from light green (very similar) to red (completely different).

Table 7— Comparison between Cosine Distance Computed by each Model and the Human Evaluation Performed

Notes and distances are in averages on the top-5 closest vectors for 112 queries on every model.

Algorithm	600K documents		12M documents	
	Cos	Eval	Cos	Eval
Word2Vec SG	0.731	**1.469**	0.785	**1.420**
Word2Vec CBOW	0.776	1.215	0.716	1.33
GloVe	**0.884**	0.703	0.692	1.27
FastText SG	0.728	1.156	**0.963**	0.25
FastText CBOW	0.748	1.131	0.930	0.466

Discussion

In this study, the three most famous word embeddings have been compared. Word2Vec SG got the best score for three out of the four rated tasks (FastText SG is the best regarding the cosine one). These results are coherent with those obtained by Muneeb *et al.*, which compared Word2Vec and GloVe with the cosine similarity task [19]. GloVe had the worst grade, however it's the fastest to train so far. Regarding FastText, it is interest-

ing to note that the morphosyntactic similarities are kept in account in the vector space creation. Moreover, the sub-vector decomposition of words allows this kind of model to be queried by words absent from the original training corpus. We can imagine this model being used for orthographic correction or acronym disambiguation.
Interestingly, the size of the training set does not heavily influence Word2Vec (Table 7), but GloVe seems to improve its quality according to the human annotators. In fact, designed with a count-based method, this algorithm is directly affected by the amount of available data to train. FastText is highly degraded with more documents. The relevance of the returning vectors remained low because of the high proportion of morphosyntactic similarities between the sent and the returned tokens.
The corpus used as a training set comes from a real work environment. Finding a good evaluation for embedding produced in such a context is a hard task, and the performances shown by some models trained on scientific literature are often biased.
Future work will assess whether the best embedding method could help for semantic concept enrichment.

Conclusion

In our case, Word2Vec with the SG architecture got the best grade regarding three of the four rated tasks.
Any end user is now able to query the word embedding models produced on a dedicated web site as well as to download high quality dimension reduction images and test sets (URL: https://cispro.chu-rouen.fr/winter/) .

Abstract

In this paper, we trained a set of Portuguese clinical word embedding models of different granularities from multi-specialty and multi-institutional clinical narrative datasets. Then, we assessed their impact on a downstream biomedical NLP task of Urinary Tract Infection disease identification. Additionally, we intrinsically evaluated our main model using an adapted version of Bio-SimLex for the Portuguese language. Our empirical results showed that the larger, coarse-grained model achieved a slightly better outcome when compared with the small, fine-grained model in the proposed task. Moreover, we obtained satisfactory results with Bio-SimLex intrinsic evaluation.

Keywords:

Natural Language Processing; Electronic Health Records

Introduction

The Electronic Health Record (EHR) was mainly designed to digitally store patients' data and improve healthcare operational efficiency. Moreover, researchers found it a rich source to support several clinical informatics applications such as medical concept extraction, disorder reasoning, and patient history summarization [1].

Natural Language Processing (NLP) and Machine Learning (ML) techniques are widely used to extract, identify, and summarize EHR data, despite their dependency on laborious manual annotation and hand-crafted features [2,3]. Recently, many studies applied Deep Learning (DL) approaches to process EHR data [4–6], achieving better performance than traditional NLP/ML methods and requiring less time-consuming feature engineering.

An important component of DL for NLP methods is the use of Word Embeddings (WE) to represent each word as a vector in a low dimensional space [7] and employ this vector as an input feature. The resulting word vectors can be used to address many other NLP-related problems like sentiment analysis [8] and paraphrase detection [9]. Several studies used WE to solve health-related tasks like drug name recognition [10], semantic similarity [11], biomedical named entity recognition (bio-NER) [12], and patient outcome prediction [6].

To the best of our knowledge, only a few studies have applied WE to the Portuguese language in the biomedical domain (e.g., [13,14]). Three main studies made a WE repository available for both European and Brazilian Portuguese (pt-br) languages using a multi-genre corpus with data from Wikipedia, GoogleNews, etc. [15–17].

Despite the success of WE in the clinical NLP domain, it is difficult to find large, representative corpora to address relevant tasks, especially based on EHR data. Wang et al. [18] provided a comprehensive set of WE training experiments from distinct resources, namely clinical notes, biomedical articles, Wikipedia, and news. They found that the WE trained from EHR had the best results in clinical information extraction tasks. The semantic similarity captured by the EHR embeddings is closer to human experts' judgments on all datasets and, together with PubMed WE, the EHR embedding model finds more relevant similar medical terms.

Roberts [19] evaluated the trade-offs between small (and representative) corpora against large (but unrepresentative) corpora for training a WE model for clinical NLP tasks. It is not easy to decide between a huge, general-purpose corpus and a small, highly-representative corpus. For instance, one can choose a medium-sized clinical notes corpus instead of a corpus of a varying set of documents, a large scientific corpus, or even a combination of both. They found that merging multiple corpora is the best option when generating embeddings.

Thus, there exists a gap in building Portuguese clinical WE models for research: we could not find a clinical WE model available for NLP tasks in Portuguese. However, to provide a consistent WE model, a set of experiments are required to prove the usefulness of the model. It is possible to evaluate the model *extrinsically* by applying it to a downstream task, or *intrinsically* by measuring the innate quality of word representations through syntactic and semantic analogies [15,20,21].

Chiu et al. [22] developed two comprehensive resources, Bio-SimLex and Bio-SimVerb, targeting the intrinsic evaluation of word representations in biomedicine. Bio-SimLex is a list of 988 word pairs (nouns) in English and their respective similarity score (defined by a group of expert annotators), which can be used to compare the similarity scores between a WE model and the ones defined in Bio-SimLex. As some studies affirm that intrinsic and extrinsic evaluation scores do not always correlate [23–25], the authors claim that their evaluation resources can serve as a predictor of performance on downstream tasks. This is especially true for the Bio-SimLex set and bio-NER task, which were highly correlated.

In this paper, we address the identified research gap in pt-br clinical WE model generation and investigate an important research question: can a clinical WE model trained with multi-specialty and multi-institutional clinical narratives achieve

good results in downstream biomedical NLP tasks? We trained a preliminary multi-institutional and multi-specialty clinical WE model and assessed its performance by (i) checking if a large, coarse-grained model applied to a Deep Learning algorithm performs as well as a small, fine-grained model for predicting a specific disease and (ii) analyzing the results on Bio-SimLex evaluation set.

Methods

In this section, we describe our training process for the pt-br clinical WE model, including the dataset, preprocessing steps, and parameter space; the deep learning algorithm used to identify Urinary Tract Infection disease (UTI); the Bio-SimLex pt-br adaptation process; and the experimental setup.

Data

To generate the WE model, we used a collection of de-identified clinical narratives obtained from a group of three hospitals in south Brazil written from January 2013 to December 2017. These narratives include 745,731 documents of different types (nursing notes, discharge summaries, and ambulatory records) and various medical specialties (Cardiology, Nephrology, Endocrinology, etc.). We will call this entire collection: GROUP-ALL. We classified GROUP-ALL as coarse-grained because of the generalized nature of its data, which does not contain data specific to one type of document, specialty, or institution.

As we intended to run an algorithm to detect UTI disease and compare the results between a fine- and coarse-grained WE model (see next sections for details), we used a subset of data from GROUP-ALL. All narratives that contained a disease name corresponding to the ICD-10 code N.39, which denotes UTI, or corresponding subclass codes were filtered for inclusion, forming the new dataset called GROUP-UTI.

Additionally, we obtained another dataset from a hospital in southeast Brazil to train the UTI disease detection algorithm (see the following sections). This dataset, named ANN-UTI, consisted of narratives annotated with corresponding ICD-10 codes related to UTI diseases. We present a few sample narratives and dataset statistics in Table 1 and Table 2.

Preprocessing

We preprocessed the narratives of GROUP-ALL dataset using the following steps sequentially: (1) sentence parsing, (2) sentence tokenization, (3) lowercasing, (4) accentuation removal, (5) numeric characters removal, and (6) stopwords removal (using NLTK stopwords).

Embedding Parameters

To train a preliminary WE model, we followed recommendations and guidelines provided by prior studies that deeply analyzed the impact of hyperparameters on word vector quality. Unlike Beam et al. [26] who strictly reproduced the parameters of Levy et al. [27], we opted to select values from clinical WE studies as the default algorithmic configuration when there were inconsistencies among the guidelines

CBOW vs. Skip-gram: Several studies affirm that, in general, Skip-gram model performs better than CBOW [26,28,29]. Hence, we used Skip-gram to train our model.

Negative sampling: Levy et al. [27] recommended using multiple negative samples [30] when using Skip-gram. We used 8 negative samples based on Boag and Kané's [31] work on training WE based on a Clinical Metathesaurus.

Minimum count: Chiu et al. [28] showed the limited effect of this parameter on overall scores. Therefore, we used the default value of 5, which reduced the GROUP-ALL vocabulary size to 56,195 unique tokens, GROUP-UTI to 5,125, and ANN-UTI to 3,203.

Sub-sampling: Chiu et al. [28] described that this parameter does not have a significant impact on extrinsic evaluation, so we set the default value of 1e-3.

Context-size: Similar to Boag and Kané [31], we set the context/window size to 8.

Vector dimension: Following Boag and Kané [31], we used 300 as the dimension size of the vectors since Chiu et al. [28] and Fanaeepour et al. [32] found little improvement using 200. Furthermore, 300 corresponds with the configuration

Table 1– Example narratives from each dataset and their granularity. Note that, narratives from ANN-UTI contains an ICD-10 code at the beginning of the note, which is the result of expert annotation i.e. labeling with the corresponding diagnosis

Dataset	Sample Narrative	Granularity

requirements of the GloVe model (that is the UTI detection algorithm baseline).

DeepCoder: An Algorithm to Identify Urinary Tract Infection

UTI is defined as "an infection anywhere in the urinary tract (urethra, bladder, ureters, or kidneys)" [33] or "the clinical syndromes of acute, uncomplicated, urinary infection" [34]. ICD-10 reserves a specific class for such problems: "N39 - Other disorders of urinary system" and 7 subclasses (N39.0, N39.1, N39.2, N39.3, N39.4, N39.8 and N39.9) to provide more detailed information for clinical evaluation.

Table 2 – Dataset sizes by number of tokens and sentences

Dataset	#Sentences	#Tokens	#Unique tokens
GROUP-ALL	2,412,055	32,023,244	287,495
GROUP-UTI	26,719	319,203	17,518
ANN-	2,030	205,318	11,494

DeepCoder was developed using a GloVe-trained WE model as input, based on ANN-UTI texts following the preprocessing steps and hyperparameter configuration described in previous sections. The algorithm is composed of a neural network architecture formed with an embedding layer as input with 500 dimensions (e), four convolutional layers with kernel = 128 (k), a Rectified Linear Unit (ReLU), and window sizes of 5, 8, 10, and 12. Between each convolutional layer, there exists a 1-max pooling layer, a global max pooling layer, and a dropout of 0.2 (d) that feeds a 128-sized Dense (i) layer and softmax activation with 8 possible outputs (7 for the ICD-10 N39 subclass codes, and 1 for a generic non-UTI code).

Experimental Setup

We based our experiments on an extrinsic evaluation using the DeepCoder algorithm. In order to predict the model performance in other biomedical NLP downstream tasks, we performed an intrinsic evaluation using the Bio-SimLex set.

Extrinsic Evaluation

The Word2Vec models trained with GROUP-ALL, GROUP-UTI, ANN-UTI datasets, and the original DeepCoder GloVe model (trained with ANN-UTI) were utilized in DeepCoder to perform the extrinsic evaluation and compare relative performance. All results were calculated using a 10-fold cross-validation. Figure 1 presents the extrinsic experimental setup overview.

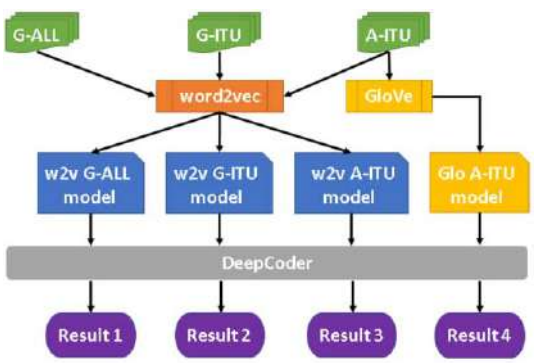

Figure 1 – Extrinsic experimental setup: each dataset was used to obtain different WE models using Word2Vec and GloVe algorithms. We used the four pre-trained WE models to create input embeddings for DeepCoder

Intrinsic Evaluation and Bio-SimLex Adaptation

To perform the intrinsic evaluation, we used the Bio-SimLex evaluation set and associated semantic similarity and relatedness scores. To evaluate a WE model, we calculated the Spearman's correlation coefficient between the similarity ratings found in the model versus the ratings defined by experts and available in Bio-SimLex.

Two researchers (one with a medical background, the other with a health informatics background) translated and adapted the terms to pt-br, observing the following instructions:

- Check if the English term exists in the Unified Medical Language System (UMLS) and has a pt-br translation. If not, discuss the best possibility between the two translators. If yes, then pick the preferable option. If multiple options, then prioritize terms:
  - Labeled as ISPREF='Y'
  - With a higher number of occurrences in GROUP-ALL dataset
- Label the word pair as General, EHR, or Biomedical – where the first stands for words from the general domain, the second represents words seen in EHR texts, and the third category contains words that are not present in EHR but are used in biomedical context (e.g., biomedical articles).

In Table 3 we present some translation examples.

Table 3 – Bio-SimLex translation examples

Term1	Term2	Score	Type
therapy/terapia	treatment/tratamento	9.32	EHR
oxide/óxido	sucrose/sacarose	0.00	BioM

It is important to highlight some issues found during the translation process, including: (i) the difficulty to translate ambiguous terms that have multiple meanings or translations, depending on the context (e.g., abstract) and (ii) word pairs without well-known synonyms in pt-br, like hindbrain and rhombencephalon, which we found only one possible word to translate both (*rombencéfalo*). In this case, we removed the word pair to avoid equal words in the evaluation set.

Due to the differences between the general domain, biomedical literature, and EHR texts, we performed three separate intrinsic evaluation runs: one using all the translated Bio-SimLex data; another with word pairs categorized as Biomedical and EHR, excluding the General category; and using only the word pairs labeled as EHR. By doing this, we tried to fairly evaluate our model which was trained exclusively with EHR text data.

Results

We summarize the results from our extrinsic evaluation in Table 4. It is possible to verify that the scores are very similar across all models. The GROUP-ALL model is the largest and least representative compared to the gold standard, and ANN-UTI is the smallest and most representative (because it contains texts from the same dataset as the gold standard). This suggests that the GROUP-ALL model takes advantage of its size to yield good performance for the UTI identification task. Likewise, the ANN-UTI models (Word2Vec and GloVe), as the more

representative models, achieve good results as expected. The GROUP-UTI embeddings yielded an inferior result, most likely due to less representative texts of less than medium-size.

The results of the intrinsic evaluation of the GROUP-ALL model, using three subsets of the Bio-SimLex are shown in Table 5. The Spearman's correlation coefficient increases when we use more specific subsets (Biomedical and EHR). Using only the word pairs labeled as EHR our model achieved a correlation score of 0.6419, which is similar to the results obtained by Chiu et al. [22] with their Skip-gram and PubMed-w2v models, varying 0.07 and 0.05 respectively.

Table 4 – Extrinsic experiments results. F1-score mean (F1 with cross-validation with 10 folds) and standard deviation (SD)

WE model	F1	SD
Word2Vec GROUP-ALL	**0.95**	**0.04**
Word2Vec GROUP-UTI	0.91	0.14

Table 5 – Intrinsic experiments results of Spearman's correlation coefficient (RHO) divided by the categories of Bio-SimLex word pairs. RHO

Categories	RHO
General+Biomedical+EHR	0.4558
Biomedical+EHR	0.5679

Discussion

The results from our empirical extrinsic evaluation confirm previous findings [19] suggesting that we have indeed a trade-off between corpus size and similarity when it comes to WE. The results imply that the answer to our research question is: yes, a large coarse-grained WE model can yield good results for a downstream biomedical NLP task.

We can highlight a few limitations of this study and consequently propose some future work. For example, the models were extrinsically evaluated for one task only; and to overcome this limitation we opted to use Bio-SimLex to emulate the results to another variety of bio-NLP tasks. But due to the difficulties found in the translation process, we think that the evaluation set lost some of its reliability, then would be better to build a specific evaluation resource for EHR pt-br data, although the obtained results are similar to Chiu et al. [22].

We would also explore hyperparameter tuning and other WE algorithms such as fastText [35], and wang2vec [36] in the future.

In this paper, we explored WE models trained with words only, although it is possible to use several approaches that focus on enhancing WE with clinical knowledge by concatenating extra information to the vector space [11,21,26,31,37,38]. It is also worth noting that despite the existence of various approaches to generate clinical embeddings, there is limited consensus among researchers on what is the state-of-the-art for each bio-NLP task.

Besides some authors [39] discuss the reliability on ICD-10 coding, our work relied on a simple annotation process containing only one disease and its specializations, which did not lead us to uncertainties and the complex ICD environment that build-up in some cases.

We also plan to enlarge our corpus by adding biomedical publications, Wikipedia, and other open source datasets in Portuguese.

Conclusions

In this study, we built WE models with different granularities and extrinsically evaluated them using a disease prediction algorithm (DeepCoder) to assess performance variation due to different word embeddings. We used an adapted version of the Bio-SimLex set to intrinsically evaluate a large, coarse-grained model in order to predict the model's performance in other biomedical downstream tasks.

We conclude that it is possible to achieve similar results using a large, coarse-grained WE model and a small, fine-grained alternative to facilitate a bio-NLP task. However, robustness of our models could be ensured by applying them to a wide range of clinical prediction tasks, as the Bio-SimLex adaptation to pt-br has some limitations and reliability issues.

Abstract

Secondary use of electronic health records using data aggregation systems (DAS) with standardized access interfaces (e.g. openEHR, i2b2, FHIR) have become an attractive approach to support clinical research. In order to increase the volume of underlying patient data, multiple DASs at different institutions can be connected to research networks. Two obstacles to connect a DAS to such a network are the syntactical differences between the involved DAS query interfaces and differences in the data models the DASs operate on. The current work presents an approach to tackle both problems by translating queries from a DAS using openEHR's query language AQL (Archetype Query Language) into queries using the query language CQL (Clinical Quality Language) and vice versa. For the subset of queries which are expressible in both query languages the presented approach is well feasible.

Keywords:

Electronic Health Records, Data Warehousing, Information Systems

Introduction

The secondary use of electronic health records (EHR) has become an important field in medical informatics [1]. Routine clinical data is reused for various scientific purposes, like prospective estimation of study cohort sizes or support of study cohort acquisition. When this routine data is scattered in various data sinks in various heterogeneous data formats, it is difficult to access. In order to improve access to the EHR, solutions have been developed to aggregate the routine data and to make it accessible via a standardized interface. Two paradigms are possible when constructing such a data aggregation system (DAS): The first method is to leave the data in its original place and to provide a standardized access by aggregating the requested data chunks on the fly using appropriate extraction transformation load (ETL) pipelines. SMART on FHIR [2] projects for example realize this paradigm by aggregating requested FHIR resources on the fly. This approach works well for patient centered access (i.e. queries operating on the data of a single patient). However, for population centered access (i.e. queries operating on data of all patients) this approach lacks indices covering the involved data sources. Without such indices, query speed performance does not scale related to the amount of queried patient data. On large volumes of EHR data this would heavily afflict the usability of FHIR related query languages like FHIR-REST-API[1] or CQL (Clinical Quality Language)[2]. The second method to provide access to aggregated routine data is to provide an additional data sink with a generic data model, into which the heterogeneous routine data is persistently transferred via an ETL pipeline. The data sink is supplied with appropriate indices, so it can be efficiently queried via a standardized query language. Examples of this architecture are i2b2 [3], openEHR [4] or OMOP [5]. HAPI[3] and VONK[4] are data sink servers that do not only use FHIR as an access interface in patient centered mode, but they also use it as the data model in which the EHR data is stored, so it can be queried in population centered mode using query languages like FHIR-REST-API or CQL.

Clinical Research Networks

In order to increase the volume of underlying patient data for larger and thus more expressive query results, DASs at different institutions can be connected to clinical research networks. Examples for such networks are PCORnet, the OHDSI research network or EHR4CR. In a DAS network a query is distributed to connected nodes, where it is independently evaluated. Each node's results are returned and combined to an aggregated result. Systems like SHRINE [6] for i2b2 or SNOW [7] for openEHR perform the query distribution and result aggregation automatically. Each network, however, only allows DASs having the same query language to be part of the network. If a DAS with a different query language is intended to be integrated into the network, the data from that DAS has to be transferred (like in [8]) into a new dedicated DAS supporting the networks query language. However, parallel support of multiple DASs containing the same redundant data at one institution creates an overhead in support and hardware.

An alternative approach is to translate queries of an incompatible DAS into the query language required by the DAS network. The current work examines the feasibility of translating queries formulated in the query language CQL into AQL (Archetype Query Language, the query language of openEHR) and vice versa. To accomplish this task, the query is first translated into an intermediate query graph model, then potentially necessary graph transformation are applied on the query graph and, finally, the graph is translated into the desired target query language.

Methods

Query Languages

Before going into detail about the translation process, the two languages shall be briefly introduced:

CQL is a functional query language. A CQL script is defined as a so called *library* in which, besides the actual queries, also

[1] https://www.hl7.org/fhir/search.html
[2] https://cql.hl7.org
[3] http://hapifhir.io
[4] https://fire.ly/vonk/vonk-fhir-server

meta information related to the queries can be defined. CQL is independent of a concrete data model, as the model to be used is explicitly defined in each CQL library. The CQL data model elements can be composed of the following data types: primitives (Booleans, Strings, numbers and timestamps), clinical codes, quantities, intervals, lists and structured types. Structured data objects, which can again contain other structured data objects, can be accessed with a path syntax (e.g. *patient.contact[0].name.family*). Besides the data model, a CQL library can define its search context, which is either *Patient* or *Population* centered. The main functional part in a CQL library are the *statements*. Each statement can be seen as an individual query. Usually a statement defines which data sources the query is operating on (e.g. *[Patient] A* or *[Observation] B*), how the elements of the queried sources are constrained (e.g. *B.valueString = 'x'*), how the various data sources have to be related to each other (e.g. *[Patient] A with [Observation] B such that B.subject = A*) and which elements of potential matches have to be returned as results (e.g. *Return Tuple {id:A.identifier, B.valueString}*). CQL provides a rich repertoire of operators (e.g. comparison, logical, arithmetic, list access, aggregation) to perform calculations on the data model.

OpenEHR's query language AQL is SQL-inspired and as well a functional language. It operates on a data model that is defined by the openEHR data modeling language ADL. OpenEHR's root data model elements are called *archetypes*. An archetype can be composed of the following data element types: primitives (Booleans, Strings, numbers and timestamps), other archetypes and generic container structures (e.g. lists). Structured data objects are accessed via a path syntax. An AQL query mainly consists of three parts: The *FROM* part defines which archetypes are queried and how these archetypes are related to each other concerning meronymity relations (e.g. *EHR A contains Observation B*). The *WHERE* part constrains the archetype elements (e.g. *B/value > 1*). The *SELECT* part defines which elements have to be returned in the results (e.g. *select A/ehr_id, B/value*). Compared to CQL, AQL provides a smaller set of operators (comparison, logical, *matches*, *exists*). For the sake of brevity archetype names in the following chapters are shortened (e.g. openEHR-EHR-OBSERVATION.LabResult.v1 → Observation[LabResult]).

Currently, the CQL translation has the following constraints: 1. The CQL queries may only contain a single statement and 2. The CQL queries are defined in the context *Population*. If a CQL query with context *Patient* has to be translated to AQL, the given patient identifier has to be integrated into the CQL statement as a constrained *Patient.identifier*.

Queries as Graphs

Queries can be seen as graphs. In order to perform the query translation, the CQL/AQL (depending on the translation direction) query to be translated is transformed into an intermediate graph model. The graph is subsequently translated into the desired target query language. The graph model is depicted in Figure 1. A graph contains a set of data model elements that are connected via relations. Although the type of these relations is not specifically defined, they could be interpreted as meronymity (i.e. *contains*) relations. Additionally, a graph contains a set of operators, which contain as parameters either other operators, data model elements or literals. A similar same approach has already been applied in [9] where AQL was translated into the query language of i2b2.

For parsing AQL queries the parser from the AQL-processor of the EtherCIS project[5] was taken and combined with a graph builder written by the authors. The parser for CQL libraries was taken from the cql-2-elm project[6] and combined with a graph builder also written by the authors. The graphs retain 1. the structure of data model elements mentioned in the query, 2. the constraints and operators on data element values and 3. which data elements have to be contained in the returned results. Whenever elements in a query are named with an alias, all references to that alias create *IsRelatedTo/ HasParameter* relations to the graph node identified with that alias.

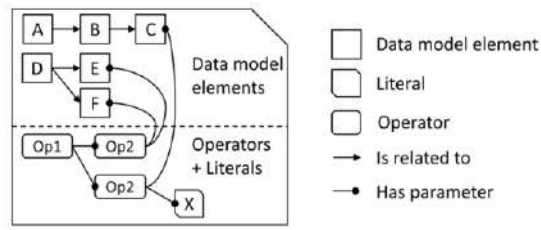

Figure 1 – Model of graphs, which are used as intermediate data model during query translation.

Graph Transformations

Because of properties of CQL/AQL that do not exist in the respective other language or non-matching properties of the incorporated data models, the graph has to be appropriately transformed, in order to fit all required properties of the target language. Currently there exist the following types of transformations: Meronymity-Equality-Transformations and their reverse, Path-Transformations, Concept-Code-Mappings, Operator-Mappings, Resolve-Quantity-Transformations, Resolve-Interval-Transformations (see Figure 2).

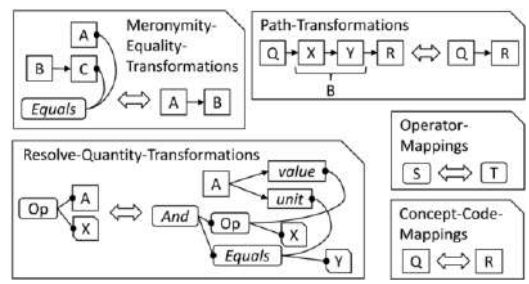

Figure 2 – Query graph transformations

Meronymity-Equality-Transformations

Meronymity-Equality-Transformations are needed because in CQL the connection between two root data model elements is represented by an equality constraint between one root element and a child element of the other root element (e.g. *[Patient] A with [Observation] B such that B.subject = A*). The definition of both involved element types (*[Observation]* and *[Patient]*) determine the type for the element *B.subject*, which would otherwise not be specified. In contrast, in AQL the main mechanism to define structural relationships between data model elements are meronymity relations, which also define the type of the contained elements (e.g. *Ehr A contains Observation[LabResult] B*). Meronymity-Equality-Transformations are parameter free. The transformation looks for any three data model elements *A*, *B* and *C*, with a relation between *B* and *C* and an *Equals* operator containing *A* and *C* as parameters. The element *C* and the *Equals* operator are deleted and the element *A* gets connected to the element *B*. The reverse Equality-Meronymity-Transformation requires a parametrization because only a defined set of related elements *A* and *B* should be transformed and the name of the newly

[5] http://ethercis.org

[6] https://github.com/cqframework/clinical_quality_language

created element *C* has to be given. For all directly connected elements *A* and *B* the connection gets removed and instead a new element *C* gets created and connected to *B*. Furthermore, a new *Equals* operator gets created receiving *A* and *C* as parameters.

Path-Transformations

Path-Transformations provide the possibility to shorten or lengthen data model element paths. They are needed because elements from the source data model, which have to be mapped to their semantically identical counterparts in the target data model, might be encapsulated in additional element wrappers. These wrappers have to be removed if they do not exist in the target data model. E.g. the intermediate element *valueQuantity* in *Observation.valueQuantity.value* (FHIR) has no counterpart in *Observation[LabResult]/value* (openEHR). The transformation can be configured to either shorten or lengthen a path. In order to shorten a path, the transformation searches for nodes *Q* and *R* connected by a list of nodes *B* and removes the intermediate nodes. The reverse transformation introduces new intermediate nodes *B* into the graph between two directly connected nodes *Q* and *R*.

Concept-Code-Mappings

Concept-Code-Mappings map element identifiers of the source data model to element identifiers of the target data model by renaming nodes.

Operator-Mappings

Operator-Mappings map operators of the source query language to operators of the target query language by renaming nodes.

Resolve-Quantity-Transformations

AQL does not contain quantities as build in types. Therefore, operators on quantity types have to be exchanged by *and*-connected clauses that check the requested value as well as the requested quantity type (e.g. *days, cm*) (e.g. *[Encounter] A where A.length > 120 days → [Encounter] A where A.length.value > 120 and A.length.unit = 'days'*). The transformation looks for data model elements *A* contained as a parameter in an operation *Op* (with potential further parameters). The node *A* get connected to two newly created data model elements *value* and *unit* and gets removed from the parameters of *Op*. Additionally, a new *equals* operator is created which gets the new *unit* node and a newly created literal *Y* as parameters. The value of *Y* has to be given as a transformation configuration and defines the unit of the quantity to be computed. The new *equals* node and the *Op* node get connected in a newly created *and.*

Resolve-Interval-Transformations

Similar to quantity types, AQL does not contain intervals as build in types. Operators on interval types have to be exchanged by *and*-connected clauses, that check the requested constraints (e.g. *[Patient] A where A.birthDate in A.contact[0].address.period → [Patient] A where A.birthDate > A. contact[0].address.period.low and A.birthDate < A. contact[0].address.period.high*).

Graphs to Queries

After all necessary graph transformations have been executed, the graph can be translated into the desired target query language via respective Graph2QueryString writers implemented by the authors.

The proposed method was tested on manually designed AQL/CQL queries and on queries contained in the AQL/CQL documentation. A query was (when translatable) translated into its respective counterpart and re-translated into its original language. The original query was compared for semantic equality to its translated counterpart as well as to its re-translation into the original query language.

Results

Translations Constraints

The proposed methodology using the currently available set of graph transformations allows the translation of all CQL/AQL queries having the following properties: A query has to contain the data type *Patient* (*EHR* in AQL) as a query source. The query may contain an arbitrary amount of additional data sources of arbitrary type. A query may return an arbitrary subset of query sources or data model elements that are reached from the data sources via paths. The paths can have arbitrary length. Data model elements can be constrained using the logical comparators listed below, parametrized with literals or with other data model elements. A query may contain the data types *Boolean*, *String*, *Integer*, *Decimal*, *Timestamp*, *Date*, *DateTime*, *Quantity* and *Interval*. Data model elements or literals can be processed with operators from the set of mutual operators listed below.

Translations are only possible for queries containing exclusively operators which exist in both query languages with the same semantics and the same interface. These operators (using their CQL-displaynames) grouped into operator categories are:

- Boolean operators *{ and, or, not }*
- comparator operators on numeric/date/timestamp types *{ =, <, <=, >, >=, != }*
- comparator operators on Strings *{ =, !=, matches }*
- operators on lists/iterators *{ in, exists, with, without }*.

All other operators either have to be substituted by appropriate graph transformations or render a query untranslatable.

CQL does not contain an equivalent to AQL's *contains* operator. This operator, which performs a type matching on a given to be contained data type, returns the matched child data element. The operator is substituted by Meronyminity-Equality-Transformations.

The mutual set of operators is reduced by the following limitations of the two languages, which could not be substituted by graph transformations:

AQL contains no arithmetic operators (e.g. *+, -, *, /*). AQL comprises a limited set of list operators (e.g. *first, last, sort, count* do not exist). It is only possible to access specific list elements via a given index or via the *matches* operator. The *contains* operator can only be used to constrain the data model structure and not to check the containment of a single element in a list (e.g. *[ProcedureRequest] A where A.notes contains 'x'*).

AQL allows no aliased valueset definitions. All valuesets have to be directly given as parameters to the operator using them, instead of having the possibility to reference a previously defined valueset with an alias. CQL, on the other hand, allows only valueset aliases based on valueset ids but no definition of valuesets by listing their contained codes. As the current implementations is restricted to CQL statements instead of CQL libraries, the usage of valuesets or therein contained codes still has to be resolved.

Table 1 shows a selection of example queries that have been automatically translated given proper graph transformation configurations.

Table 1 – Automatically translated example queries

CQL	AQL
[Patient] A where A.active = true and A.gender = 'male'	select e from EHR e where e/active = true and e/gender = 'male'
[Patient] A where exists(A.name B where B.given = 'John')	select e from EHR e contains composition a[HumanName] where a/given = 'John'
[Patient] A with [Encounter] B such that not(exists(B.discharge)) and B.subject = A	select e from EHR e contains composition a[Encounter] where not exists a/content[Discharge]
[Patient] A with [Observation] B such that B.code = 'Calcium' and B.valueQuantity > 10'mg' and B.subject = A	select e from ehr e contains observation a[LabResult] where a/code = 'Calcium' and a/valueQuantity/value > 10 and a/valueQuantity/unit = 'mg'

Figure 3 pictures an example of an CQL query being transformed into AQL. The query represents a request for patients having at least one *Calcium* laboratory measurement with a value of more than 10. The CQL query is parsed into the uppermost graph depicted in Figure 3. Successively, Meronymity-Equality-Transformations, Path-Transformations and Concept-Code-Mappings are applied to the graph (parametrized with the configurations from Table 1, CQL → AQL). The Meronymity-Equality-Transformation links the *Patient* node with the *Observation* node, which is the required representation in AQL. The Path-Transformation removes the *valueQuantity* node, because in the openEHR data model the value element is a direct child element of the *LabResult* archetype. The Concept-Code-Mappings rename the nodes *Patient* and *Observation* as *Ehr* and *Observation[LabResult]*, as those are the semantically equivalent data elements in the openEHR data model. Finally, the transformed graph is translated into an AQL query String.

Table 2 – Manually defined configurations used in the example in Figure 3. The column headings reference the nodes from Figure 2.

CQL → AQL		
Path-Shorten-Transformations		
Q	**B**	**R**
Observation[LabResult]	{valueQuantity}	value
Concept-Code-Mappings		
Q	**R**	
Ehr	Patient	
Observation[LabResult]	Observation	
AQL → CQL		
Equality-Meronymity-Transformations		
A	**B**	**C**
Patient	Observation	subject
Path-Lengthen-Transformations		
Q	**B**	**R**
Observation[LabResult]	{valueQuantity}	value
Concept-Code-Mappings		
Q	**R**	
Ehr Observation[LabResult]	Patient Observation	

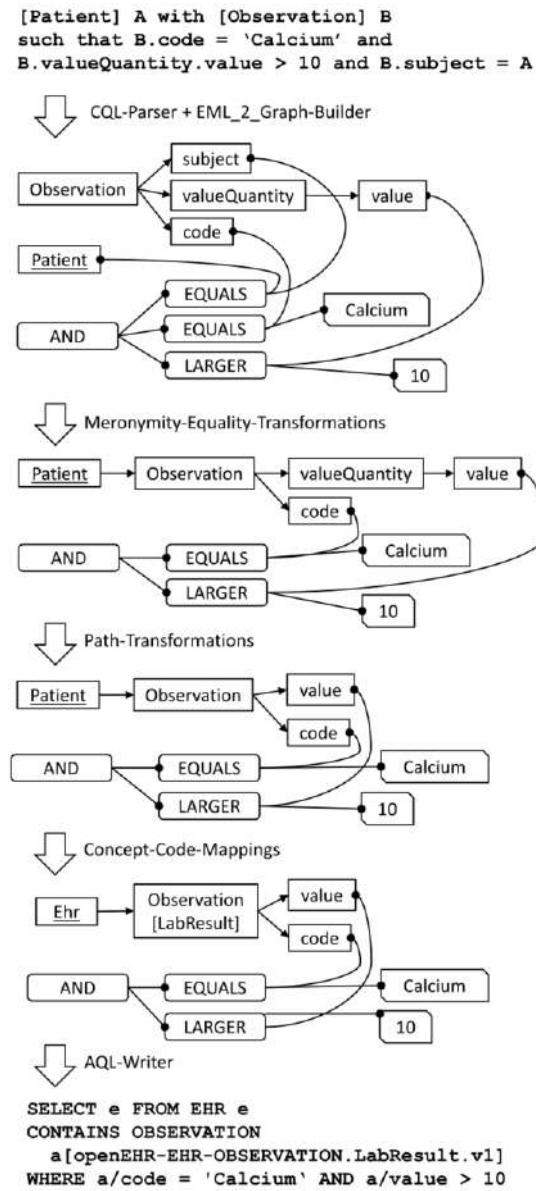

Figure 3 – Translation of an CQL query into AQL. Underlined nodes denote elements that have to be included in the result

The translation from AQL to CQL goes accordingly with the transformation configurations from Table 1, AQL → CQL. It is noted that the order of the execution of the different transformation types remains the same, so the re-translation is not according to the reverse direction in Figure 3, which has to be considered in the transformation configurations. The AQL query is first parsed into a graph. Subsequently the Equality-Meronymity-Transformation creates the child node *subject*, connects it to the *Observation[LabResult]* node, removes the relation between *Ehr* and *Observation[LabResult]* and adds a new *Equals* operator with *subject* and *Ehr* as parameters. The Path-Transformation adds the node *valueQuantity* between *Observation[LabResult]* and *value*. The Concept-Code-Mappings rename the nodes *Ehr* and *Observation[LabResult]* as *Patient* and *Observation*. Finally, the graph is translated into a CQL query String.

Discussion

The approach to translate a query into another query to improve or facilitate its evaluation is known as query rewriting [10]. The early work on query rewriting is related to view-based relational database querying and deals with the translation of queries formulated in the same language for both, source and target. In recent years query rewriting was as well used in conjunction with graph data query system, e.g. [11] resembles the presented approach, whereas there XQuery was translated into SPARQL.

The discussed graph model and the graph transformations have been specified and implemented by the authors. Both elements could be exchanged by a standard from the graph computing community like e.g. Owl to model graphs and graph transformation frameworks like GROOVE to model the transformations.

Although the used graph model is similar to the parser graphs produced by each of the systems, it was more convenient for the authors to use a separate model in order to be independent of possible system specific modeling paradigms.

The concept-mappings and path-transformations could be substituted by a mechanism using FHIR ConceptMaps, which encode the mappings from elements of one data model to equivalent data model elements in a target system.

When applying the presented approach on productive data models, the configuration of the various transformations could become cumbersome when the data models are large. It would be beneficial if some configurations could be automatically deduced by an analysis of the source and the target data model. When both data models are annotated with terminology codes, the configuration of concept-mappings could be deduced automatically by identifying equivalent data model elements annotated with the same codes.

An issue that could appear when applying query translations in combination with concrete query engines system implementations could be that the translations are semantically equivalent, but they can contain differences in their syntactical structure. E.g. the two CQL queries *[Patient] A with [Encounter] B such that B.patient = A* and *[Patient] A where exists [Encounter] B where B.patient = A* are semantically equivalent, but a query execution engine could handle the execution of a *with-such-that* expression differently than a *where-exists* with a nested sub query.

An aspect not yet covered by the presented approach is the translation of *valueset*, *concept*, *code* and *codesystem* definitions. Due to the omnipresence of valueset references in the query examples of both query languages, the presented approach could have difficulties to be applied in productive systems without this issue being solved.

A further aspect not tackled in the presented approach is how query results are returned by the respective systems. Both systems have their own method and syntactical encoding for delivering results. For that topic, proper adapters would have to be developed as well. The example from Figure 3 for example returns complete patient objects, which are serialized differently by the respective systems. In order to prevent differences in serializations, the return types of translatable queries could be restricted to primitive types (e.g. patient ids instead of complete patient objects).

As the presented approach is still work in progress, it can be extended whenever the query language specifications are changed or extended and thus set of mutual operators grows. E.g. the AQL specification already contains announcements of future language elements like arithmetic operators, an extended *matches* operator or alias definitions (i.e. *let*).

Conclusions

An approach was presented to translate Clinical Quality Language (CQL) queries into Archetype Query Language (AQL) queries and vice versa. Several examples were shown to illustrate the capabilities of the presented apprach and for one example the translation process was illustrated in detail. As CQL and AQL do not comprise the same sets of operations, the translation capabilities of the presented approach are restricted to a subgroup of possible queries, which have to be composed of a set of common operators of both query languages. Despite this limitation, queries expressible in both languages can be automatically translated, which would allow both query systems to be transparently included in a distributed research network of the other type.

Acknowledgements

An implementation of the presented approach in Java is available at https://gitlab2.informatik.uni-wuerzburg.de /gef18bg/cdw_querymapper. The authors thank B. Haarbrandt, A. Zautke and G. Vella for helpful comments. This research was funded by grant of German Federal Ministry of Education and Research (Comprehensive Heart Failure Center Würzburg, grants #01EO1004 and #01EO1504).

Abstract

Laboratory data collected in the electronic health record as part of routine care can be used in secondary research. For example, the US Department of Veterans Affairs maintains a data warehouse covering over 20 million individuals and 6.6 billion lab tests. However, data aggregation in such a data warehouse can be difficult. In order to retrieve all or nearly all of one type of lab result with a high degree of precision, we perform clinical concept adjudication, which is the process of an expert determining which database records correspond to a target clinical concept. In this work, we develop an interactive machine learning tool to "extend the reach" of expert laboratory test adjudicators. Our tool provides access to automatic laboratory classification in a user-facing front end that covers all steps in an adjudication workflow, in order to lower barriers to collaboration, increase transparency of adjudication, and to promote efficiencies and data reuse.

Clinical Laboratory Information Systems; Systems Integration; Supervised Machine Learning

Introduction

Clinical laboratory data are crucial to medical research, including retrospective studies and clinical trials. Laboratory data collected in the electronic health record (EHR) during the care process can be used in research (termed "secondary use") [1]. For example, serum creatinine lab test results, collected during routine clinical care, serve as safety endpoints for a "point of care" trial comparing the efficacy of antihypertensives [2]. Research requires all serum creatinine results to be retrieved using a unique database identifier, but reality is not this simple.

The United States Department of Veterans Affairs (VA) maintains a data warehouse covering 20 million individuals and 6.6 billion lab tests (as of 2014) [3], but as others have noted "data aggregation across the VHA is highly problematic" [4]. As one example, if we search for "creatinine" in the warehouse's LabChemTest dimension table, we find >1000 matching lab test types, many of which are not truly serum creatinine. If the query requires "creatinine" followed by "serum," it retrieves a shorter (64 lab types) and much more specific list, but many true positives are missed. Therefore, in order to retrieve all or nearly all the serum creatinine results with a high degree of precision, we perform *clinical concept adjudication*, which is the process of an expert determining which database records correspond to a target clinical concept.

The clinical concept adjudication process currently used in our research center has been previously described [5] and is designed to harmonize lab test results from 144 independent VA clinical laboratories (Figure 1). In brief: (1) Clinical subject matter experts (SMEs) design a search for appropriate laboratory test names. For example, if hemoglobin is the target concept, search terms might include "HGB" or "Hemoglobin", and several Logical Observation Identifiers Names and Codes (LOINCs). (2) Database technicians retrive candidate database records. For each record, the technicians also pull associated metadata, including specimen types (e.g. whole blood, urine, cerebrospinal fluid), units, distribution of numeric results, and laboratory test names. Many SMEs do not have technical expertise to perform a database pull, or they do not have permission to execute such a pull. Database technicians deliver these results to SMEs using an Excel spreadsheet that can be sorted and filtered (Table 1). (3) Two SMEs label each record, evaluating for appropriate specimen types, units, distribution, and test names. (4) SMEs resolve disagreements, producing a consensus labelling. (5) Database IDs and consensus labels of

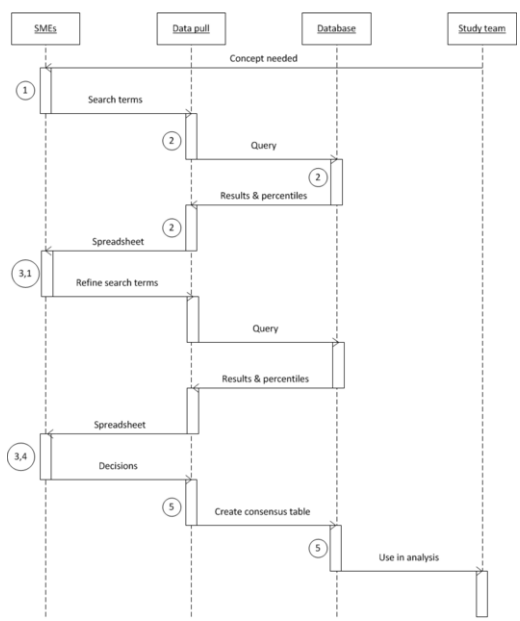

Figure 1– Sequence diagram. The workflow between subject matter experts, data technicians, the database, and the study team is illustrated.

Table 1– Example data used in adjudication. The task is to label each row, identified by the ID column, with a label, shown in the SME Label column, based on data in the remaining columns. The Lab Test Name, Topography, and LOINC columns identify the name and specimen type of the lab test. The Count column shows the number of lab test results associated with the ID, and p1, p50, and p99 (as well as others not shown) describe the first, 50th, and 99th percentiles of values of these results.

ID	SME Label	Lab Test Name	Topography	LOINC	Count	p1	p50	p99
1	Yes	SODIUM	SERUM	Missing	115053	126	140	149
2	No	RANDOM URINE SODIUM	URINE	Missing	734	6	52	194.1
3	No	SODIUM	URINE	Missing	89	5	49.5	155.9
8	Yes	SODIUM	SERUM	2947-0	126	133.2	140	144.7
9	No	SODIUM	URINE,24HR	2947-0	98	13.8	150	877.7
92	No	SODIUM	PERITONEAL	2950-4	10	124	132	138.8
461	Yes	SODIUM*IA	BLOOD	2950-4	714	125	139	170.9

"yes" or "no" for each record are stored in a new database table, and the spreadsheet is stored for future reference. Note that steps (1)-(3) are often iterated if the search terms need refinement.

Several drawbacks to this process exist. First, several steps in this process are time-consuming. Step (2) can take hours to run, because it may require computing on millions of values for each database ID. Step (3) requires SMEs ultimately to address each row (often about 1000) of a spreadsheet. The current process requires manual transmission of information and requires the SME and database technician to wait on each other. Second, the adjudicated concept can go out-of-date as new database records are added. Third, it is difficult for the final consumer (i.e. the study team performing analyses) to understand, validate, or adapt the new database table that contains the final adjudicated concept. This is partly because of the manual transmission of work products, which can result in the initial search terms (or other work products) being lost, or at least not available to final consumers.

Therefore, we sought to develop a machine learning tool to "extend the reach" of expert laboratory test adjudicators, so that they do not need to classify each data element manually. We aimed to provide access to automatic laboratory classification in a SME-facing front end for continued use by adjudicators. We intend our tool to cover all steps in the workflow (including the initial search for laboratory test names, the consensus process, and the database storage of SME decisions), in order to lower the barrier to collaboration among the group, to increase transparency of the adjudication process, and to promote efficiencies and reuse of adjudicated laboratory tests across the entire VA.

Prior work. Previous authors have faced similar lab result harmonization problems. For instance, the LOINC standard has been developed to identify clinical laboratory test results [6], and previous authors have described mapping their local data to this standard [7], but mappings of local laboratory tests to LOINC may be erroneous [8]. In another example, the Mini-Sentinel program received laboratory results from twelve data partners and encountered inconsistent units and LOINC availability, among other challenges, many of which were addressed by manual quality checking [9]. As an example from VA data, we found LOINC wrongly coded as body fluid sodium (2950-4) when it should be coded as serum/plasma (Table 1). This means that LOINC alone cannot be used to accurately retrieve all test types for a single clinical concept.

Early work has shown that lexical comparison of test names followed by subject matter expert review can integrate a more detailed set of laboratory test codes (LOINC) with a less detailed one (SNOMED procedures) [10]. To facilitate the mapping of local lab terms to LOINC, The Regenstrief LOINC Mapping Assistant (RELMA) was developed [11,12]. As a practical example of lab test harmonization, a large group of 44 European hospitals developed an internal dictionary of laboratory observations and mapped it to LOINC, but they found that some tests were not referenced in LOINC [13]. More advanced work has been been done to share results for LOINC mapping, to take advantage of "crowdsourcing" [14,15], and to perform automated mapping to LOINC using machine learning, which assigned about 70-80% of local terms to the correct LOINC [16]. Finally, work has been performed to address laboratory unit conversions [17] and standardizing laboratory test *results* across multiple institutions, as distinct from standardizing simply the type of test [18].

In our data warehouse, lab tests are already mapped to LOINC, but imperfectly. We also often need to aggregate several granular LOINCs into one more general concept. Our current lab adjudication process accomplishes this, but with many roles and manual steps (Figure 1).

Methods

We developed a machine learning system to predict whether a candidate lab test type clinically belongs within the concept of interest, based on a set of lab tests already labelled by SMEs as belonging or not. Seven lab tests were studied: alkaline phosphatase (ALP), alanine transaminase (ALT), albumin (ALB), high-density lipoprotein cholesterol (HDLC), sodium (Na), magnesium (Mg), and hemoglobin (HGB). We chose the following initial features for use by these algorithms. We used a bag-of-words encoding for longer textual fields like the test name, topography, component, and specimen. We used a categorical encoding for short textual fields, including the VA hospital site identifier, the lab result units, and the LOINC. We used as-is the numerical fields describing the number of results and their distribution. We included as a feature a Kolmogorov-Smirnov statistic that compares, for one lab test type, the distribution of its results to the distribution of all positive training examples' results [19].

Table 2– Machine learning results (accuracy) for each of 7 lab tests, using 3 different learning methods: LASSO (LR), support vector machines (SVM), and random forests (RF). Also shown are the total number of database IDs, the number of IDs labelled positive in the "ground truth" SME labelling, and the number of associated observations (lab test results).

Data Set	Number of Database IDs	Number of Positive Database IDs	Number of Observations	LR	SVM	RF
ALP	1588	747	38,297,131	0.98	0.97	0.98
ALT	716	341	84,180,150	0.98	0.94	0.92
ALB	3351	601	114,613,056	0.97	0.92	0.98
HDLC	742	358	79,767,824	0.98	0.91	0.98
Na	322	153	7,821,081	0.97	0.98	0.99
Mg	2066	502	17,768,685	0.97	0.95	0.99
HGB	1737	830	135,382,741	0.97	0.95	0.99

We evaluated this basic system using seven datasets that had been already adjudicated by VA experts (Table 2), and using three algorithms: logistic regression with an L1 penalty (also known as the least absolute shrinkage and selection operator, or LASSO), support vector machines (SVM), and random forests. Initial development and testing of learning algorithms was performed in Python using the scikit-learn package [20]. We used 10-fold cross validation to evaluate the accuracy of the system using each algorithm.

After the basic learning system was developed and validated, an interactive adjudication interface was implemented as a web application, as described in detail below. This system is available to VA SMEs in a hosted environment, as well as to the public at https://github.com/nfillmore/active-adjudication.

Results

Machine learning

Ten-fold cross-validation accuracy was high for all seven laboratory tests, and for all three methods (Table 2). For 6 out of 7 laboratory tests, random forests achieved the top cross validation accuracy, and LASSO achieved second place or better. Random forests achieved the fastest convergence per training example, and LASSO consistently achieved >90% cross validation accuracy at 100 or fewer training examples (Figure 2).

Operationalizing as web application

After the basic learning system was developed, an interface was designed as a web application, with a front-end written in JavaScript (Figure 3). We implemented the back-end (including LASSO) entirely in Java, which we found removes the need for any research group to install their own machine learning pipeline. The application covers the the laboratory adjudication workflow from initial assignment of the lab concept to a SME and generating search terms, to saving the final consensus adjudication for study use. The web application is hosted in a secure environment where VA SMEs can access it, and its source code is available for use by the public at https://github.com/nfillmore/active-adjudication.

Support for search term generation

Recall that in the current process for lab adjudication, data pull personnel must wait on SMEs to generate search terms, and SMEs then wait to receive an Excel spreadsheet. In order to avoid this inefficiency, we integrated the initial search into our interactive tool. The SME specifies search terms and can see results immediately. We accelerate this process with pre-computed value percentiles for all lab test identifiers in the VA system (this took over a month of wall clock time). After refining the search terms, the SME can begin labelling examples, although the query can be modified later without losing any labels already input.

Support for adjudication

The labeling interface allows SMEs to view both the original table of data elements and the feature matrix for the learning algorithm. These tables can be viewed separately or side-by-side, with support for sorting by any column. As the SME labels examples, statistics are recomputed in real time. The default feature matrix is as described above for the basic system, but SMEs may add or remove any features (a process termed *feature engineering*), including features corresponding to a

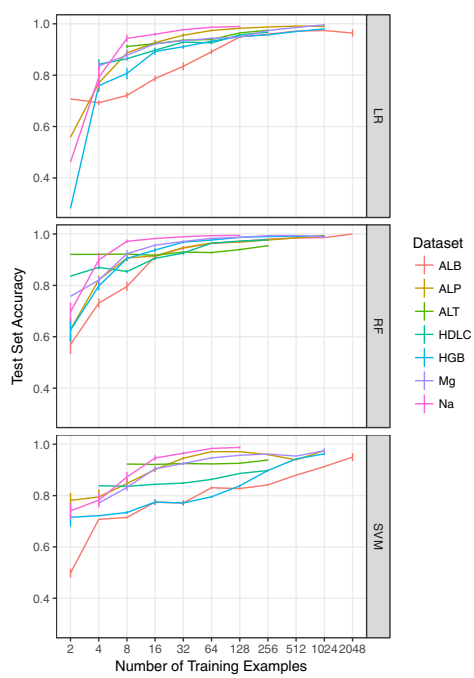

Figure 2– Learning curves for LASSO (LR), random forests (RF) and support vector machines (SVM)

single word or phrase. For example, if the SME needs to retrieve measurements of serum immunoglobulin free light chains, the phrase "free light" is more specific than either "free" or "light" by itself, and thus the SME may want to add this two-word feature, which is not available to the learning system by default.

Support for consensus labelling

The current adjudication process requires SMEs to resolve labelling conflicts. Our application facilitates this by displaying any conflicts and prompting for a consensus label. As in the main labelling interface, the application uses machine learning to predict the consensus label.

Support for finalizing and sharing results

Because lab adjudication does not involve any protected health information, adjudicated labels can be freely shared among different researchers, but there is currently no simple mechanism to do this within VA's nationwide network of researchers. Therefore, our tool offers such a mechanism. Each adjudication can be published to a searchable list of "Completed Adjudications", tagged with the target lab, the group that carried out the adjudication, the date of completion, and other information. These adjudications can be viewed and exported for use in individual research projects. In some cases, an adjudication might be close to what a research group is looking for, but not an exact match for their target concept. Thus, the tool also allows published adjudications to be "forked", i.e., copied into a new adjudication instance, where labels and search criteria can be modified as needed, exactly as if the adjudication had been created from scratch by the new researcher. The lineage of forking is tracked and displayed to users, to promote appropriate credit as well as transparency. To promote division of labor, even incomplete adjudications are viewable and forkable by other researchers, but these are clearly marked as incomplete.

Discussion

We have developed a tool that uses interactive machine learning to assist lab adjudication experts. Among the three learning methods tested, LASSO performed nearly as well as the others, with the advantage that it is easier to interpret the model's predictions. We found no large differences in classifier performance among the seven lab tests for which we simulated annotation. Because of the rapid convergence of the learning methods, only about 100 lab data elements need to be adjudicated, and the rest (about 1000, depending on the lab test) can be inferred with high accuracy, which is theoretically a 10-fold improvement in adjudication time. In practice, the expert could label all data elements with > 1000 observations and allow the system to predict the rest.

SMEs within the VA now have access to machine learning assistance for laboratory data integration, without the need to implement a learning pipeline. In addition, we have precomputed and stored percentiles of numerical laboratory values, so these are available rapidly to SMEs. Our web application covers all steps of the laboratory adjudication workflow (Figure 1, Figure 3), including capturing the initial query, and writing to the database for future use.

Our system can also be used by SMEs outside the VA, after creation of an appropriate backing database of precomputed metadata and percentiles of laboratory values. Creating such a database is straightforward and instructions are available with the software.

Figure 3– Screenshots of our tool: (A) Adjudication task creation. (B) Interactive annotation and machine learning for adjudication. (C) Sharing adjudicated results. Details on these steps are in the text.

We envision several feasible improvements to our system. First, a quantitative study of SME time saved could be undertaken. To facilitate this, we have already incorporated time-stamp logging of user actions into the software. Second, we could adapt the system to monitor the database for updates and ask for new labels as appropriate to keep concepts up-to-date. Third, we could use an approximation scheme for streaming computation of percentiles, so that the precomputed numerical distributions do not go out of date as new observations are collected [21].

In comparison to RELMA, we incorporate collaboration among multiple roles (e.g. SME, database technician), and we incorporate the aggregation of multiple potential LOINC code points. Machine learning has been applied to lab data cleaning [16], but to our knowledge *interactive* machine learning has not. Our web application covers all parts of the clinical laboratory test adjudication workflow, greatly decreasing the work required of SMEs, and it introduces further advantages by capturing work products that otherwise could be lost, increasing transparency, and encouraging sharing.

Conclusions

In this work, we developed an interactive machine learning tool for laboratory test adjudicaton. Our tool provides access to automatic laboratory classification in a SME-facing front end for continued use by adjudicators. The tool covers all steps in an adjudication workflow, and in doing so, lowers barriers to collaboration, increases transparency of adjudication, and promotes efficiencies and data reuse.

A Concept for Graph-Based Temporal Similarity of Patient Data

Matthias Ganzinger, Jens Schrodt, Petra Knaup

Institute of Medical Biometry and Informatics, Heidelberg University, Heidelberg, Germany

Abstract

Computer-based decision support systems are often used for dedicated tasks such as the detection of sepsis. However, positive predictive values for sepsis detection are reported to achieve only around 46%. In this paper we describe a novel approach to use temporal data of electronic patient records based on similarity measures. We apply the concept of case-based reasoning, which is well-established in many fields of medical informatics. Temporal patient data are organized in a time-graph structure. For the quantification of similarity between cases, we exploit graph theory based approaches. For development and evaluation of our time-graph similarity frame we use the open MIMIC III dataset. In a later phase, we envision to transfer our concept from sepsis to other diseases.

Keywords:

Medical Informatics, Computer-Assisted Decision Making.

Introduction

Computer-based clinical decision support systems (CDS) are important elements for improving the quality of patient care. A relevant clinical example is the early detection and management of sepsis. Sepsis is a systemic reaction of the human body against inflammatory infections with approximately 154,000 diagnosed cases in Germany per year leading to as many as 56,000 deaths per year [1]. Early detection and start of treatment are crucial factors for improving survival and complete recovery [2].

CDS have been a field of research in medical informatics for several decades. In recent years, the field was complemented by data science approaches analyzing vast amounts of patient-related and disease-related data in order to build computer models of diseases. Terms commonly used for such concepts are systems medicine, personalized medicine, or precision medicine. One of the ideas that are currently under discussion in systems medicine is to identify similar patients or cohorts within comprehensive patient-related databases such as electronic health record (EHR) systems [3]. However, the concept of providing clinical decision support on the basis of treatment experiences made with past patient cohorts has been established in medical informatics as case-based reasoning (CBR) already in the 1980s based on previous works in cognitive sciences [4, 5].

Currently, temporal data are rarely used in similarity-based decision support systems. To change this, it would be necessary to bring existing temporal data into a form that supports reasoning on these data. For CBR, the case of a patient would have to be described considering all relevant temporal events. Such a temporal profile or network of different event values over time could be used to find a similar patient in the case base, whose case shows a similar sequence of temporal events in addition to the similarity of attribute values. This could lead to improved clinical conclusions for diagnosis and therapy or medication. For our example of sepsis, this would mean to compare the course of disease of current patients with those who had developed a sepsis in the past in order to detect sepsis in an early stage to save time until treatment is started.

Since there are no established approaches for temporal similarity in CBR, we describe a possible model for the development of such a similarity measure in the course of this manuscript. This includes potential forms of representing temporal data for similarity and reference data sets for the development process.

Patient Similarity and CBR

Technically, historic treatment information is represented as a patient case. Each case is described by a set of attributes, often represented as structured fields in the database of an EHR system. To quantify similarity of two individual cases, a so-called local similarity measure is defined to compare the values of a certain attribute for the two cases. Global similarity between two cases is gained by computing and weighting the importance of attributes and merging local similarity measures into a single value. Great care has to be taken to choose an appropriate similarity measure that takes into account the characteristics of the respective attributes. For example, the similarity of the body weights of two patients might be calculated as the Euclidian distance between the values. For attributes with discrete value domains, such as ABO blood groups, the context for which similarity is being calculated has to be considered. For example, when looking at the risk of developing coronary heart disease (CHD), blood group values of A, B, and AB might be considered more similar to each other than compared to O. The reason is that bearers of blood group O seem to have a significantly lower risk to develop CHD than bearers of the other groups [6]. For other diseases, a different assumption of similarity might be more conclusive. In these cases, value distributions or expert knowledge can be used to establish a numeric similarity value.

Due to the development of big data analysis initiatives, more and more patient related data sources are expected to become available in a structured way for research on clinical decision support systems. Using these sources for finding similar patients is only possible if suitable similarity measures exist and are correctly chosen for the respective attributes.

Our group has conducted research on similarity measures in a systems medicine research project on multiple myeloma. For this project we developed an IT architecture for systems medicine applications that rely on the concept of patient similarity. As one result we established a novel similarity measure that considers survival data (e.g., progression free survival, or overall survival) as they are measured in clinical trials for the computation of similarity. However, in the course of our research we found additional aspects of patient similarity that have not been taken into consideration sufficiently so far

due to the lack of appropriate similarity measures. Specifically, these additional aspects are temporal relations among symptoms and events like diagnostic and therapeutic measures. In the everyday life of a physician it is often essential to know the sequence of such events to get an appropriate diagnosis [7].

Decision Support for Sepsis Diagnosis

Supporting early diagnosis and management of sepsis has been subject to previous studies. Corfield et al. describe a single, not computer-based, score as an early warning sign for sepsis [8]. In terms of computer-based CDS, one approach is to generate sepsis alerts if a number of criteria is met by entries in the electronic medical record of a patient [9]. While this system had no false negative results, its positive predictive value was only 44.7%. Amland et al. report on a similar system with a likewise positive predictive value of 46% [10]. Such results suggest the necessity for further research to improve accuracy of computer-based CDS for sepsis. Considering temporal aspects might help to fill this gap [11].

Temporal Abstraction

Temporal abstractions are qualitative representations of temporal intervals with respect to a specific context [12]. Such abstractions are used to derive higher level concepts from raw, quantitative data. For example, individual measurements of body temperature could be aggregated to intervals and labelled with qualitative descriptors like “normal temperature” or “hyperthermia”. A widely used set of temporal abstractions has been defined by Allen [13, 14]. He describes a system of thirteen basic relations such as “before”, “overlaps”, or “during”, covering all relations that are possible between two temporal intervals. Temporal abstractions can be used to reduce complexity when working with temporal dependencies.

Temporal Data Structures

Temporal relations among health related events could be an important source of information for diagnosis and prognosis of patients. Thus, such relationships in patient data are in focus of many research activities such as temporal mining. A basic question for the development of a temporal similarity measure is how data should be organized and stored for efficient processing. Traditionally, medical events are recorded in the form of tables either as paper charts or electronic database tables. To support temporal information, the 2001 edition of the SQL standard query language for relational databases supports temporal tables. However, this extension does not focus on working with temporal relations among entities, but provides means to model the time when entries are valid in the real-world context. This is similar to conserving the state of a database into a snapshot which makes it possible to reproduce the data for time points in the past. So the word ‘temporal’ has a different meaning in the SQL standard. As a consequence, temporal relations have to be implemented outside the database management system into an application with the potential requirement to transfer large amounts of data. The goal of such an application should not be to save different states of database tables over time but to save and compare temporal data like patient events in a timeline.

Time-Graphs

An intuitive representation of temporal relationships among medical data might be graphs or networks. Medical events could be presented as nodes while edges show the temporal relations among them. Interestingly, the term *temporal network* is widely used in computer science, but usually not in the sense that the network shows temporal sequences. Instead, the term describes the research on the development of networks over the time. In research on social networks, for example, it is investigated how the contacts of a person change by comparing the respective network at different points in time [15].

To avoid confusion with such temporal developments of graphs, the term *time-graph* is used for sequential graphs throughout this proposal.

A graph-based representation of temporal EHR data has been shown to work by Liu et al. in a paper on temporal phenotyping [16]. They introduce temporal phenotypes as a set of basis graphs that are combined to construct an observed temporal graph. The authors describe the application of similarity-based regularization for calculating the temporal phenotypes. However, the aim of their work is not to identify similar patients in the sense of CBR but to predict medical events such as the onset risk of heart failure.

Thus, additional research is necessary to establish time-graphs for the use of finding patients with similar temporal disease development. This could be achieved by calculating the similarity of time-graphs each representing one patient.

Graph Similarity

Graphs have been studied for a long time in graph theory. One problem related to comparing two graphs is the task of determining their structural identity or the existence of an isomorphism between them. In addition, quantifying the similarity of graphs and subgraphs has been of interest in many application areas like analyzing the world wide web, business process models (BPM), timetables, schema matching, or chemical structures [17–21]. Comparable results have not yet been researched for time-graphs. No specific time-graph similarity approach is known to the authors. Nevertheless, there are some approaches that are related to graph similarity, but it has not been investigated yet, if they can be applied for medical time-graphs.

One generic approach that has been demonstrated to work with BPM, for example, is the *graph edit distance*. It is capable of measuring similarity between two graphs by assessing the number of modifications necessary to transform one graph into the other [22]. A different method for quantifying similarity among two graphs is using an iterative framework based on the idea that two nodes or edges are similar if their neighbors are similar. Since similarity is propagated to adjacent elements during iterations, this method is also called similarity flooding [20]. Another method is *NetSimile*, which calculates different node-specific values, like the number of neighbors, the clustering coefficient of a node, and others. These attributes are finally aggregated into one value that describes the similarity of two graphs using the Canberra Distance [23]. These graph similarity approaches are candidates for being transferred to time-graphs.

Graph-Based Temporal Similarity

Taking up the concept of case-based reasoning, we develop a computer-based CDS for early detection of sepsis aiming for high accuracy. Specifically, we will develop a novel measure for calculating temporal similarities of disease progress among patients. This measure relies on graph-theory concepts. Later, we plan to extend our approach to other disease patterns.

Methods

The main research question of our project is as follows: How could temporal medical data of different patients be used to identify patients with a similar temporal profile for clinical decision support systems?

This question is divided into three sub-questions:

1. How can medical data be represented as a time-graph?

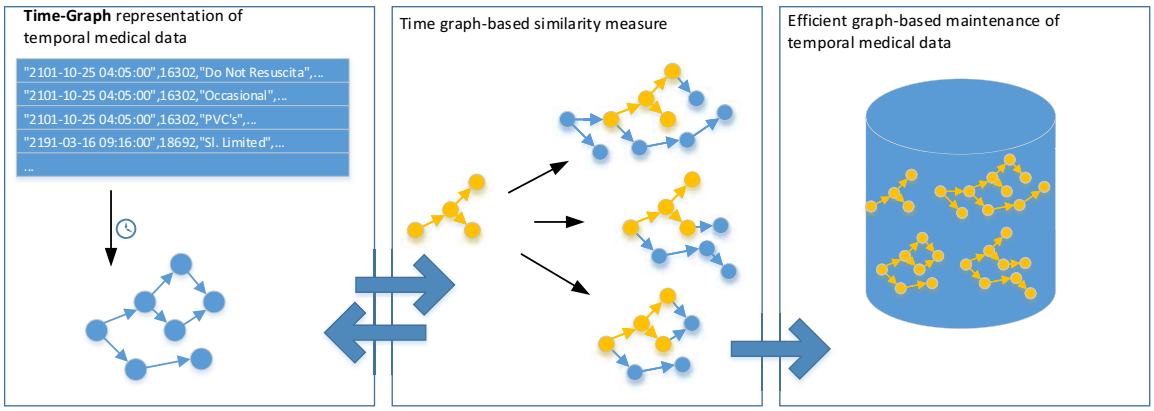

Figure 1 – Main Parts of the Time-Graph Similarity Framework.

2. What similarity measure can be used on time-graphs?
3. How can time-graphs be stored efficiently?

To answer these questions, our objective is to develop a new approach of making temporal aspects of medical data available in decision support systems, especially with respect to similarity-based approaches like case-based reasoning. We aim to establish graphs of clinical events as an innovative representation of temporal relations among these events. Here, we will consider concepts like networks, directed/undirected graphs, weights of edges, trees, and the significance of cyclic, i.e. reoccurring parts. The challenge is to find a graph-based representation of temporal medical data that provides an optimized basis for similarity quantification. To support case-based reasoning, a novel graph-based similarity measure for time-graphs in the form of a framework of methods is part of this approach. For this framework we investigate graph-theoretical approaches for the assessment of graph similarity. A set of criteria to classify these methods for applicability in the medical CBR context is established. As part of this development, graph similarity methods are tested in various disease-specific scenarios.

Finding the most similar patient with respect to his time-graph in a big case base can be very time-consuming, making efficient management of graph-based data structures essential. Thus, we investigate which kind of database management systems could form an appropriate basis for storing time-graphs. Specifically, we compare relational data base systems with temporal index structures with dedicated graph-based database systems. The exact requirements towards such database systems depend on the characteristics of the graph-based similarity measure.

Results

Our concept is comprised of three major blocks, corresponding to our research questions. First, research on the graph-based representation of temporal medical data is performed. Second, a novel similarity measure for temporal data in a graph representation is developed. In a third block, existing database technologies for efficient storage and similarity retrieval of graph-based temporal data are reviewed.

In addition, a user interface for temporal queries on the database is part of the concept. For research and testing of our approach, we use the MIMIC III database [24]. This dataset provides data of approximately 40,000 patients who were treated in an intensive care unit (ICU). All data are annotated with timestamps making them ideal for temporal research in clinical context.

Time-Graph Representation of Temporal Medical Data

As the first step, the MIMIC III database is analyzed with data mining tools for cases that can be used as blue prints for the development of a time-graph representation of the case documentation. In this phase, we consider cases suitable, if the temporal relation between events is known *a priori*. Medical treatment guidelines are helpful to identify such cases. For example, the guidelines for diagnosis and treatment of sepsis list a number of conditions that have to be met within a certain timespan. Thus, we will mine the database for patients who are diagnosed for sepsis and other diseases commonly occurring in an ICU context with temporal aspects. This will result in a set of reference cases with typical temporal disease progress is identified in the MIMIC III dataset.

Further, an appropriate graph-based representation for patient cases is established. Existing approaches will be reviewed: The most straight-forward approach is to form a timeline where all data entries are lined up in order of the respective timestamps. In this approach, each node has one edge pointing to the subsequent node. A timeline already allows to compare the temporal developments of different cases. However, in this naïve approach no difference is made between different classes of events. As a consequence, we will investigate more complex representations that also consider different classes of nodes. Nodes within each class have a linear temporal order, but are interwoven with nodes of other classes. In contrast to a timeline, such additional edges might help to better represent event-specific temporal relations. For example, known cause-effect relations such as the administration of antipyretics and the consecutive decrease of body temperature are modelled into the graphs.

Further research is made regarding the most suitable topology of the resulting graph. Possible topologies include directed graphs with or without cycles, weighted graphs, and trees.

Time-Graph-Based Similarity Measure

We investigate methods described in the literature for calculating the similarity between two graphs for their applicability on time-graphs. Aspects to be considered are the topology of the graphs and the possibility to work with sub-graphs. This is important, since the time-graph of medical events of a newly diagnosed patient is likely not as extensive as that of a patient who has finished treatment. We investigate similarity methods of different categories such as graph

isomorphism (e.g., edit distance based measures [22]), iterative methods like similarity flooding [20], and feature extraction methods like NetSimile [23].

The base methods for graph-based similarity are adapted to fulfil requirements of temporal graphs. For this development process, cases of the MIMIC III database are used as models and test cases. Criteria for the successful development of the similarity measure are defined during this task. They are based on plausibility checks and correlation analysis of the cases determined as similar by the new similarity measure. The graph-based temporal similarity measure developed in this work packages can be used by itself, but also in combination with conventional similarity measures based on attribute values. In this task, we investigate, how such different types of similarity measures can be combined to calculate a comprehensive similarity value. The approach will be based on the paradigm that global similarity is comprised as a combination of weighted local values. In this task, a suitable algorithm for combining the different similarity measures into one global value will be researched.

Efficient Graph-Based Maintenance of Temporal Medical Data

Electronic health record data are usually stored in relational databases with no specific focus on temporal data retrieval. Graph databases are potentially good candidates for high efficiency, especially in combination with a time-graph data model. In addition, in this kind of databases not only the raw data is saved like it is the case in traditional relational databases but also the connections between the different entities of the raw data are saved. This aspect makes graph databases potentially more efficient than relational databases but it still has to be investigated if this is still true for temporal data like it is used in our case.

We investigate if relational databases such as PostgreSQL can be used as an efficient storage for time-graphs. Specifically, we assess if existing SQL standard extensions support our graph-oriented similarity measure. We also evaluate proprietary temporal extensions that exist for some open-source database management systems. Further we investigate if dedicated index tables can support queries for similarity retrieval. The idea for such index tables is to pre-calculate temporal relations (respecting temporal abstractions) within cases to allow for fast retrieval without the need of calculating temporal relations at query time.

In contrast to relational databases, graph databases are designed to store graph data structures. In this task, we will investigate open source graph databases such as neo4j for their applicability in our context. Special focus lays on the efficient retrieval of similar cases. We will compare the respective query possibilities for retrieving cases based on subgraphs. One criterion for the assessment of the database management systems is the availability of features for efficient similarity retrieval. Further, the query times are compared for the different approaches.

For using the database system selected in tasks 3.1 and 3.2, data have to be prepared first. To do this, we will follow the extract, transform, and load (ETL) approach that is well-established for example in the context of data warehouses. Thus, we will develop ETL processes to make a subset of MIMIC III data available in our temporal database. Depending on the specific database management system, we will use open-source ETL software such as Talend Open Studio or KNIME to automate this process.

Discussion

In this manuscript, we present a comprehensive approach for the establishment of a graph-based similarity measure temporal patient data. The first step will be the development of a time-graph representation for temporal medical data as basis for the remaining parts. Further, efficient storage approaches and graph-based temporal mining are investigated.

In this phase, the development will be performed on the well-established open data set MIMIC III for patients suffering from sepsis. Being ICU derived data, this data set has a rather fine-grained temporal resolution compared to other fields of EHR data. After establishing this primary application, we are going to extend our research to other ICU related disease patterns as well as to other clinical areas, where documentation frequency and data types differ from ICU data. In addition, we are going to validate our findings with other clinical data sets.

Abstract

Severe maternal morbidity (SMM) is broadly defined as significant complications in pregnancy that have an adverse effect on women's health. Identifying women who experience SMM and reviewing their obstetric care can assist healthcare organizations in recognizing risk factors and best practices for management. Various definitions of SMM have been posited, but there is no consensus. Existing definitions are further limited in that they 1) are often rooted in existing clinical knowledge (which is problematic as many risk factors remain unknown), leading to poor positive predictive performance (PPV), and 2) have limited scalability as they often require substantial chart review. Thus, in this paper, a machine learning framework was introduced to automatically identify SMM and relevant risk factors from electronic health records (EHRs). We evaluated this framework with EHR data from 45,858 deliveries at a large academic medical center. The framework outperformed a state-of-the-art model from the U.S. Centers for Disease Control and Prevention (AUC of 0.94 vs. 0.80). Specially, it improved upon PPV by 59% (CDC: 0.22 vs. our model: 0.35). In the process, we revealed several novel SMM indicators, including disorders of fluid or electrolytes, systemic inflammatory response syndrome, and acidosis.

Keywords:

Electronic health records, machine learning, severe maternal morbidity.

Introduction

Severe maternal morbidity (SMM) is a physical condition that results from, or is aggravated by, pregnancy and has an adverse effect on a woman's health. [1] SMM is an umbrella for various phenomena, including but not limited to, cardiomyopathy, hemorrhage, organ failure, pregnancy-induced hypertension and embolism, pulmonary embolism sepsis, seizure shock, severe amniotic fluid embolism, and uterine rupture. SMM can be considered a near miss for maternal mortality because, without in-time identification and treatment, these conditions can lead to maternal death [2; 3]. Thus, SMM is utilized as a new indicator of the quality of maternal health. [4] Its prevalence has steadily increased in low- and middle-income countries, as well as the developed world. [4-6] It now affects around 60,000 women in the U.S each year. [6] At the same time, the U.S. Department of Health Resource and Services Administration has increasingly focused on reducing the rate of SMM and improving its survival rate [7].

Identifying women who experience SMM and reviewing their obstetric charts can enable clinicians and healthcare organizations, more generally, to better understand the primary etiologies and contributing factors of SMM. In doing so, this can lead to a refinement of care management practices to prevent SMM or improve the quality of its management. However, there are major challenges in identifying SMM, which partially arise due to the lack of a consensus definition. For instance, the Centers for Disease Control and Prevention (CDC) has provided a definition based on 25 SMM indicators in the form of diagnosis and procedure codes [1]. The CDC definition is straightforward to specify and, thus, easy to implement in that International Classification of Disease (ICD) codes are readily available in hospital discharge data. However, it does not indicate the severity of maternal morbidity and, as a result, its application leads to many false positives and negatives. [8]

Another popular definition of SMM has been proposed by experts from the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM). This definition is a guideline that allows for each birthing facility to determine their own SMM criteria [8; 9]. The guidelines are based on two primary factors: i) admission to an intensive care unit (ICU) or ii) transfusion of four or more units of blood. [7] These may be supplemented by other factors, such as intubation for at least 12 hours, organ system failure, and unanticipated surgical intervention [8]. Although SMM identification approaches built upon the guidelines can achieve high levels of performance [8], they have several deficiencies. First, the approach designed for one facility cannot be directly applied by another facility. This is because the risk factors used are often facility-specific and are unique unto a facility. [6] Second, the process of SMM identification requires substantial manual effort in the form of in-depth chart reviews, which incurs a nontrivial amount of time and effort.

Recent studies have shown that machine learning algorithms along with data in electronic health records (EHR) can be leveraged to identify or predict a variety of diseases [10-11]. For example, supervised machine learning algorithms were applied to identify different types of cancers and their progression pathways [11]. Another example [10] is the application of deep learning algorithms to predict Alzheimer's disease in its early stage. To identify SMM during delivery hospitalizations, we introduce a machine learning framework that incorporates data in EHRs. This framework has several notable benefits in that 1) it leverages standardized clinical terminologies as inputs, and thus models developed under the framework can be applied in EHRs of other facilities; 2) it can deal with over a thousand clinical concepts with reduced manual effort; and 3) it allows for the discovery of novel factors to identify SMM.

Methods

We begin this section with a description of the data workflow as shown in Figure 1. First, before feeding data into the classification model, we annotate EHRs as SMM cases and controls. The classification model is then evaluated in terms of area under the receiver operating characteristic (ROC) curve (AUC). Lastly, risk factors are ranked according to odds ratios and their contributions to the performance of the classification models.

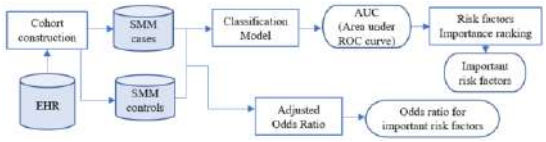

Figure 1– Data workflow

Dataset

We collected 13 years of data (2005 to 2018) from the Vanderbilt University Medical Center (VUMC) EHR system, which includes 45,858 deliveries for obstetric inpatients. This dataset includes patient demographics (e.g., age and race), admission notes, discharge summaries, and clinical concepts in the form of diagnoses (ICDs) and procedures (CPTs). A summary of the medical concepts and demographics are provided in Tables 1 and Table 2, respectively. We note that the diagnosis and procedure codes were transformed into standard terminologies defined under the Observational Medical Outcomes Partnership (OMOP) common data model, operated by the Observational Health Data Sciences and Informatics (OHDSI) consortia [12]. All these codes in this study are called medical concepts.

In Table 1, it can be seen that deliveries with SMM have more assigned diagnoses and procedures than those without SMM. This implies that deliveries with SMM are more complicated. There was a total 3,972 unique diagnosis concepts and 1,581 unique procedural concepts. In Table 2, it can be seen that there was a greater percentage of black women experiencing SMM (24%) than those without (18.5%).

Cohort construction

Table 1– Summary statistics of diagnosis and procedural concepts assigned to patients

Class	Statistiscs	# of Diagnoses Assigned	# of Procedures Assigned
SMM	Mean	31.3	22.7
	Median	27	20.5
	IQR	22	16
Non-SMM	Mean	9.7	8.1
	Median	8	8
	IQR	6	5

IQR: inter-quartile range

We use the criteria *four or more units of blood transfusion or ICU admission* developed by the ACOG to identify SMM candidates [8]. Using this criterion, 594 SMM candidates were identified. Obstetricians then reviewed the charts for these candidates and excluded 182 candidates who did not experience SMM. Our final cohort contained 412 SMM cases (0.9% of all deliveries). We assume that all of the remaining deliveries were controls. We acknowledge that the controls may contain a small number of SMM cases that cannot be captured by the ACOG criteria. A recent study [8] shows the number of missed cases is likely too small to impact the performance of identification models.

SMM identification models

Feature engineering

For each instance, we extract their assigned diagnoses and procedures represented by medical concepts using the OMOP common data model. Each medical concept is treated as a binary feature, where 1 indicates a patient was assigned the concept during the delivery and 0 otherwise.

Since the number of diagnoses (3,972) and procedures (1,581) is substantially larger than the number of positive instances, which may influence the performances of machine learning models. As such, we aim to do feature selection before applying machine learning models. To orient the system to be more generalizable, we adopt a filter feature selection algorithm without using class information (i.e., SMM vs. Non-SMM) and machine learning models. The feature selection algorithm ranks the concepts according to their frequency occurring in the investigated patient population. We incrementally add top ranking features into the machine learning models. Specifically, we train models using the top 10%, 20%, 40%, 80% and 100% of the features

Table 2– Summary statistics of patient demographics

Class	Age (years)		Race (%)	
SMM	Mean	28.1	White	259 (62.9%)
	Median	28	Black	99 (24.0%)
	Q1	23	Asian	13 (3.1%)
	Q3	33	Other	41 (10.0%)
No evidance of SMM	Mean	28.1	White	30,626 (67.4%)
	Median	28	Black	8,396 (18.5%)
	Q1	24	Asian	2,316 (5.1%)
	Q3	32	Other	4,108 (9.0%)

Q1: first quartile; Q3: third quartile

Balanced versus unbalanced cohorts

As noted earlier, the dataset is highly imbalanced - less than 1% of the women experienced SMM. As such, learning models based on the observed case to control ratio could lead to bias in the model. To mitigate this problem, we randomly sample controls (Non-SMM) from the data to investigate case:control ratios in the form of 1:1, 1:4, 1:16 and 1:64. In addition, we evaluated how the ratio impacts the performance of machine learning models to identify SMM from the natural case:control ratio.

Regularized logistic regression models

We train four types of models:

M_0: ⟨CDC-25, no learning⟩ The CDC model, which leverages 25 indicators to identify SMM. This model is considered as the baseline.

M_1: ⟨diagnoses, ridge logistic regression⟩ The features are diagnosis concepts and ridge logistic regression (L_2) is used as machine learning models. Under this category, we train regression models using top 10%, 20%, 40%, 80% and 100% of the diagnosis codes, and datasets with case:control ratios as 1:1, 1:4, 1:16 and 1:64.

M_2: ⟨procedures, ridge logistic regression⟩ The features are procedural concepts and ridge logistic regression is used as machine learning models. We use the same strategy in M_1 to train the regression models.

M_3: ⟨diagnoses and procedures, ridge logistic regression⟩ The features are diagnosis and procedural concepts and ridge logistic regression is used as machine learning models. We use the same strategy in M_1 to train regression models.

For each model, we apply 10-fold stratified cross-validation. The performance of models is measured in terms of sensitivity (SN), specificity (SP), positive predictive value (PPV), and AUC.

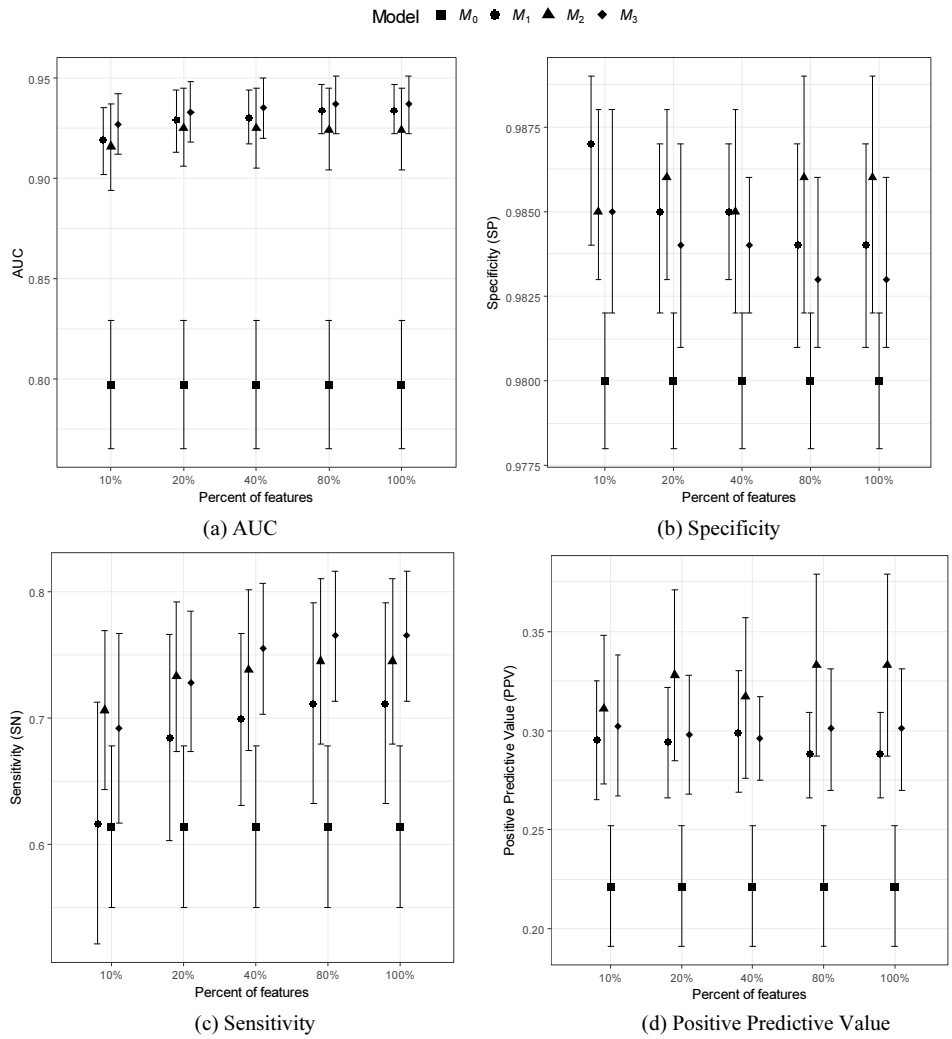
Medical concept ranking algorithm

To determine which medical concepts play more important roles in identifying SMM, we use the following equation to rank concepts:

$$F_{imp}^{j} = \sum_{i=1}^{10} \frac{AUC_i}{\sum_{i=1}^{10} AUC_i} \beta_i^j,$$

where F_{imp}^{j} is the overall importance of the j^{th} concept and β_i^j is the coefficient of the j^{th} concept for the i^{th} cross-validation model. The medical concept importance is adjusted by the model performance (AUC) and the importance of a concept within a model (coefficient). The larger the value of F_{imp}^{j} is, the more important the j^{th} concept is. For instance, imagine we train two models m_1 and m_2 on two medical concepts c_1 and c_2, such that the AUC of the models was 0.8 and 0.9, respectively. It was found that the coefficients of the two concepts in m_1 and m_2 was (0.6, 0.4) and (0.8, 0.2) respectively. According to our approach, the importance of medical concept c_1 is (0.8 / (0.8 + 0.9)) × 0.6 + (0.9 / (0.8 + 0.9)) × 0.8, or 0.71.

We learn a logistic regression model based on the medical concepts with the largest importance scores, along with age and race. Odds ratios are calculated for each feature in the SMM and non-SMM classes along with their corresponding p-values. The OR was adjusted for age and race and the p-value was subject to a Bonferroni correction.



(a) AUC (b) Specificity

(c) Sensitivity (d) Positive Predictive Value

Figure 2– SMM recognition performance as a function of the number of features in the logistic regression model

Results

Influence of the number of features

We use the natural proportion of cases to controls to train and validate models using the top 10%, 20%, 40%, 80% and 100% of concepts. The performance (in terms of AUC, SN, SP, and PPV and the corresponding 95% confidence interval) is depicted in Figure 2.

In Figure 2(a), it can be seen that M_1, M_2, and M_3 outperform the baseline M_0. Their performance improves as more features are added into these models, with an increase in AUC from 0.919 to 0.937. At each percentage of features, model M_3 exhibits the best performance of all three models. Model M_3 with 80% of features achieves the best AUC of 0.937, which is 18.6% better than M_0 (0.790).

Figures 2(b) and 2(c) show the specificity and sensitivity with respect to the percentage of features considered. It is observed that the best specificity is achieved at 10% of the features for M_1, improving by about 1% over the baseline model M_0, while the sensitivity improves by 25% from 0.614 for M_0 to 0.765 for M_3 (which occurs when 80% of the features are used). Figure 2(d) shows the PPV for the models. The PPV clearly improves through M_1, M_2, and M_3, where M_2 has the best PPV 0.347 (which occurs when 80% of the features are used), which is 57% better than that achieved by the baseline M_0.

Influence of the case:control ratio

Figure 3 shows the identification performance under different case:control ratios with all the features. It is notable that the performance does not always improve as the sampling ratio increases. M_1 and M_3 achieve the best AUC for the 1:64 sampling ratio while M_2 achieves the best AUC at 1:4.

Important concepts

We rank features using M_3 with 80% of concepts because it exhibits the best AUC under a natural ratio of cases and controls. Out of 5,553 concepts, the top 10 positive concepts are reported in Table 3. The ranks of these features are reported, along with their concept names and odds ratios.

The concepts in Table 3 can be categorized into three groups. The first group is respiratory-related, including the 4th concept. This has face value as patients with acute respiratory failure may need to be intubated or are dependent on ventilation. This leads to the second group, which includes the 1st, 2nd, and 5th concepts. These concepts indicate that most of the patients who are intubated or need ventilation assistance experience SMM. The procedural concept "*Critical care, evaluation and management of the critically ill or critically injured patient*" (3rd concept) is positively associated with SMM.

In addition, three novel risk factors (7th, 8th, and 9th concepts) were found to be associated with SMM in this study. Most of the patients that were assigned these concepts experienced SMM. To the best of our knowledge, these concepts have not been reported in the literature nor are they in the CDC definition.

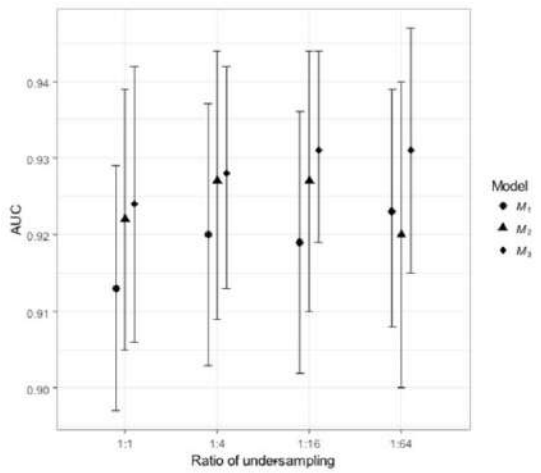


Figure 3– AUC performance as a function of SMM case:control ratio

Table 3– The most important concepts that are positively associated with SMM (p-values smaller than 10^{-7})

Rank	Concept Name	Type	OR (95% CI)	Patients with this concept	SMM Patients with this concept
1	Dependence on ventilator	Condition	1938.9 (388.3 – 35217.1)	16	15
2	Intubation, endotracheal, emergency procedure	Procedure	1461.1 (428 – 9151.5)t	25	23
3	Critical care, evaluation and management of the critically ill or critically injured patient; first 30-74 minutes	Procedure	1735.4 (1076.8 – 2969.8)	184	166
4	Acute respiratory failure	Condition	1272.3 (644 – 2892.8)	80	72
5	Ventilation assist and management, hospital inpatient/observation, initial day	Procedure	1232.5 (663.6 – 2557.3)	95	85
6	Trauma and postoperative pulmonary insufficiency	Condition	1007.1 (486.4 – 2444.6)	62	55
7	Disorders of fluid and electrolytes	Condition	685.4 (261.3 – 2351)	27	23
8	Systemic inflammatory response syndrome	Condition	561.3 (229.1 – 1682.8)	12pt	23
9	Acidosis	Condition	325.8 (201.4 – 544.4)	82	59
10	Sepsis	Condition	308.2 (162.5 – 617.8)	44	31

Discussion and Conclusions

SMM often leads to adverse outcomes, including prolonged length of stay and an increased rate of postpartum readmission. The machine learning-based framework introduced in this paper can enable the automatic identification of SMM events, based on diagnosis, procedural and demographic features, and provide intuition into risk factors associated with SMM. In particular, this work has two notable findings.

First, the framework shows that the machine learning approach outperforms the baseline model (CDC criteria) in terms of AUC, positive predictive value and sensitivity. As such, we believe that a greater number of SMM cases can be identified through our framework, with a smaller false positive rate, than that is currently achieved through current best practice. This should substantially reduce the amount of manual effort to identify SMM instances. In addition, since we rely on the OMOP common data model, the proposed framework is likely to be generalized to other institutions.

Second, our model uncover potentially novel concepts that are positively associated with SMM. 85% (23 of 27) patients diagnosed with fluid and/or electrolytes disorder experienced SMM during their delivery hospitalization. Similarly, 82% (23 of 28) patients diagnosed with systemic inflammatory response syndrome developed SMM.

Despite these findings, it should be recognized that this is a pilot study and there are several limitations that need to be addressed as this line of research moves forward.

First, we assumed that our constructed control group does not contain any SMM cases; however, this is not guaranteed. It is challenging to solve such a limitation in a pilot study. This is because it would require substantial effort to review all 45,446 control instances to identify missed SMM cases. A recent study indicates that there may exist 1 SMM cases per 10,000 samples in the control group [9]. Still, given to the small missed-case:control ratio (1:10000), this situation likely has little impact on the performance of the SMM identification models.

Second, we only applied the simplest machine learning algorithm-logistic regression in this study and many other advanced machine learning algorithms are missing. We anticipate adding neural networks, decision tree, support vector machine (SVM), and gradient boosting classifier in our next-step study to improve SMM identification performances.

Third, more advanced feature selection algorithms can be used to preselect candidate features feeding the machine learning models. In this study, we preselected candidate features feeding machine learning models based on their frequency occurring in the patient population, which does not consider correlations between features. The performance of machine learning models can be improved by removing duplicated features.

Fourth, we only considered diagnosis and procedural features and neglected many other important features including laboratory variables, medications, and vital signs, which may be related to SMM.

Fifth, the concepts assigned to patients were considered in an atemporal fashion. It can potentially boost identification performance to model temporal relation between concepts. Yet chronological information between concepts reflects how SMM develops and is handled. Such information would be useful for characterizing how at-risk patients were managed.

Abstract

Severe maternal morbidity (SMM) encompasses a wide range of serious health complications that would likely result in death without in-time medical attention. It has been recognized that various demographic factors (e.g., age and race) and medical conditions (e.g., preeclampsia and organ failure) are associated with SMM. However, how medical conditions develop into SMM is seldom investigated. We hypothesize that SMM has a progression path, which is associated with a sequence of risk factors rather than a set of independent individual factors. We implemented a data-driven framework that leverages electronic health records (EHRs) in the antepartum period to learn the temporal patterns and measure their relationships with SMM during the delivery hospitalization. We evaluate the framework with two years of data from 6,184 women who had delivery hospitalizations at Vanderbilt University Medical Center. We discovered 69 temporal patterns, 12 of which were confirmed to be significantly associated with SMM.

Keywords:

Electronic health records, Pregnancy Risk Factors

Introduction

Severe maternal morbidity (SMM) such as severe hemorrhage, uterine rupture, organ failure, embolism, pulmonary embolism, and seizure is a physical condition that either result from or is aggravated by pregnancy and has an adverse effect on a woman's health.[1] It has been recognized that women with SMM often have a longer length of stay, higher medical cost at the time of delivery, and potentially worse neonatal and postpartum outcomes than those without SMM [2]. SMM has been utilized as an indicator of the quality of maternal health and the cost of healthcare.[3; 4]

Although the definitions of SMM are different from one study to another, its prevalence has steadily increased worldwide. [4; 5] Around 60,000 women are now affected in the US every year. [6; 7] Learning the risk factors of SMM, and predicting it early can potentially improve the quality of women's health and reduce healthcare costs.

Given the complexity of SMM and its worldwide prevalence, health practitioners and researchers at the national and state level have made considerable progress to learn the risk factors for SMM [9; 10]. It has been recognized that various factors including demographics (e.g., age and race), lifestyle (e.g., tobacco use and alcohol consumption), and medical conditions (e.g., preeclampsia and eclampsia, gestational diabetes mellitus, and prior cesarean section) are related to SMM. Yet almost all studies to date relied on hypothesis-driven approaches to learn risk factors, which have several drawbacks. First, they only investigated a small number of predetermined risk factors and neglected many other factors which may contribute to SMM. This is due to the fact that these studies relied on experts' experiences to determine candidate risk factors which can cost a huge amount of manual effort. Second, most studies did not consider the temporal relationships between risk factors. This is important because women with SMM, rarely transition directly from a healthy state to SMM or death. Rather they tend to progress along a continuum from one health status to another and, eventually, to severe morbidity or death.

To overcome these drawbacks, we introduced a data-driven framework to learn the progression path for SMM in the antepartum period (i.e., pregnancy before delivery). We focused on this period because our aim was to discover temporal patterns of risk as early as possible so that appropriate interventions could be applied to prevent SMM or reduce harms caused by SMM. In addition, this framework is built using on-the-shelf data and, thus,considered a large number of candidate risk factors with minimal manual effort. In particular, we leveraged data in electronic health records (EHRs) to learn temporal patterns between maternal conditions, in terms of International Classification of Disease (ICD) codes and measure the relationships of the temporal patterns with SMM. This work is notable because it shifts the investigations of SMM risk factors from atemporal to temporal manner.

Methods

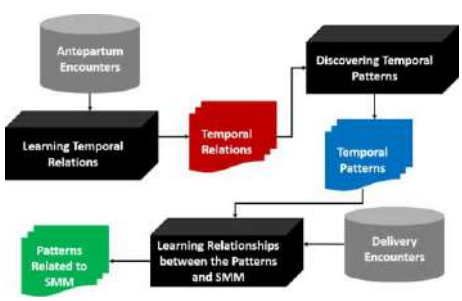

Figure 1. An overview of the data-driven framework to learn temporal patterns related to SMM.

Our data-driven framework consists of three components: i) a data mining algorithm to learn temporal relations between diagnoses in antepartum period, ii) a statistical model to

identify temporal patterns from temporal relations, and iii) a regression model to identify SMM related temporal patterns. An overview of the framework is depicted in Figure 1.

Dataset

Table 1. Statistics of age, race, and length of EHR for patients with and without SMM

Factor	SMM $N = 69$	Non-SMM $N = 6,115$
Age (mean ± SD)	29.1 ± 5.3	28.9 ± 5.5
Race (%)		
White	43 (62.3%)	4,129 (67.5%)
Black	16 (23.2%)	1,020 (16.7%)
Asian	7 (10.2%)	393 (6.4%)
Other	3 (4.3%)	573 (9.4%)
Length of EHR (in weeks)	78.2 ± 73.1	73.9 ± 68.8

The data is based on 6,184 obstetric patients who had a delivery encounter at Vanderbilt University Medical Center (VUMC) between 2015 to 2017. For each patient, the data documents: 1) demographics (age and race), and 2) clinical concepts during antepartum and delivery encounters. For each encounter, we have admission and discharge dates and the set of ICD-9 codes. The data in the antepartum encounters were leveraged to learn temporal relations between ICD-9 codes and the data in the delivery encounters were used to determine if a patient experienced SMM or not. We used 25 SMM indicators in the form of ICD-9 codes, as defined by the Centers for Disease Control and Prevention (CDC) to identify SMM cases [1]. Summary statistics of patients with and without SMM are shown in Table 1.

Encounter: An encounter corresponds to a hospital visit, which has the admission and discharge date. Encounters in this paper are denoted as $E_1, E_2, \cdots, E_n$.

Code: A diagnosis is specified as an ICD-9 code or procedure code. ICD-9 codes are used for billing services and are assigned to EHRs by physicians in patient care or by medical coders after the discharge of an encounter. The time when an ICD code is assigned to EHRs of a patient within an encounter does not necessarily represent the exact time when the patient received the corresponding diagnosis. However, ICD-9 codes across encounters should have temporal relations. For instance, if code 648.01 was assigned in one encounter ranging from February 3 to February 4, and code 655.83 was assigned in another encounter ranging from March 3 to March 5, then 655.83 was diagnosed after 648.01, and the temporal relationship exists between them. We denoted a code as c_i. If an encounter E_k has m different codes, then we will represented all codes in the E_k as $\{c_1, c_2, \cdots, c_m\}$.

Code sequence: A code sequence is an ordered series of codes coming from disparate encounters. For example, as shown in Figure 2, this patient has three antepartum encounters with 4 code sequences: $\{c_1 \rightarrow c_2 \rightarrow c_4,\ c_1 \rightarrow c_2 \rightarrow c_5,\ c_1 \rightarrow c_3 \rightarrow c_4,\ c_1 \rightarrow c_3 \rightarrow c_5\}$.

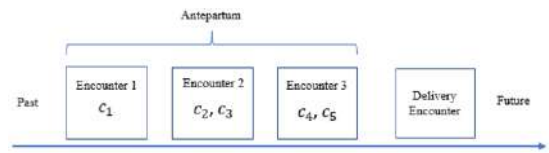

Figure 2. An example of four temporal perinatal encounters of a patient. Codes were assigned in each of the three antepartum encounters.

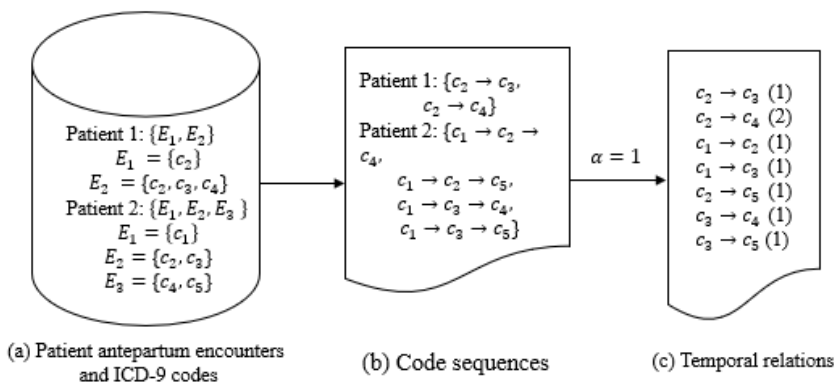

Figure 3. An example of learning temporal relations from six code sequences extracted from five encounters

Building Temporal Relations

We designed a sliding window-based algorithm to build temporal relations between diagnosis codes. The ordered relation between a pair of codes within a code sequence as:

$$Code_{relation}(c_i, c_j) = \begin{cases} \frac{1}{(p(c_i)-p(c_j))^2}, & (0 < p(c_j) - p(c_i) \leq \alpha \\ 0 \quad , \quad otherwise \end{cases} \quad (1)$$

where $p(c_i)$ is the position of a code c_i in a code sequence and α is the window size. The position of the first code of a sequence is set as 1 and the position of the last code is the length of a sequence.

Figure 3 shows an example to illustrate the algorithm. There are two patients P1 and P2, with 2 and 3 encounters, respectively. Each encounter has several diagnosis codes assigned. For the first patient, the first encounter contains one code c_2 and the second encounter contains three codes c_2, c_3, c_4. The code sequences for the first patient are $\{c_2 \rightarrow c_3,\ c_2 \rightarrow c_4\}$. It is notable that $c_2 \rightarrow c_2$ is not included in code sequences because c_2 appears in both encounters and $c_2 \rightarrow c_2$ does not convey any temporal information between encounters. The code sequences for the second patient are $\{c_1 \rightarrow c_2 \rightarrow c_4,\ c_1 \rightarrow c_2 \rightarrow c_5,\ c_1 \rightarrow c_3 \rightarrow c_4,\ c_1 \rightarrow c_3 \rightarrow c_5\}$. If we set window size α is 1, we can learn the strength of temporal relation for each pair of codes within a code sequence via Eq. (1). The total strength of the temporal relation for a pair of codes is the summary of temporal strength of that pair of codes across all sequences. Temporal

relations and their strengths are depicted in Figure 3c . For instance $c_2 \rightarrow c_4$ appears in two code sequences and the its temporal strength in each of the code sequence is 1 accoridng to Eq. (1), and thus its total strength is accumulated across the two sequences.

Discover temporal patterns

We applied statistical matching methods [12] along with statistical models to identify temporal patterns from the learned temporal relations. For an investigated temporal relation $c_i \rightarrow c_j$, we defined patients containing c_i as cases, and patients without containing c_i as controls. We selected most similar controls and cases in terms of age, race and EHR length. Based on the selected cases and controls, we used a Chi-square test to test the significance of $c_i \rightarrow c_j$ after Bonferroni correction. A code relationship was considered a temporal pattern when the p value was smaller than 0.05.

Learn relationships of temporal pattern with SMM

We used logistic regression to model relationships between antepartum temporal patterns and SMM during delivery hospitalization. Age, race, and length of EHR are included in the model as confounders. For each temporal pattern, logistic regression is applied to evaluate its adjusted relative risk (aRR) on SMM. The significant temporal patterns are reported with the 95% confidence interval of aRR.

Table 2. Temporal patterns related to the fetal abnormality

Subcategories	Temporal Patterns	Summary of the Pattern
Diabetes mellitus	648.01 → 655.83	Antepartum diabetes may lead to suspected fetal abnormality
Cervical shortening	649.73 → 644.03	Cervical shortening increases the risk of threatened premature labor
Fetal growth retardation	764.90 → 656.53	Fetal growth retardation may affect the management of mother
Uterine size date discrepancy	649.63 → 656.53	Uterine size date discrepancy is associated with poor fetal growth
Fetal abnormality	656 → 655.81	Suspected fetal abnormality and placental problem
Advanced maternal age	659.61 → 660	Women with advanced maternal age tend to have obstructed labor
Antepartum complication	644.03 → 655.73, 648.93 → 644.03	The antepartum complication may lead to threatened premature labor that is associated with decreased fetal movements

Result

Temporal relation patterns

Sixty-nine temporal patterns were found in the study. These patterns were categorized into two groups: i) fetus abnormality (Table 2) complicating pregnancy (Table 3). An example of a mother's conditions leading to fetus abnormality is 648.01 (Diabetes mellitus) → 655.83 (suspected fetal abnormality), which implies that a mother with antepartum diabetes tends to have an abnormal fetus. An example of a mother's health conditions leading to complicating pregnancy is 649.73 → 644.03, which indicates cervical shortening increases the risk of threatened premature labor.

Temporal patterns were further categorized into a set of subtypes including obesity, type 2 diabetes, hypertension, opioid dependence, tobacco use, abdominal pain, advanced maternal age, urinary tract infection, hypothyroidism and historical delivery condition such as previous cesarean section. Drug addictions lead to complicating pregnancy. In addition, mothers with drug addictions usually suffer from posttraumatic stress disorder (309.81), viral diseases (647.63) and mental disorders (648.43).

Obesity, diabetes mellitus, and hypertension are correlated with each other (642.03 (Benign essential hypertension) → 648.03 (diabetes mellitus) and 642.23 (transient hypertension) → 649.13 (obesity complicating pregnancy)), and they together complicate pregnancy. Abdominal pain (789.09), advanced maternal age (659.63), urinary tract infection (599.0), hypothyroidism (244.9) and historical cesarean section (654.23) also complicate pregnancy.

Temporal patterns related to SMM

Among the 69 temporal patterns, 12 (or 17.4%) were significantly associated with SMM. The degrees of the associations between the 12 patterns and SMM are depicted in Figure 4. For example, women that had antepartum drug dependence and mental disorder had greater than 8-fold risk of SMM in their delivery. Similarly, antepartum conditions hypertension and diabetes (642.03 → 648.03, 648.03 → 642.03 and 648.03 → 642.23) increase the risk of SMM. Other temporal patterns that may lead to SMM include obesity, advanced maternal age, viral disease, and tobacco use disorder.

Discussion

Severe maternal morbidities (SMM) during delivery often results in adverse outcomes, including a prolonged length of stay and an increase of postpartum readmissions. In this study, we introduced a data-driven framework to infer temporal relational patterns between diagnoses during the antepartum period and analyzed their associations with SMM. This work has two notable findings.

First, we demonstrated that there are temporal patterns that suggest progression paths for SMM. For instance, pre-existing health conditions including hypertension, diabetes mellitus, and

obesity appeared to develop into comorbidities in the antepartum period, complicating pregnancy. Additionally, lifestyle factors, such as drug/opioid-dependence and tobacco use disorder, may also complicate pregnancy. It was also found that the well-being of a fetus is associated with adverse antepartum conditions. For instance, mothers with diabetes mellitus tend to have abnormal fetus.

Table 3. Temporal patterns related to complicating pregnancy

Subcategories	Temporal patterns	Summary of the Pattern
Obesity	278.01 → 649.11, 278.01 → 649.13, 648.01 → 649.11, 278.00 → 649.13, 649.12 → 648.83, 642.93 → 649.13, 659.63 → 649.13, 642.23 → 649.13, 642.03 → 649.13, 649.13 → 642.03	Obesity, especially morbid obesity, complicating pregnancy
Hypertension	796.2 → 642.23, 796.2 → 649.13, 401.1 → 642.03, 401.9 → 642.03, 648.03 → 642.03, 642.03 → 649.13, 642.23 → 649.13, 250.00 → 642.23, 648.03 → 642.23, 796.2 → 642.33, 796.2 → 649.13	Pre-existing hypertension, elevated blood pressure reading, antepartum hypertension complicating pregnancy
Diabetes Mellitus	250.01 → 648.01, 250.00 → 648.01, 250.00 → 648.83, 250.00 → 642.23, 250.00 → 648.03, 648.01 → 649.11, 790.29 → 648.83, 642.03 → 648.03, 648.03 → 642.23, 648.01 → 649.11	Type I and II diabetes with abnormal glucose tolerance complicating pregnancy; antepartum diabetes may cause some suspected fetal abnormality
Drug/opioid Dependence	304 → 648.31,304 → 648.30, 304.00 → 648.30, 304.00 → 648.33, 304.00 → 648.43, 304.00 → 649.03, 304.01 → 648.31, 304.01 → 648.30, 304.01 → 648.33, 648.31 → 649.01, 648.33 → 647.63	Drug dependence and opioid dependence are related, together complicating pregnancy; drug/opioid dependence is associated with mental disorder
Tobacco	648.31 → 649.01, 305.1 → 648.30, 649.03 → 648.30, 304 → 649.03, 648.33 → 649.03	Tobacco use disorder is associated with drug/opioid dependence; both could complicate pregnancy
Other	309.81 → 648.30	Other conditions such as posttraumatic stress disorder, thyroid dysfunction, urine infection complicating pregnancy, pain
	244.9 → 648.13, 244.9 → 648.91	
	599.0 → 646.63	

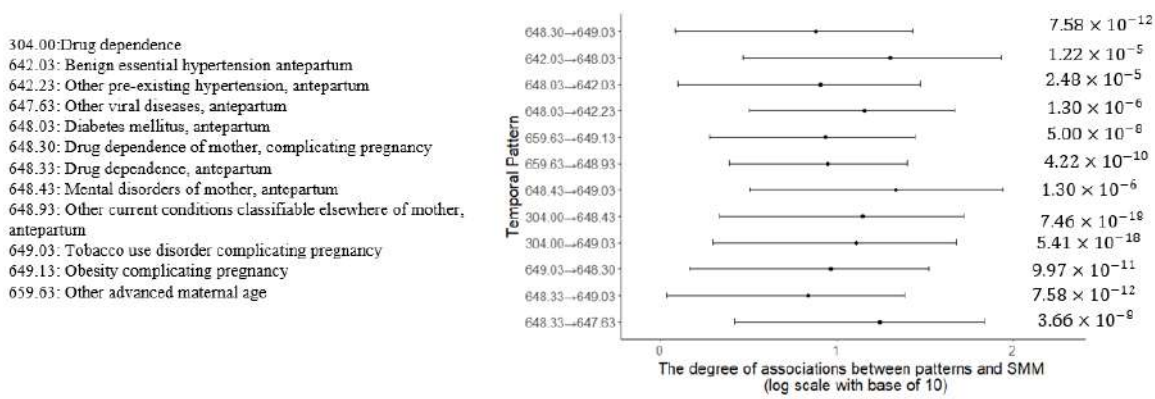

Figure 4. The adjusted relative risk of relationships between temporal patterns and SMM.

Second, we found that antepartum drug dependence and mental disorder are strongly related to SMM. Early identification of these high-risk mothers and adopt appropriate intervention strategies may improve care quality of SMM management and reduce harms caused by SMM.

At the same time, we note that this is a pilot study, and there are several limitations that need to be addressed.

First, we investigated a small number of SMM instances, which may limit our findings in this study. For instance, many potential temporal patterns may be missed in our investigated patient population. In addition, we only considered diagnoses

within antepartum periods, which may miss risk factors of SMM ahead of the antepartum period.

Second, we only studied temporal patterns between diagnosis codes and neglected other rich health information including medications, vital signs, and labs which could provide insights into SMM.

Third, this study was conducted in a single institute and should be expanded in many other institutes to conclude more general recommendations about managing SMM.

Fourth, we used a simple and natural temporal relation learning algorithm to learn temporal patterns. More advanced temporal pattern mining algorithms including Allen's algebra and graph neural networks can be applied in future studies.

Conclusion

This research broadens our current knowledge of the continuum of maternal health in the United States by inferring the association between antepartum comorbidities and SMM. Our work suggests that mothers with drug dependence, hypertension, diabetes mellitus, viral disease, and tobacco use disorder have an increased risk of SMM. While further investigation is needed, we believe that healthcare organizations should focus their attention on childbearing women with these conditions in the antepartum period.

Abstract

We describe the process of creating a User Interface Terminology (UIT) with the goal to generate a maximum of German language interface terms that are mapped to the reference terminology SNOMED CT. The purpose is to offer a high coverage of medical jargon in order to optimise semantic annotations of clinical documents by text mining systems. The first step consisted in the creation of an n-gram table to which words and short phrases from the English SNOMED CT description table were automatically extracted and entered. The second step was to fill up the n-gram table with human and machine translations, manually enriched by POS tags. Top-down and bottom-up methods for manual terminology population were used. Grammar rules were formulated and embedded into a term generator, which then created one-to-many German variants per SNOMED CT description. Currently, the German user interface terminology contains 4,425,948 entries, created out of 111,605 German n-grams, assigned to 95,298 English n-grams. With 341,105 active concepts and 542,462 (non FSN) descriptions, it corresponds to an average of 13 interface terms per concept and 8.2 per description. An analysis of the current quality of this resource by blinded human assessment terminology states equivalence regarding term understandability compared to a fully automated Web-based translator, which, however does not yield any synonyms, so that there are good reasons to further develop this semi-automated terminology engineering method and recommend it for other language pairs.

Keywords:

Natural Language Processing, Systematized Nomenclature of Medicine, Translations

Introduction

In medical documentation, user interface terminologies (UITs) bridge between the language in use by clinicians and the standardised language of reference terminologies. Interface terms vary between specialties, professional groups and dialects and undergo constant evolution due to medical progress and dynamics of language [1]. We present a cost-effective, manual, incremental approach to acquire and create interface terms with the goal to map them onto a reference terminology (SNOMED CT), both using bottom-up and top-down approaches.

Health care terminologies are crucial resources for semantic interoperability. Despite their differences in architecture and scope (e.g. ICD-10 as a classification system for diseases vs. SNOMED CT as an ontology for all aspects of electronic health record (EHR) content), there is a principal distinction between:

- Labels (fully specified names, reference terms), which aim at providing self-explaining descriptions of the meaning of concepts, often paralleled by formal definitions in ontologies or text definitions in thesauri.
- Interface terms (non-preferred synonyms), which represent the jargon used by clinical practitioners in their daily documentation and communication.

Take the SNOMED CT preferred term "*Primary malignant neoplasm of lung*" as an example. This term is precise but artificial. Screening the complete PubMed corpus yields no single occurrence of this term, and it would be very unlikely be found in clinical documents either. Its popular synonym "*lung cancer*", retrieves 120,682 documents from PubMed and is common in clinical documents and problem lists. Another example is "EKG", an acronym-term we retrieved 12,208 times in a corpus of cardiology discharge summaries, while the full term “Elektrokardiogramm” does not occur a single time. Reference terms are characterised by precision; interface terms by brevity. This highlights the need for interface terms, wherever content is automatically extracted from texts [2]. This has recently been emphasised by the European project ASSESS CT (Assessing SNOMED CT for Large Scale eHealth Deployments), which recommended broad efforts to be invested into UITs [3] linked to reference terminologies like SNOMED CT, rather than into translations proper. For humans, the possible fuzziness and ambiguity of interface terms (in this case, it may not be quite clear whether lung metastases are in the scope of "lung cancer") is a minor problem due to context and implicit understanding within a user group, whereas word sense disambiguation is still a major problem for machines.

A major use case for UITs is the provision of dictionary entries for natural language processing (NLP) systems. Other use cases are related to structured data entry using data acquisition forms, whenever the terms should be close to the user's language preferences. Limitations of UITs lie in the conceptual content of the underlying reference terminology (in this case SNOMED CT). There is still a substantial amount of interface terms that cannot be precisely mapped to terms of a corresponding domain terminology.

Interface terms can be single words like "pancreas" or "dermatology", compound words like "lymphangiosarcoma", acronyms like "ARDS" or multi word terms like "hereditary factor VIII deficiency disease". Possible sources of interface terms include:

- Automatic and manual term translations
- External, generally accessible corpora of the target language (e.g. books, publications, articles etc.);
- Institution-specific value sets and term collections;
- Clinical corpora constituted by EHR narratives (privacy protection must be taken into account).

Lexical ambiguity (e.g. "delivery" in "drug delivery" vs. "delivery of a baby") is characteristic for interface terms, and

it rarely runs parallel between languages (e.g. in German, words for the delivery of goods, substances or babies are completely distinct). Especially short acronyms are prone to ambiguities (e.g. "MI" means "myocardial infarction" in cardiology, but "macular ischemia" in ophthalmology; "DM" may be expanded to "diabetes mellitus", "diameter", "disease management", or "dermatomyositis" according to its context. Only long acronyms like "NSTEMI" can be expected to have a unique meaning. Ambiguous acronyms are mostly unproblematic once they occur as constituents of a longer term, in which they are univocal (example: "type 2 DM").

In the following we describe the ongoing construction of a German UIT for SNOMED CT, which uses the English SNOMED CT description table for the semi-automated construction of German-language interface terms.

Material and Methods

SNOMED CT

SNOMED CT [4] is the most comprehensive healthcare terminology on the globe, with use in over 50 countries. The current international SNOMED CT version (July 2018) consists of 340,659 active representational units, known as *SNOMED CT concepts*. They have an exclusive meaning and a unique machine-readable identifier. *SNOMED CT Descriptions* include a *Fully Specified Name* (FSN) for each concept, together with one or more synonyms. FSNs represents the concept with an official, ideally self-explaining name. Synonyms share meaning with FSNs but find more common use in displaying or selecting a desired FSN. The meaning of SNOMED CT concepts is, in addition, delineated by text definitions and formal axioms in Description Logics. E.g., *Gastritis* is defined as logically equivalent to a disorder with inflammatory morphology that is located at some stomach structure.

SNOMED CT's increasing adoption in German-speaking countries (with Switzerland and Austria already being members of SNOMED International, whereas Germany is still negotiating) prioritises harmonisation with local language and terminologies. This has motivated the authors to develop a semi-automatic, resource-aware and pragmatic method for creating an experimental German UIT linked to the current international version of SNOMED CT. The methodological framework developed might be applied to other languages [5]. This UIT feeds the currently largest SNOMED CT use case in the German-speaking country, *viz.* semantic annotations of clinical texts within the hospital information system of the Austrian healthcare provider KAGes, using natural language processing [6].

Procedure

The starting point of the interfacing process was the set of over 700,000 English SNOMED CT terms ("Descriptions") from the international version. This list contains, apart from the official labels (Fully Specified Names), one preferred term (dependent on the release) and zero-to-many synonyms. SNOMED CT terms are characterised by many repetitive substrings, exemplified by the term "magnetic resonance imaging of hip". That there are 1,620 occurrences of "magnetic resonance imaging" and 1,239 occurrences of "of hip" in SNOMED CT shows the potential of a modular approach to term translation.

N-gram Table as Core Translation Resource

In order to harvest such repetitive passages, a language-specific rule set was created and implemented in Python 3 to chunk decomposed terms down into shorter units, constituting word *n*-grams with *n* ranging from *1* to *6*. Here "word" encompasses, to a minor extent, also sub-word entries needed for single-noun composition, which is particularly common in German. SNOMED CT terms therefore can be constituted by one to many n-grams, e.g. "Escherichia coli" is a 2-gram, which can equally stand alone, or occur in a longer term like "Escherichia coli antibody". In addition to the n-grams with $n > 1$, also all single words were added. In summary, n-grams include complete and partial constituents of the SNOMED CT labels and descriptions. The result was an .xlsx table with currently enclosing close to 550,000 English-language n-grams, ranked by their decreasing frequency in the source, i.e. the SNOMED CT's description table. It is structuredin the following collumns:

- *"ID"* – n-gram identifier code;
- "N-gram English": from words to n-grams, ($n < 7$);
- *"Length"*: number of tokens in the n-gram (n);
- *"Count"*: n-gram frequency in the source SNOMED CT description file;
- *"N-gram German 1"*, *"N-gram German 2"*... German translations of English n-grams.

We started populating this table with German terms, started four years ago with limited resources (one part-time terminologist and several medical students). Along time it has been subject to constant optimization and quality improvement heuristics. The description of some of these heuristics (mostly developed as a sequence of trial-and-error cycles) will occupy the remainder of this section. The main goal of this description is to outline a general methodology for modular and incremental CIT developments for new language with limited resources.

Translation Heuristics

The first step was to tackle large amounts of easily machine translatable content. Method of choice was Google Translate. For surprisingly many more common medical terms, for example *"arm"*, *"status"*, or *"hormone"*, but also *"cholecystectomy"* or *"tendon sheath"*, useful translated content could be harvested. Several limitations were observed: (i) each translation only yielded one target n-gram (no synonyms are provided when inserting source terms in a batch), (ii) single English words were often undefined in terms of POS (part of speech, e.g. noun, adjective, verb), like *"set"*, *"back"*, *"general"* and therefore ambiguous, (iii) the translation of numerous words did not correspond to the medical meaning (e.g. *"delivery"* translated into *"Lieferung"* and not into the translations relevant to medical context like *"Entbindung"* or "Gabe"), (iv) less common medical or chemical terms were not translated, and the untranslated term was returned, instead (which then was preserved, waiting for manual correction).

Given SNOMED CT's richness in concepts for biological organisms, for which Latin terms are common and identical across languages, we harvested a large number of terms that occurred identically in the English and Spanish versions, assigned to the same concepts (e.g. *"Homo sapiens"*, *"Ascaris lumbricoides"*, *Angina pectoris"*, *"Anorexia nervosa"*). Thus, they could be safely added to the German version.

For the left-over of untranslatable content, manual input was required. It required mainly addition of new German n-grams and modification of the existing human or machine generated ones, addition of synonyms (e.g. *"Leber- " to "hepatisches"*), as well as appending grammar tags to both manual and machine created words (e.g. *"hepatisches|JJ"* to mark it as an

adjective and "-" to mark *"Leber-"* as a prefix-like morpheme). Humans also revised the machine generated terms by evaluating randomly sampled sets of the generated terms, often revealing major systematic errors in the machine translation. Mistranslations are deleted and revised, untranslated terms grouped by certain patterns (e.g. ending with "acid" and changed to the German ending "säure" by repetitive search / replace actions). Manual work was prioritized according to the guiding principles: (i) n-gram frequency; (ii) clinical relevance; and (iii) single words.

To ensure all SNOMED CT concepts get covered in one primary form, we set the goal of at least one translation for every single word n-gram (n=1), Such atomic units represent individual interface terms or parts of larger composite interface terms. Semantic composition is not robust multiword n-grams. Therefore, we considered multi word n-grams down to a frequency of eight. Less frequent n-grams were left out, because of the enormous amount of multiword n-grams. The decision in favour of manual translating multiword terms was positive whenever:

- The formation of a multiword term in the source language was not paralleled by a translation in the target language. E.g. "*malignant neoplasm*" translates not only into "maligne Neoplasie" but also into "*Malignom*"; and "oral solution" does not translate into "*mündliche Lösung*", but into "*Lösung zur oralen Einnahme*".
- One component of a multiword term was ambiguous and could be disambiguated in the composition. E.g. "*back pain*" in "*Rückenschmerzen*" ("back" = "Rücken"), and "*back door*" into "*Hintertür*" ("*back*" = "*Hinter-*").

The application of these rules often results in a labour-intensive walkthrough of the whole n-gram table.

Addressing German Language Features Like Inflection and Composition

German word inflections heavily depend on gender, tense, person, number, declination type and case. All entries, be they manual or automatically made, need therefore to be reviewed and enriched with grammatical information. This task relies mainly on human editing, using however machine support for pattern-based search-replace actions. Automated term creation with correct inflection suffixes requires a distinction between nouns, adjectives, verbs, prepositions and determiners, yielding the following tagging suffixes:

- Singular gender or plural tags for nouns (|NN|N, |NN|F, |NN|M, NN|P)
- Cases for verbs (|VV|N, |VV|G, |VV|D, |VV|A)
- Markers for adjectives (|JJ)
- Preposition tags depending on case (|PP|N, |PP|G, |PP|D, |PP|A)
- Definite and indefinite articles (|DET|D, |DET|I)
- Noun tags of Latin words or other nouns for which single-noun composition is not allowed (|NL|N, |NL|F, |NL|M, |NL|P)

Tags can be omitted in multi word entries where, e.g. due to a preposition, the inflection case is already determined.

In addition, all numbers were substituted by placeholders (ð, ðð, ððð etc. depending on number of digits and decimals) in the n-gram table. (While the decimal denominator in English is point in German comma is used.)

Single word composition is an important feature of the German language, e.g. with "[Fracture] of the big toe" translated into "*Großzehen[fraktur]*". Such composition patterns are characterised by inversion (with the head morpheme trailing) and by inconstant addition of infixes to the modifying morphemes. This requires the addition of translations to English prepositional phrases starting with "of", which not only translates to a structurally similar German genitive construction ("der Großzehe"), but also to morpheme-like prefixes like "Großzehen...", tagged by bracketing underscores ("_Großzehen_"). In certain instances, we use the additional tag "%VOID%". "%VOID%" is used as an empty word and can be suffixed with tags and thus gaining an inflection attribute. It also prohibits noun compositions (which are otherwise standard between neighbouring nouns). The German n-gram "zur Benutzung%VOID%|PP|G" (to use) illustrates how %VOID% can avoid unwanted word composition, while enforcing the next phrase set into genitive case. If "%VOID%" were absent, the German word "Benutzung" would potentially be attached to a noun right to it, resulting in a disallowed nominal compound. Other tags are %SWAP% and %RIGHT%, with the former swapping the right and the left portion of a phrase (due to different word order in German), and the latter putting a word to the end of a phrase, typically a separable verb prefix, e.g.: "stops" □ "hört mit|PP| %RIGHT% auf".

Top-down and Bottom Up Term Harvesting

Both top-down and bottom-up term harvesting has been used. Top-down means an intellectual effort of enriching English n-grams with additional translations. E.g., when encountering the English term "diabetes mellitus" (together with the identical German term) the editor might remember that there is a synonym "Zuckerkrankheit" to be added. One problem of this method is that it requires extensive manual editing, and is only performed when a manual reviewer goes through the list checking for missing synonyms (starting at very frequent and relevant terms), requiring an excellent command of medical terminology.

Bottom-up describes lexicon population starting with content from representative corpora (clinical texts, biomedical literature, existing terminologies in the target language), from which terms are extracted and mapped to corresponding n-grams in the source language. The advantage of this method is the adjustment of the interface term vocabulary to preselected document genres, covering specific jargon. N-gram hit lists (ordered by decreasing frequency) extracted from these corpora are excellent sources of commonly used terms in the context that is to be covered. One source prepared for our project was a hit list with 4,000 de-identified dermatology summaries, which resulted in 24,000 n-grams ($n \geq 3$). After filtering out entries already included in the master n-gram table (and their inflectional variants), terminologists walk through the hit list and try to identify a corresponding English term for each entry in the master n-gram table.

In cases of doubt, translations are marked for further analysis and discussion. Translation resources such as and offline dictionaries, online translation tools (web search for usage frequency and contexts, various online dictionaries, Linguee, Oxford German Dictionary, DUDEN Wissennetz), term clusters retrieved from the UMLS metathesaurus as well as German titles of Medline-indexed citations (marked as [tt] in the Medline records) have proven useful.

Tooling

Appropriate tooling for distributed, cooperative terminology work is still a desideratum. N-gram editing and maintenance is currently done via a Microsoft Excel table, shared via a repository, which assures that only one instance of this table

can be edited at a time. This Excel n-gram was enriched by macros written in the VBA script language. E.g. the "exploration macro" and "modify and add macro". The former retrieves already existing word and sub-term translations for a given n-gram. The addition of synonyms is supported by a "*Modify and Add Macro*". It allows batch additions of synonyms. When entering an n-gram (e.g. "*Neoplasie|NN|F*") with a synonym (e.g. "*Neubildung|NN|F*") it iterates through the complete n-gram list and suggests additions (e.g. "*Basalzellen-Neubildung*" to "*Basalzellen-Neoplasie*"). Other macros are used for plausibility checking, e.g. identifying disallowed tags.

Term Generation

Term generation is done with a series of language specific Python 3 scripts. In a nutshell, they take the chunked English description table, translate each chunk by n-gram table lookups, thus collecting n-gram translations and assembling them into complete SNOMED CT description translations. In this process, the tagged words are interpreted by a variant generator, which generates inflectional variants, following an inbuilt noun phrase grammar. It also produces single word compounds, using specific tags and rules as explained above. The problem of this generative approach is its combinatorial explosion: if a SNOMED CT term consists of four n-gram chunks, each of which with 3 translations, $3^4 = 81$ terms are generated. To mitigate the growth of generated terms, as well as to improve quality we pursued two approaches. To increase translation of longer n-grams, in order to avoid uncommon term associations, and complete translations of very long terms, which are unlikely to occur in clinical texts, such as FSNs resembling textual definitions[1].

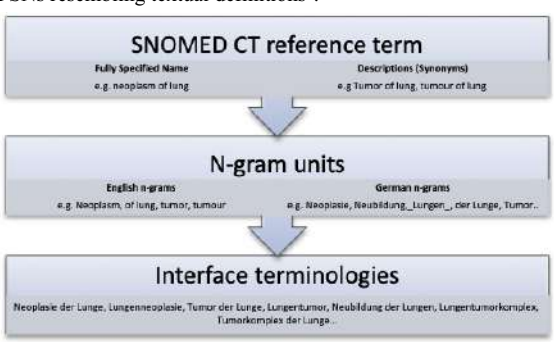

Figure 1 –Interface Term Generation

Quality Checks and Updates

Due to the large size of the UIT, only random samples are regularly quality-checked, assuming that frequent systematic errors also surface in these samples. Errors are traced back, either to the n-gram table or to the inflection and composition routines in the Python scripts. A challenge is also the biannual update of the n-gram table, together with the resulting interface term list, when a new international SNOMED CT version is released. Changes include addition, alteration and removal of concepts. During each version release, we have observed a growth of the n-gram resource. This opens the opportunity to fill in terms, e.g. more detailed pharmacological ingredients that previously were missing.

[1] Such as "pT2: Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion (nasal cavity and ethmoid sinus) (finding)"

Validation Study

The last 2018 version of the UIT was used for a blinded validation study. 200 concepts were randomly selected, and for each of them, one of the German UIT entries – together with the English description in original from – was randomly selected. For each English description, an alternative translation was created using DeepL [7], a machine translation website based on neural networks. For each of three terminologists, a custom translation list with 200 term translations, 100 from DeepL, and 100 from the German UIT was generated. The selection was done by chance, and the terminologists were not informed about the source. For each translation four pieces of information were required: (i) assessment of *Content comprehensibility* (regardless of style and grammar), (ii) *Grammar* (regardless content errors or bad word choices), (iii) *Style & Spelling*, for each of which using a five-point Likert scale (1 - very bad, 5 very good). Finally, an "ideal" manual translation for the term was added by each terminologist.

Results

The German User Interface Terminology currently encompasses 4,425,948 entries, automatically generated from a core vocabulary of 111,605 German n-grams, assigned to 95,298 English n-grams. With 341,105 active concepts and 542,462 (non FSN) descriptions, this corresponds to an average of 13 interface terms per concept and 8.2 per description.

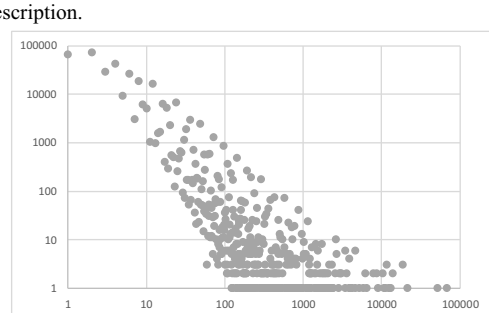

Figure 2 –Distribution of Synonym Sets in UIT. Logarithmic axes:x-Axis: size of synonym set, y-axis: frequency of sets of this size

Fig. 2 shows the distribution: most sets have one to 10 members, but there were outliers with more than 10,000 members, due to term compositionality. Table 1 provides the rating results.

Table 1 –Likert Scale Rating of Translations (Arithmetic Means of 300 Human Ratings per Category)

SNOMEC CT User Interface terminology (UIT)			**DeepL machine Translator**		
Content	Grammar	Spelling / Style	Content	Grammar	Spelling / Style
4.6	4.7	4.4	4.6	4.9	4.6

These results need to be interpreted in the light of the fact that DeepL provided only one translation per concept, whereas the UIT produced much more (mean: 12.1, median 3 translations per term). Whereas the DeepL result can be assumed to correspond to the most popular translations, our sampling

algorithm had picked out the UIT completely randomly. However, the results show clear deficits regarding grammar, spelling and style issues of the current state UIT. Finally, a case insensitive, spelling variation tolerant match between the translation suggested by the users and the UIT entries occurred in 299 of 600 cases.

Discussion

Is it worthwhile investing in terminology acquisition as well as UIT maintenance, in the light of ever increasing performance of machine translation tools? Already in 2013, we had found rather surprising translation results proposed by Google Translate [8]. We suggested a combination of translations done by medical students and done by machine translations; the method we have been using in the described UIT project. Still, machine translation systems have problems with the generation of compound nouns, as well as with the production of sufficient numbers of term variants and combinations. Also, their power depends on the amount of training data they are fed; good results can therefore not be expected for rarely used terms or languages that have less content on the Web.

We are currently supporting the construction of an interface terminology for Portuguese, using the Spanish version from SNOMED International as source language. For this language pair, the power of web-based machine translation systems seems to be much poorer than for German / English.

The advantage of interface terminologies is obvious when re-structuring narrative content of the EHR in terms of SNOMED CT. This opens up the ability to be linked with aggregation terminologies, such as the International Classification of Diseases (ICD-10 or the upcoming ICD-11) [9]. Apart from classification systems of diseases and procedures, such semantic standards are rarely used in routine documentation. As long as interface terminologies act in the background, where they are only used by text mining software, their size and their tendency to over-generate term variants (most of which are never found in any text) do not constitute a problem. This changes if interface terms are to be used by humans; here, uncommon terms should be filtered out before use in order to limit the variety of terms per concept. Such filter criteria could use large clinical corpora together with a general corpus such as Wikipedia and require that a generated term was used at least once. This may, however, obviate the translation of long artificial terms like the one cited above, which are unlikely to be found in any clinical document.

Extracting them from a narrative can be thought of as a result of fuzzy matching between the narrative and multiple term candidates, an approach to be exploited, especially with new, powerful word embedding methods and deep learning.

Another route for translating medical terms capitalises on the fact that large parts of them derive from Latin or Greek roots and share a regular morphology. Such terms can be automatically translated by rewriting rules [10,11]. A machine learning process can learn from two language sets, identify letter-based patterns and apply these rules for the automatic translation of new terms. The word "bronchoscopy" ending with "-oscopy" would be such an example that could be detected by this method and automatically translated by inferring rewriting rules ("Bronchoskopie"). The accuracy of this method depends on how many pairs of terms get compared.

Conclusions

We presented an approach to acquire interface terms from SNOMED CT reference term translations and data from various clinical corpora and map these interface terms onto SNOMED CT reference terms. During the process we focused on frequent words both in SNOMED CT and in clinical texts with the goal to cover all commonly used medical terms and their synonyms, integrating them into our system. An analysis of the current quality of the UIT by blinded human assessment terminology states equivalence regarding term understandability compared to a fully automated Web-based translator. This tool, however, yields much less synonyms, so that there are good reasons to further develop our semi-automated technology and recommend it for other language pairs.

Abstract

Emergency department (ED) overcrowding has been a pain point in hospitals across the globe. "Frequent flyers," who visited the ED at a much higher rate than average, account for almost one third of ED visits even though they represent only a small proportion of all ED patients. In this study, we used data-mining methods to cluster ED frequent flyers at a large academic medical center in the US. The objective was to identify distinct types of frequent flyers, and the common characteristics associated with each type. The results show that the frequent flyers at the ED have three subgroups each exhibiting distinct characteristics: (1) the elderly with chronic health conditions, (2) middle-aged males with unhealthy behavior, and (3) adult females who are generally healthy. These findings may inform targeted interventional strategies for patients of each subgroup, who likely have distinct reasons for visiting the ED frequently, to reduce ED overcrowding.

Keywords:
Data Mining; Hospital Emergency Service; Cluster Analysis

Introduction

ED overcrowding has long been an issue in hospitals across the world [1–3]. Frequent flyers, which are generally defined as patients who visit the ED four or more times per year [4,5], represent as little as 4.5% to 8% of all ED patients but account for as much as 28% of all ED visits [6]. Accordingly, hospitals have a vested interest in characterizing their populations of ED in order to determine how to reduce their impact on ED operations.

Researchers in the field of emergency medicine have written extensively about the typical characteristics of ED frequent flyers. However, there is still too much variation; frequent flyers simply are not a homogenous group. Within the literature, there is a general consensus that three factors are associated with the number of times a frequent flyer visits the ED per year: mental illness, substance abuse and dependence, and alcohol abuse [7–9]. Additionally, employment status and government insurance are often correlated with high ED use [6,10,11]. For instance, younger age groups were also implicated in ED overuse due to the characteristics of the neighborhood surrounding the hospital or the type of hospital from which the data was acquired [6,7]. In some cases, researchers observed a bimodal age distribution with increased risks in frequents users who were either 25 to 44 years old or over 64 years old [7]. Similarly, research has generally found that males and minorities tend to use the ED more frequently, but findings are sometimes inconsistent. For example, a 2005 study conducted by Blank et al. concluded that the sex and race composition of their ED frequent flyer population did not differ substantially from that of their general ED population, which was 51% female and 57% white [10]. Another study conducted by Milbrett and Halm indicated that the frequent flyer population at their "large Midwestern urban hospital" was "commonly" female, middle-aged and white [11].

Thus, there is no "one-size-fits-all" list of characteristics that apply to all hospitals. In order to support hospital-level decision making, a different approach to uncovering these subgroups is necessary. There is a need to identify hospital-specific subgroups and characteristics of frequent flyers. Clustering, or the process of organizing objects or measurements into groups, is a promising method. It differs from mere classification in that the groups used in classification are pre-defined groups, whereas the groups exposed by clustering do not exist beforehand [12]. As an automated unsupervised method, it is also less labor-intensive than manually identifying subgroups in a population and therefore is realistic to be implemented in real-life settings. In previous work, clustering techniques have been used on ED data to both predict patient outcomes or characterize ED usage. In 2007, Huang et al. used the K-means algorithm to cluster patients according to medical utilization, discovering that their population of frequent flyers also tended to utilize other medical services more often [13]. In a similar vein as Huang, Hastings et al. used latent cluster analysis (LCA) to reveal medical utilization clusters among elderly ED patients [14].

In this paper, we performed cluster analysis on 1748 unique patients who have visited the ED more than 4 times in a year at an UC medical center to identify characteristics of subgroups. We applied two commonly used cluster methods that are able to handle mixed data types: the K-prototypes algorithm and Partition-Around-Medoid (PAM). Finally, we discuss the three subgroups of frequent flyers that emerged from our analysis and the implications for using subgroup level interventions to reduce ED misuse.

Methods

Data description and processing

The data received from UCI Medical Center consisted of records of 1748 unique patients. Some data was derived from other data elements; for instance, blood pressure and height were used to yield a computed hypertension, which was cross-referenced against patients' medical history. Computed hypertension is used in the final analysis in lieu of both blood pressure and height. Patient medical history was also used to determine whether the patient had any history of substance abuse, mental illness, or cancer. The data contains both categorical attributes and continuous attributes. Categorical attributes include: hypertension, Diabetes, Binge drinking, tobacco, gender, employment, insurance, substance abuse, other mental illness, and cancer. Continuous attributes include: age, Body Mass Index (BMI), average emergency severity index (ESI), heart rate (HR), blood pressure (RR), temperature (TempC) and oxygen saturation (SpO2). Table 1 provides descriptive statistics of our dataset. Decimals in the table indicate percentages for categorical variables.

Table 1-Descriptive statistics

Variables	Mean (SD)
Demographic	
Gender (Male=1)	.52
Age	46 (18)
Race (Hispanic)	.47
Race (White)	.36
Race (Black)	.05
Race (Asian)	.08
Race (Others)	.04
Medical history	
Cancer (Yes=1)	.18
Diabetes (Yes=1)	.16
Other mental illness (Yes=1)	.33
Health indicators	
BMI	28 (7.3)
HR	91 (16)
RR	18 (2.2)
TempC	37 (.27)
SpO2	98 (1.9)
Hypertension (Normal)	.21
Hypertension (Prehypertension)	.44
Hypertension (Stage1)	.26
Hypertension (Stage2)	.07
Hypertension (ZHT Crisis)	.02
Binge Drinking (Daily or almost daily)	.21
Binge Drinking (Weekly)	.09
Binge Drinking (Monthly)	.07
Binge Drinking (Less than monthly)	.17
Binge Drinking (Never)	.57
Substance Abuse (Yes=1)	.12

Cluster methods

While K-means is often regarded as the most widely used cluster method, it can only handle numerical data [15]. Though categorical data can be transformed through techniques such as one-hot encoding, important information may be lost in the process. Another commonly used cluster method, K-modes, can only handle categorical data, and similarly, while we can condense numerical attributes into categorical ones, how the intervals are defined is also in question. Therefore, to handle the mixed data type we have, we choose the K-prototypes algorithm. To validate the resulting clusters produced by the K-prototypes algorithm, we used PAM on the same dataset. For each attribute, we performed the Kruskal-Wallace test to see if there exists any statistically significant difference across the three clusters. To sketch an overview of the subgroup characteristics, we combined several sub-categories, for instance, for tobacco use, "never" and "former" are combined to be "no". Since cluster analysis is unsupervised, we do not know how much natural clusters exist in the dataset. Therefore, we computed the Silhouette coefficient as well as the gap statistics to decide how many clusters we should expect from our dataset.

K-prototypes

K-prototype was first proposed by Huang in 1998 [16]. It differs from k-modes in that k-prototypes allow clustering of datasets with mixed data attributes, utilizing a combined dissimilarity measure. Another feature of K-prototypes is that for each resulting cluster, the algorithm returns a real data point from the original dataset as the "prototype" or the representation of the cluster. Cluster methods such as K-means usually return an averaged centroid instead of a real data point.

PAM

PAM, also known as the k-medoids algorithm, clusters data according to medoids [17]. The user inputs the desired number of clusters and the algorithm selects a random set of k items to be the set of starting medoids. Then, the algorithm constructs clusters by iterating through the remaining observations and assigning them to the "closest" medoids. "Closeness" in a PAM analysis is determined by a distance function. Euclidean distance is frequently used in k-means and similar clustering techniques where the data being clustered is entirely continuous. However, because our dataset contains several categorical variables, we used Gower distance, which is capable of handling dichotomous, continuous, and categorical data [18].

Optimal number of clusters: The Silhouette Coefficient & The Gap Statistic

To select the optimal number of clusters to feed into PAM, we used silhouette width. Silhouettes allow users to visualize the quality of a specified number of clusters [19]. When the data has been partitioned in a manner that closely tracks the "natural" cluster, silhouette width is generally high. As Figure 1 shows, when there are 3 clusters, the Silhouette coefficient reaches the peak, which indicates that more natural clusters can be produced. The gap statistic is another way to decide the optimal number of clusters, which is illustrated in much detail in Tibshirani et al.'s paper [20]. Simply put, the higher the gap statistic is, the more natural the resulting clusters will be. Figure 2 shows the gap statistic where there are local peaks at $k = 3$ and $k = 5$. However, the Silhouette coefficient hits a local minima at $k = 5$ but peak at $k = 3$. Balancing the Silhouette coefficient and the Gap statistic, we decided to use $k = 3$ as the number of clusters for the following cluster analysis.

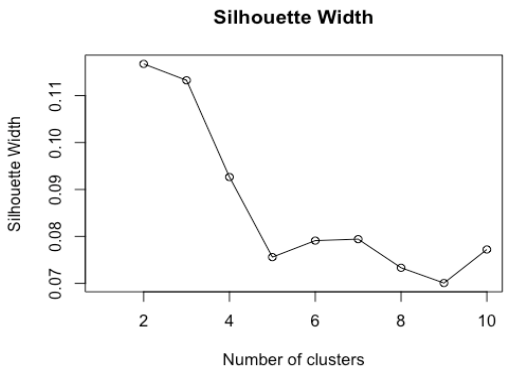

Figure 1 – The Silhouette Coefficient

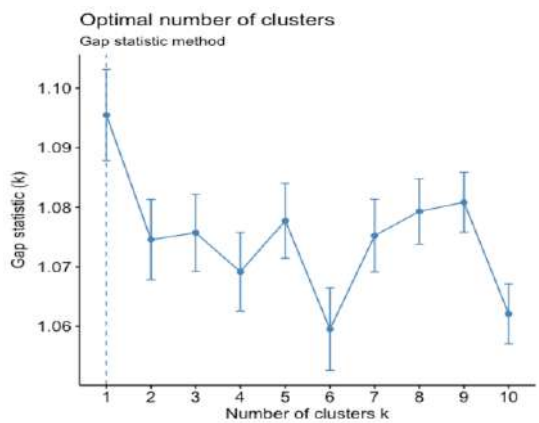

Figure 2 – The Gap statistic

Results

In Table 2, we present the demographical characteristics of the three clusters produced by K-prototypes and PAM. In Table 3, we present the medical history features of the subgroups. In Table 4, we present the health indicator features of the subgroups. The p-values of the Kruskal-Wallace test are marked next to each attribute. The results of K-prototypes are listed on the left of each column, and the results of PAM are on the right. For attributes that contain multiple categories, we only report the categories that are of the majority within the clusters.

Table 2 – Demographical features of subgroups (: p< 0.001)*

Attributes	Cluster 1		Cluster 2		Cluster 3	
Size	379	399	685	520	684	829
Gender* (Male=1)	.44	.64	.62	.73	.36	.24

Table 3 – Medical history features of subgroups

Attributes	Cluster 1		Cluster 2		Cluster 3	
Size	379	399	685	520	684	829
Cancer* (Yes=1)	.38	.37	.16	.09	.09	.14
Diabetes* (Yes=1)	.28	.24	.18	.13	.07	.14
Mental illness* (Yes=1)	.39	.37	.31	.37	.32	.29

Table 4 – Health indicators of subgroups

Attributes	Cluster 1		Cluster 2		Cluster 3	
Size	379	399	685	520	684	829
BMI	26.1	26.0	28.4	27.8	28.0	28.6
HR*	84.3	87.8	87.4	92.7	98.9	92.0
RR*	17.9	17.9	17.8	17.8	17.9	17.9
TempC*	36.8	36.8	36.8	36.8	36.9	36.9
SpO2*	97.3	97.4	98.0	98.0	98.4	98.3
Binge Drinking (Yes=1)*	.27	.23	.49	.83	.30	.28
Tobacco Use (Yes=1)*	.10	.07	.37	.70	.32	.12
Substance Abuse (Yes=1)*	.06	.07	.15	.25	.13	.07

Next, we summarize and describe the distinguishable characteristics of the three subgroups that have emerged from the cluster analysis. The two algorithms seem to diverge in deciding the Binge Drinking and Tobacco Use categories for cluster 2, but if we compare them across different subgroups, they still remain meaningful. Overall we observed differences that are statistically significant across the three groups through the Kruskal-Wallace test.

The Elderly Subgroup

The two cluster algorithms all clearly identified the elderly subgroup, whose members have an averaged age of 67.1~72.9. More than 62% of this subgroups are retired and primarily white. Members in the elderly subgroup also have relatively healthy habits and normal BMI, with the highest proportion (73%~77%) that has never engaging in binge drinking, the highest proportion (90%~93%) of currently non-smokers, and the highest proportion (93%~94%) without substance abuse problems. However, the elderly subgroup has a larger proportion that have cancer (38%) and diabetes (28%), compared to the middle-aged subgroup where the proportion of having cancer is 16% and diabetes is 18%, and the adult subgroup (where the proportion of having cancer is 9% and diabetes 7%).

The Middle-aged Subgroup

The largest proportion of the middle-aged subgroup are unemployed (76%) and male (62%~73%) with an averaged age of 44~49 years old. Compared to the elderly subgroup, the middle-aged subgroup has a lower proportion with cancer (16%) and diabetes (18%). However, the middle-aged subgroup has less healthy habits in general – 30%~66% are current tobacco smokers and 15%~25% have substance abuse issues, which are higher than the elderly subgroup (6%~7%). The

middle-aged subgroup also has higher BMI are considered as overweight concerning their age groups.

The Adult Subgroup

This subgroup consists of primarily unemployed (72%) females (64%~76%) that are generally below 40 years old (younger than the middle-aged subgroup). They have the least proportion of having cancer (9%) and diabetes (7%). Compared to the middle-aged subgroup, they have healthier habits – less proportion are current smokers (12%~32%) and only 7%~13% have substance abuse issues. This subgroup also has higher than average BMI and are considered obese concerning their age group.

Discussion

While the two algorithms have some slight discrepancies in deciding certain characteristics, many of their results are consistent. Comparing across the three subgroups, our findings are consistent with previous literature that older population, unemployed population and patients with mental illnesses are more likely to become frequent flyers. However, one significant contribution of our study is that the frequent flyer population consists of subgroups that are substantially different from each other. If only looking at a macro level, these subgroup characteristics may be easily obfuscated. For instance, the general characteristics such as chronic health conditions simply do not apply to all subgroups – the middle-aged subgroup and the adult subgroup seem to have other concerns that lead to their overuse of the ED resource. In addition, the adult subgroup that has the lowest proportion of having chronic health conditions and unhealthy behaviors also takes up a large part of the frequent flyer population, and reasons behind this are rarely explored in existing literature. More investigation needs to be done for the adult female subgroup in order to understand their concerns. Unemployment and burdens of child raising could be factors that contribute to this subgroup's overuse of ED resource. The elderly group who need to cope with chronic health conditions may have difficulty commuting to the right medical facility, and ED may be the most feasible choice in such situations. For the middle-aged male subgroup, less healthy behaviors such as binge drinking and substance abuse may play a bigger role in overusing the ED resource. Thus, simply implementing interventions that are built upon the general frequent flyer characteristics is not able to address the concerns faced by the those different subgroups. Hospitals may consider first investigate what subgroups of frequent flyers constitute the patient populations at their EDs, why certain subgroups are more likely to make repeated visits to EDs, and devise separate intervention programs that target at those subgroups to address their varying needs.

The frequent flyer population at different locations may differ significantly, and our study has suggested cluster analysis as a feasible and promising exploratory stage to understand which subgroups constitute their frequent flyer population at a particular site. Simply borrowing intervention programs from hospitals at different locations or of different settings may fail to suit the needs of the particular frequent flyer subgroup at one hospital.

Limitations and Future Work

Our analysis was based on the structured Electronic Health Records of patients at a single academic medical center, and therefore the results may not be generalizable to hospitals at other locations or of other settings. In addition, while our analysis was able to reveal the subgroups of the frequent flyer population of the study site, the data we used lacks the explanatory power to uncover why these three groups become frequent flyers of ED. It is our future work to extend the analysis to clinical notes that contain richer information of patients' visits.

Conclusions

We performed cluster analysis on 1748 frequent flyers at an academic Medical Center. Three subgroups with substantially different characteristics have emerged from our analysis: the elderly subgroup with chronic health conditions, the middle-aged male subgroup with unhealthy behaviors and the adult female subgroup that are generally healthy. Our findings suggested that the commonly used general characteristics may not apply to all subgroups and different subgroups may face varying challenges in reaching out the right medical resource. Our study sets the stage for more tailored subgroup-level interventions to reduce ED overuse in hospitals across the world.

Abstract

As the problem of drug abuse intensifies in the U.S., many studies that primarily utilize social media data, such as postings on Twitter, to study drug abuse-related activities use machine learning as a powerful tool for text classification and filtering. However, given the wide range of topics of Twitter users, tweets related to drug abuse are rare in most of the datasets. This imbalanced data remains a major issue in building effective tweet classifiers, and is especially obvious for studies that include abuse-related slang terms. In this study, we approach this problem by designing an ensemble deep learning model that leverages both word-level and character-level features to classify abuse-related tweets. Experiments are reported on a Twitter dataset, where we can configure the percentages of the two classes (abuse vs. non abuse) to simulate the data imbalance with different amplitudes. Results show that our ensemble deep learning models exhibit better performance than ensembles of traditional machine learning models, especially on heavily imbalanced datasets.

Introduction

Misuse and abuse of prescription drugs and of illicit drugs have been major public health problems in the United States for decades. A "Public Health Emergency" declared in 2016 [1] and several official surveys [2] all show that the problem has been getting worse in recent years. For example, the most recent reports from the National Survey on Drug Use and Health (NSDUH) [2] estimate that 10.6% of the total population of people ages 12 years and older (i.e., about 28.6 million people) have misused illicit drugs in 2016, which represents an increase of 0.5% over 2015. According to the Centers for Disease Control and Prevention (CDC), opioid drugs were involved in 42,249 known deaths in 2016 nationwide [3] . In addition, the number of heroin-related deaths has been increasing sharply over five years and has surpassed the number of firearm homicides in 2015 [4] . The emerging new problems, such as the epidemic of illicitly manufactured fentanyl (IMF) [5] , marijuana-related traffic accidents [6] , and marijuana use among adolescents [7] are posing further increasing threats to public health.

To fight this epidemic of drug abuse, methods of social media monitoring with wider scope and shorter response time are needed. Social media, such as Twitter, have been proven to be sufficient and reasonably reliable data sources for social-level detection and monitoring tasks [8] . Twitter is a popular social media platform that has 100 million daily active users and 500 million daily tweets [10] (messages posted by Twitter users), most of which are publicly accessible, on a wide range of topics.

We are using algorithms for filtering and classification for acquiring abuse-related tweets for analysis and monitoring. Filtering is the very first and most basic step toward extracting potentially useful tweets from the large number posted every day. Filtering, by itself, even with standard drug names (e.g. heroin), generally does not suffice to produce a dataset pure enough for practical use. Thus, machine learning classifiers have to be trained to further identify tweets that are related to drug abuse. However, most abuse-related Twitter datasets have the problem of imbalanced class distributions. Typical datasets, collected with only the names of drugs, may have 5% to 30% of positive (abuse-related) tweets, due to the topic diversity and language irregularity of tweets. The percentage of positive tweets decreases sharply when more keywords, especially slang names for drugs (e.g., snow) and abuse behavior keywords (e.g., snorting), are included in a tweet dataset. The imbalanced class distribution and the noisy nature of the Twitter data make it hard to train a classifier with good performance.

In this paper, we propose an ensemble of two types of deep learning-based methods as better options, among classifiers, for situations in which the collected data is inevitably imbalanced, because they are more robust than traditional machine learning models. Our ensemble deep learning model combines word-level CNN models and character-level CNN models to perform classification. We compare our models with baseline models on a dataset we collected, where we can configure the class distribution of positive versus negative tweets in the training data and test data. By changing the percentage of positively and negatively labeled data in the dataset, we can simulate the imbalanced datasets that were collected by different means. We validate the performance of different models in a variety of settings to gain a clearer picture of how imbalanced data affect classification performance.

Related Works

Large scale surveys, such as NSDUH [2] , Monitoring the Future [11] , the MedWatch program [12] , and the results derived from these surveys [13] , clearly show that there is an epidemic of drug abuse across the United States. However, a recent report [14] states that the estimated number of deaths due to prescription drugs could be inflated due to the difficulties in determining whether a drug is obtained by prescription or not. We assert that the ambiguities highlighted in this new report raise questions about the reliability of the earlier surveys,

and thus, such a report illustrates the potential value of social media-based studies.

In fact, several studies found positive correlations between Twitter data and real world data. Chary et al. [15] performed semantic analysis on 3.6 million tweets with 5% labeled and found significant agreement with the NSDUH data. Hanson et al. [16] conducted a quantitative analysis on 213,633 tweets discussing Adderall, and found positive geo-temporal correlations. Furthermore, Shutler et al. [17] performed a qualitative analysis of prescription opioid-related tweets and found that indications of abuse were common. On the other hand, several studies focused on designing machine learning models to preform tweet classification. Mahata et al. [18] performed a comprehensive study on using deep learning models to identify mentions of drug intake in tweets. Katsuki et al. [20] trained support vector machine (SVM) on a dataset of 1,000 tweets for classification of tweets for relevance and favorability of online drug sales. Hu et al. [19] showed the potential of applying deep learning models in a drug abuse monitoring system to detect abuse-related tweets. Sarker et al. [9] proposed an ensemble of traditional machine learning models to classify drug abuse tweets and non-abuse tweets of certain drugs. Other studies focus on social media users, such as Fan's work [26] utilizes user interaction networks to identify opioid users on Twitter. In this paper, we will be developing ensemble deep learning models to expand the classification of tweets to a border scope of drugs and their abuse behaviors with better performance in the unbalanced class distribution settings.

Methods

In this section, we present the definition of the *drug abuse-related risk behavior detection problem*, our methods for collecting tweets, our methods for labeling tweets, and our ensemble deep learning approach.

Problem Definition

In this paper, our first goal was to build a Twitter dataset consisting of tweets that are related to drug abuse risk behaviors (**positive** tweets), and tweets that are not (**negative** tweets). The "drugs" in the term "drug abuse risk behaviors" in this study include Schedule 1 and Schedule 2 drugs and their derivatives [21] , including marijuana, heroin, cocaine, fentanyl, etc. The reasons we included *marijuana* even though it is legalized in several states are that: **(1)** Marijuana is still a controlled substance in the federal law, whether for medical use or recreational use; and **(2)** Marijuana can still cause harm to adolescents [7] , can cause "use disorder" [13] , and is related to traffic fatalities [6] . The term "abuse risk behavior" can be defined as "The existence of likely abusive activities, consequences, and endorsements of drugs." Tweets that contain links to or summarize news and reports related to drug abuse, and tweets that merely express opinions about drug abuse, are counted as negative in this study. Our main goal in this paper is to train a model that can accurately classify positive and negative tweets in a highly imbalanced (drug abuse) dataset.

Data Collection

Although there are human-labeled drug abuse Twitter datasets (e.g. Sarker's dataset [9]) available, due to Twitter's data policy, which prohibits the direct sharing of tweet contents, by the time we access the tweets in that dataset, more than 40% of tweets are either removed or hidden from the public. This significantly affects the quality and integrity of existing publicly available datasets. Therefore, we need to build a new dataset from scratch. In our framework, raw tweets are collected through a set of Application Programming Interfaces (Twitter APIs) via keyword filtering. By defining a set of keywords, the API will fetch tweets that contain any of the keywords from either the real-time stream of tweets or from archived tweets. For a more complete coverage of drug-related topics, we selected three types of keywords: **(1)** Full and official names of drugs, e.g. marijuana, cocaine, OxyContin, fentanyl, etc.; **(2)** Slang terms for drugs, e.g. pot, blunt, coke, crack, smack, etc.; and **(3)** Drug abuse-related behaviors and symptoms, e.g., high, amped, addicted, headache, dizzy, etc. The number of keywords we used is limited to 400 by the Twitter APIs.

Data Annotation

We built a comprehensive guide, accessable at **https://goo.gl/tqWddS**, based on Sarker's guide [9] . Each one of the three members in our research team with experience in health informatics annotated the 1,794 tweets from Hu et al.'s study [19] independently following the guide. A final label for each seed tweet is determined by majority voting from the three labels.

To acquire annotated tweets rapidly, at low cost, and with increased percentage of positive tweets, we **(1)** used these labeled tweets as *"seed"* tweets to train a SVM classifier; **(2)** ran the SVM classifier on the unlabeled dataset, and randomly sampled 5,000 machine labeled tweets that have a prediction probability (esitmated with Platt scaling) > 0.8; and **(3)** posted the 5,000 tweets (without identification information) onto the Amazon Mechanical Turk (AMT) crowdsourcing platform for annotation. AMT is a well-known crowdsourcing platform where Posters can post Human Intelligence Tasks (HITs) and Workers finish HITs for micro-payments. A literature study [22] evaluated AMT as a thrustworthy platform to obtain human labeled data. The same guide is used to guide the Workers on how to annotate the tweets. Each tweet is posted as one HIT that requires the Worker to label it as positive or negative following the guide. Each HIT is replicated as three *assignments* to be completed by three individual Workers. We set the price of each assignment to be $0.05, a very generous price compared to what was reported in Buhrmester's work [22] All HITs are completed within hours after being posted. The final label of each tweet is aggregated from the three labels by majority voting. We also label 1,000 tweets randomly sampled from the 5,000 tweets with our annotator as a measure of quality check.

Feature Extraction

Machine learning models require numerical features to work. Feature extraction transforms text features into numerical features in the form of vectors. To cover the content ambiguity in drug abuse-related tweets, a variety of feature extraction methods are used in this study. In our word-level, CNN models, we use pre-trained word embedding models that were trained on large corpora to transform words into dense vectors. We tested several pre-trained models as Mahata's work [18] suggested. With our word-level CNN model, the *Drug Chatter* embedding had the best average performance on our dataset; thus, it was chosen as the pre-trained, word embedding model for this study. The details of the tested, word embedding models are shown in Table 1. Each tweet is converted to a sequence of 400-dimensional vectors. Considering that the length limit of each tweet nowadays is 280 characters, the sequence length is set to 40. In our char-level CNN, the preprocessing step only turns all characters to lower case as suggested by [23] . Each char. is then converted into a 128-dimensional trainable

randomly-initialized vector. Instead of being fixed, the character embeddings are trained along with other layers in the model.

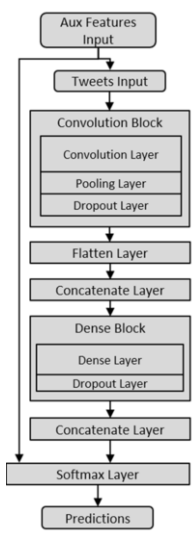
Table 1. Details of Pre-Trained Word Embedding

Name	Model	Corpus	Dimension
GoogleNews	Word2vec	~100 billion words	300
Glove Common	Glove	~42 billion words	300
Godin	Word2vec	~400 million tweets	400
Drug Chatter	Word2vec	~1 billion tweets	400

We also replicated the features extracted in Sarker et al. study [9] , including: **(1)** The tokenization process; **(2)** The abuse-indicating term features, consisting of the presence and the counts of abuse-indicating terms obtained from Hanson et al. [16] ; **(3)** The drug-slang lexicon features, consisting of the presence and the counts of terms longer than five characters found in an online drug abuse dictionary [24] ; **(4)** The word cluster features, represented by 150-dimensional one-hot vectors, were constructed by identifying words that belong to certain word clusters in a dataset [9] that contains 150 drug-related word clusters; and **(5)** The synonym expansion features, accomplished by identifying all synonyms of all nouns, verbs, and adjectives in the tokenized tweets using WordNet [25] .

An Ensemble Deep Learning Model for Drug Abuse Detection in Sparse Twitter-Sphere

In this section, we present our novel, ensemble deep learning model for drug abuse risk behavior detection by integrating extracted features from tweets into CNN models. Our ensemble model takes the outputs of multiple prediction models, word-level CNN (**W-CNN**) and char-level CNN (**C-CNN**) [29] in our case, and feed them to a meta-learner that provides the final predictions. We designed W-CNN and C-CNN for this task. In fact, both the W-CNN and the C-CNN share a similar structure as shown in Figure 1.



Input Parameters

Parameter	W-CNN	C-CNN
tweet input dimension	[40,400]	[280,128]
aux feature dimension	[154,]	[154,]

Convolution Block Parameters

Parameter	W-CNN	C-CNN
kernel width	{2,3,4,5}	{3,5,7,10}
# kernels	128 for each kernel width	256 for each kernel width
activation function	Relu	Tanh
pooling	MaxPooling	GloablMax-Pooling
dropout	Uniform-Dropout with rate=0.1	Alpha-Dropout with rate=0.1
# blocks	2	1

Dense Block Parameters

Parameter	W-CNN	C-CNN
# hidden units	1024	1024
activation function	Relu	Selu
dropout	Uniform-Dropout with rate=0.5	Uniform-Dropout with rate=0.5
# blocks	2	2

Figure 1. Ensemble CNN Model Structures

The inputs of our W-CNN are vectors of shape [40, 400] where 40 is the maximum sequence length (number of words allowed) in an input tweet, and 400 is the length of the pre-trained word embeddings. The input of our C-CNN is shaped as [280, 128] where 280 is the maximum possible length of a tweet, and 128 is the length of the vector representation of each character in the charset. The auxiliary features in the input include: **(1)** The synonym expansion features in the form of synonymous words are directly concatenated with the input tweets (before they are transformed into vectors); and **(2)** The remaining auxiliary features, in the form of 154-dimensional vectors, are concatenated to the last hidden layer of the dense layers. For each convolution kernel size, the W-CNN model has two convolution layers with ReLU activation functions stacked together. Each is followed by a max-pooling layer.

The C-CNN model has one convolution layer for each convolution kernel size with Tanh activation function, followed by a global-max-pooling layer that performs max-pooling over all outputs of convolution layers with different kernel sizes. Both models have one dense layer block, consisting of two dense layers with 1,024 hidden units each, and one Softmax output layer with two units. The activation functions are slightly different, as the W-CNN model uses ReLU, while the C-CNN model uses SELU. The output of the last hidden layer is concatenated with vectors of abuse-indicating term features, drug-slang lexicon features, and word cluster features, before being fed into the output layer.

Finally, a number of independently trained CNN models of both types are ensembled together by using majority. Model ensembles were also used in Sarker et al. study [9] to reduce variability and bias, in order to improve prediction performance. We apply the same ensemble strategy to both our deep learning models and the baseline models.

Experimental Design

Our main objective in this experiment was to directly compare the performances of the ensemble traditional machine learning model and the ensemble deep learning model. For the ensemble traditional machine learning model, two of each type of baseline models, six in total, are trained and ensembled together. For the ensemble deep learning model, six models of three types (two for each type) are used. The three types are denoted as follows. **(1)** "*char_aux*" is the char-level CNN model with auxiliary features. **(2)** "*char_cnn*" is the plain char-level CNN without any auxiliary features. **(3)** "*word_aux*" is the word-level CNN model with all auxiliary features. For deep learning models, it is extremely easy to overfit, due to the rather small number of training and test data elements; thus, the model is saved at each training epoch, and the best epoch is found among the saved models. For each class distribution scenario, each model is trained with the same six sets of training data and tested on the corresponding test data. All results reported are averaged results from the 6-fold cross-validation.

Experimental Results

Data Annotation Results

From Jan 2017 to Feb 2017, we collected 3,265,153 tweets in total. The *"seed"* dataset that we annotated to be used to train the pre-filter consisted of 1,794 tweets, including 280 positive labels and 1,514 negative labels. Our annotator achieved the agreement score of 0.414, measured by Krippendoff's Alpha. For the AMT labeled dataset, we removed duplicate tweets from it, with a resulting dataset containing 4,736 tweets with 2,657 positive labels and 2,079 negative labels. The agreement score is 0.456 measured by Alpha, which can be considered as a reliable result in our study as demostrated in [27] , since: **(1)** We are performing data annotation with data aggregation to reduce variability, instead of typical content analysis [28]; **(2)**

The Krippendoff's Alpha is sensitive to data imbalance; and **(3)** We focus on sparse and imbalanced data distributions. For the 1,000 tweets for quality check, we received the Kappa score of 0.910 between our final labels and the labels we obtained from AMT. This is showing that our annotation guide was followed consistently by both our annotators and AMT Workers.

To simulate the data imbalance scenarios, we configured the class distribution and pre-sampled the dataset into six blocks for each distribution scenario, for 6-fold cross-validation. Each model was trained and tested on the same sets of training and test data to ensure a fair comparison. The number of data points included in each distribution scenario was maximized, but it was inevitably different between scenarios. Table 2 shows the dataset in each class distribution scenario.

Table 2. Dataset Variants

Class distribution (positive: negative)	# of training data items	# of test data items
50:50 split	3450	690
40:60 split	2850	570
30:70 split	2450	490
20:80 split	2150	430
10:90 split	1900	380

Drug Abuse Detection Results

Table 3 shows the results for all individual models and two ensemble models. The ensemble model results are separated from the individual models for easier viewing. The highest value of each measure is marked in bold font. There is an interesting trend in the results of the ensemble models. When the data is balanced or nearly balanced, the traditional ensemble machine learning model has a better performance than the ensemble deep learning model. At 50:50 and 40:60 splits, the ensemble machine learning model is superior over the ensemble deep learning model for most of the criteria. This is partially due to the relatively small dataset size. When the data becomes more imbalanced, e.g., at a 30:70 split, the ensemble deep learning model becomes better and has a higher F1-score for positive labels, compared with the traditional ensemble machine learning model. At 20:80 and 10:90 splits, the ensemble deep learning model takes the lead, most significantly in each measure for positive labels. The larger model capacity and the ability of the deep learning models to learn more complex non-linear functions, can better distinguish the semantic differences between positive tweets and negative tweets, when the distribution of classes is heavily imbalanced.

Looking at individual machine learning models, Random Forest and SVM showed a strong performance on all datasets, and they perform well when the dataset is balanced. Naïve Bayes also has a good performance on a balanced dataset, but on an imbalanced dataset, it is heavily biased towards negative labels and has a poor performance for positive labels. Deep learning models generally have more stable performance, compared to traditional machine learning models, across all datasets, and a smaller difference between precision and recall, but their peak performances are not as good. Comparing between deep learning models, auxiliary features do not provide C-CNN significant performance boost, and W-CNN performed worse than the C-CNN model. However, in additional results that are not shown in this paper due to space limitations, auxiliary features give the plain W-CNN model a performance boost.

By investigating the performance of each individual model and the ensemble model that includes it, we can see that our ensemble strategy works well for deep learning models, as most

of the measures for the ensemble model are higher than for any of its components corresponding measures. This effect was only observed a few times for traditional machine learning models. We expect that, by using more complicated ensemble strategies, deep learning has the potential to reach an even better performance level.

Conclusions

In this study, we investigated how the data imbalance issue influences the performance of classifiers that are trained for identifying tweets that are related to drug abuse. We first collected a dataset with a broad selection of drug abuse-related keywords and slang terms. We explored the use of the Amazon Mechanical Turk platform as a reliable source for acquiring human-labeled tweets, and we obtained a solid dataset. We designed an ensemble deep learning classification model with both word-level and char-level CNNs, and we conducted a direct comparison with traditional machine learning models on our dataset, with simulated class imbalance. Experimental results show that our ensemble deep learning models have better performance than traditional machine learning models when the data is off-balance. Results also show that the ensemble strategy we used is effective for improving deep learning models. Finally, our analysis of the collected three million tweets, labeled by our model, shows an interesting temporal pattern that agrees with our intuition.

Abstract

Early detection of Alzheimer's disease (AD) has become increasingly important. Healthy monitoring technology focusing on behavioral changes is a promising approach in this vein. Among such technologies, handwriting features measured by digital tablet devices have attracted attention as potential indicators for detecting AD and mild cognitive impairment (MCI). However, previous studies have mainly investigated features in single tasks, and it remains unclear whether combining the features of multiple tasks could improve the performance of detecting AD and MCI. In this study, we investigated features in five representative tasks used in neuropsychological tests collected from 71 seniors including some diagnosed with MCI and AD. We found that our three-class classification model improved diagnosis accuracy by up to 11.3% by combining features of multiple tasks, for a final accuracy of 74.6%. We also suggested that drawing behaviors during multiple tasks might be useful for estimating disease progression simply by utilizing the labels of disease groups.

Keywords:

Dementia, Handwriting, Classification

Introduction

As the world's elderly population increases, the number of people living with dementia is rising rapidly, making dementia an increasingly serious health and social problem. According to a previous survey, around 47 million people globally were living with dementia as of 2015, corresponding to about 7.6% of the world's over-65-year-olds [1]. At the same time, diagnostic coverage worldwide remains low and dementia is often undiagnosed. Even in high-income countries, only 40–50% of dementia sufferers have received a diagnosis [2, 3]. The low diagnosis coverage makes it difficult for many patients and their families to receive appropriate support and care. In addition, while dementia affects the individuals with the disease, it also affects their supporters—including relatives and the wider society—because people with dementia require constant and costly care for years. In fact, healthcare costs have risen significantly, reaching over $818 billion USD in 2015, and this figure is estimated to rise to $2 trillion USD by 2030 [4]. One strategy to reduce some of this cost is early intervention at the mild cognitive impairment (MCI) or preclinical stages. In fact, longitudinal studies suggest the possibility of early intervention at the MCI stage to reduce the progression to dementia [5]. An intervention that could delay the onset of Alzheimer's disease (AD) by five years is estimated to result in a 57% reduction in the number of AD patients and to reduce 45% of the projected Medicare costs [6].

Health monitoring technology focusing on behavioral features is expected to help improve diagnosis coverage and to detect AD at an earlier stage by expanding opportunities for receiving assessment from the clinical setting to more varied situations including everyday situations. For example, previous lab studies have suggested that behavioral features in gait, speech, and eye movement can be useful indicators for identifying AD and MCI [7]. Being able to infer AD and MCI from these behaviors with better accuracy and wider applicability would be tremendously useful.

One promising behavior to explore is drawing behavior. An advantage of this approach is ease of data collection brought about by the popularization of portable devices such as tablets and smartphones. Drawing behavior assessments such as the Clock Drawing Test (CDT) [8] and the Trail Making Test (TMT) [9] have proven useful for measuring cognitive decline and detecting AD and are commonly used in conventional in-clinic neuropsychological tests. Recent research on drawing behaviors using tablet devices has shown the possibility of automatic detection of patients with cognitive or motor impairments [10–22]. For example, [10] extracted pressure and kinematic features during several tasks including the CDT, while [11] investigated frequencies, velocities, and temporal features during a variant of the TMT. These features have been shown as differentiating healthy subjects and AD patients. Although previous studies have demonstrated how we can build a model for detecting AD and/or MCI by using behavioral features during individual drawing tasks, whether and how we can improve the model performance by combining behavioral features during multiple tasks remains unexplored. In addition, most of these studies focused on developing a classification model for differentiating patients with MCI and AD. Being capable of inferring disease progression on a scalar or ordinal scale defined by in-clinic cognitive assessment scores or biomarkers such as amyloid beta and tau deposition would extend the scope of application, for example, through visualization of the effects of intervention and prevention.

In this study, we investigated drawing behaviors during five representative tasks used in in-clinic neuropsychological tests collected from 71 Japanese seniors including some diganosed with MCI and AD. We extracted a series of drawing behavioral features including pressure, velocity, acceleration, jerk, and in-air and on-screen durations and then built a three-class classification model to distinguish healthy controls (HCs), patients with MCI, and patients with AD. Through

Table 1 – Demographics of participants.

Status	No. of participants (Female)	Mean age (SD)	Mean MMSE score (SD)
HC	36 (21)	70.0 (5.0)	28.3 (1.5)
MCI	25 (15)	75.9 (5.3)	26.8 (3.1)
AD	10 (7)	76.7 (6.0)	18.8 (3.9)

comparison, we found that the model using features in all five tasks could improve accuracy by up to 11.3% by combining the features of multiple tasks, achieving a final accuracy of 74.6% (chance rate 40%). We next investigated using the model for inferring disease progression on a continuous scale. Specifically, we first trained our model to differentiate three groups using only drawing features and disease labels (HC, MCI, and AD), and then we investigated whether the model could estimate in-clinic cognitive assessment scores. The results showed that the scores estimated by the model were significantly correlated with in-clinic cognitive assessment scores, even though we did not use the assessment scores themselves. These results indicate that our approach focusing on drawing behaviors during multiple tasks might be useful for inferring AD progression.

Materials and Methods

Participants

A total of 71 participants were enrolled by the University of Tsukuba Hospital. Ten participants were patients with AD, 25 were patients with MCI, and 36 were HCs. All participants were evaluated with the Mini-Mental State Examination (MMSE), a screening measure of global cognitive functioning [23]. Table 1 shows the number of participants (female), mean age, and mean MMSE score for the HC, MCI, and AD groups.

None of the participants in the HC group were diagnosed as having MCI or dementia before the experiment. The definitions of the MCI and AD groups were based on diagnosis by psychiatrists through medical examinations including structural magnetic resonance imaging, blood tests, and neuropsychological tests. More specifically, the doctors followed the guidelines and criteria in [24] for MCI and [25] for AD. Informed consent was obtained from all participants in accordance with a procedure by the ethics committee, the University of Tsukuba Hospital (H29-65).

Apparatus

A digital drawing tablet (Wacom Cintiq Pro 16) was used to acquire handwriting movements. The detailed specifications of the tablet are as follows: external dimensions (width × depth × height) 410 × 265 × 17.5 mm, spatial resolution 3840 × 2160 dots, pixel size 0.090 × 0.090 mm, temporal resolution 30 ms, and pressure levels 8,192.

The data include 3D coordinates (x, y, z) and the pressure of the pen-tip, altitude and azimuth of the pen, a binary variable (1 for writing state and 2 for erasing state), and timestamp.

When the stylus touches the start button, the software starts acquiring the data, and a black line reproducing the written trace appears. Thus, participants can monitor in real-time what they are writing.

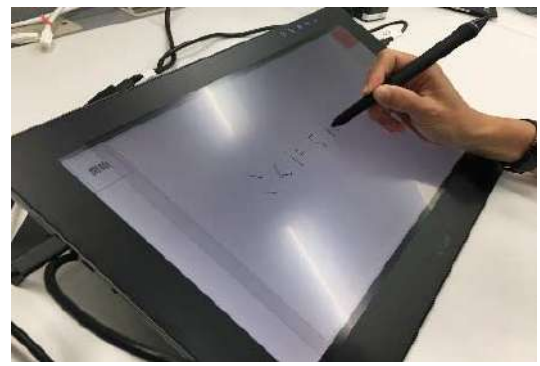

Figure 1 – Example of writing a spontaneous sentence.

Experimental procedure

Participants were seated on a chair with the digital tablet placed on a desk and could freely adjust the position of the device. Each participant was asked to perform five tasks:

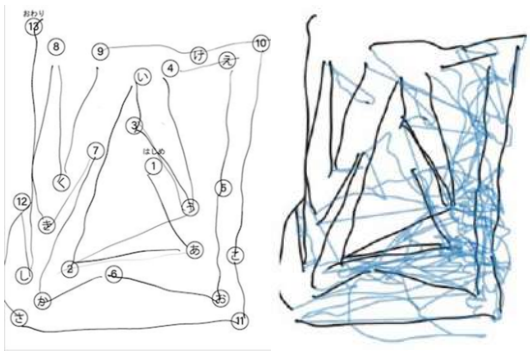
1. Writing spontaneous sentences. This task is included in the Mini-Mental State Examination (MMSE) [23]. Paticipants are asked to write any complete sentences on a sheet.
2. Drawing crossed pentagons. This is also a part of the MMSE. At first, participants see a figure of two intersecting pengagons. Then they are asked to draw the same figure as shown on a sheet.
3. Trail Making Test (TMT) part A. This task requires participants to draw lines connecting consecutive numbers randomly distributed on a sheet [9].
4. TMT part B. This is similar to the TMT part A, but instead of just linking numbers, participants are required to draw lines connecting numbers and letters alternately in their respective sequence [9].
5. Clock Drawing Test. This test asks participants to draw an analog clock-face showing 10 minutes after 10 on a blank sheet [8].

Figure 1 shows an example of writing a spontanous sentence on our tablet device.

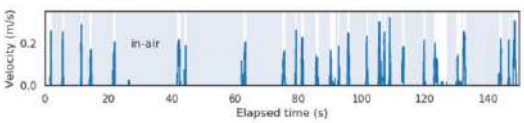
Data analysis

Pressure profiles were obtained from the apparatus as a raw dataset. Numbers of segments were counted to characterize the handwriting behaviors. As kinematic parameters, velocity (m/s), acceleration (m/s^2), and jerk (m/s^3) of the pen-tip movements over the 2D coordinates (x, y) on the tablet surface were computed. The durations (s) of on-screen and in-air stylus pen movements were considered as timing parameters. Figures 2 and 3 show examples of the handwriting behavioral features.

After completion of all five tasks, a three-class classification analysis using the handwriting parameters calculated to distinguish HC, MCI, and AD was performed. To investigate whether the model can be used to estimate in-clinic cognitive assessment scores, correlation analysis between MMSE scores and our model scores was also conducted.



(a) Left: final outcome and right: extracted on-screen (black) and in-air (blue) trajectories



(b) On-screen pen-tip velocity and in-air duration (shaded area)

Results

Three-class classification models

On the basis of the extracted handwriting features, classification analysis using a generalized linear model with a logit link function was performed. In order to differentiate HC, MCI, and AD, we assigned 0, 1, and 2 as targeted values, respectively. Explanatory variables were selected by means of a stepwise method to optimize the Akaike's Information Criterion (AIC). We evaluated three-class classification performances of the models using features of single tasks and all tasks.

Tables 2 and 3 show the accuracy and the selected features of the resultant classification models. As shown, the model that used features of all tasks improved the diagnosis accuracy by up to 11.3% and achieved an accuracy of 74.6% (chance rate 40%). The classification performance of this best model is presented in Table 4.

Table 2 – Classification performance.

Tasks	Accuracy (%)
MMSE sentences	67.6
MMSE pentagons	66.2
TMT part A	69.0
TMT part B	63.3
CDT	67.6
All tasks	74.6

Table 3 – Selected variables in classification models.

Tasks	Selected variables
MMSE sentences	Age, mean velocity, and mean pressure
MMSE pentagons	Age, mean pressure, CV of pressure, in-air duration, and mean velocity
TMT part A	Age, in-air duration, and CV of acceleration
TMT part B	Age, CV of pressure, CV of jerk, and on-screren duration
CDT	Age, number of segments, in-air duration, and CV of jerk
All tasks	Mean velocity and mean pressure (MMSE sentences), mean pressure (MMSE pentagons), on-screen duration (TMT part A), CV of pressure (TMT part B), and number of segments, in-air duration, and mean pressure (CDT)

Table 4 – Classification performance of the model using features from all tasks.

		Actual		
		HC	MCI	AD
Estimated	HC	35	11	1
	MCI	1	10	1
	AD	0	4	8

Estimation of in-clinic cognitive assessment scores from the classification models

We next investigated whether the three-class classification model could estimate in-clinic cognitive assessment scores. Specifically, we explored the relationship between a parameter in the classification model and the MMSE score.

The generalized linear model with the logit link function estimates a continuous and ordinal score that can be interpreted as a probability parameter of a Bernoulli trial. Here, we may regard this as a predicted disease progression score of AD. A correlation analysis was performed between the disease progression scores predicted with the models and the MMSE scores. According to the Pearson's correlation coefficients, our predicted disease progression score obtained from the model combining features of multiple tasks was most strongly correlated with the MMSE scores among all models ($r = -0.70$, Table 5).

Figure 4 shows the best predicted scores according to the labels of the groups. Figure 5 indicates the relationship between the best predicted scores and MMSE scores.

Table 5 – Pearson's correlation coefficients between predicted disease progression scores and MMSE scores.

Tasks	*r*	*p*-value
MMSE sentences	–0.38	$<1.0 \times 10^{-3}$
MMSE pentagons	–0.51	$<1.0 \times 10^{-5}$
TMT part A	–0.59	$<1.0 \times 10^{-7}$
TMT part B	–0.60	$<1.0 \times 10^{-7}$
CDT	–0.65	$<1.0 \times 10^{-9}$
All tasks	–0.70	$<1.0 \times 10^{-11}$

Discussion

As stated in the introduction, healthy monitoring technology focusing on behavioral changes has shown promise for early detection of AD. Among these technologies, handwriting behaviors measured by digital tablet devices are attracting attention as potentially useful indicators. The objectives of the present study were to investigate the effectiveness of combining behavioral features of multiple drawing tasks for detecting AD and MCI and the possibility of estimating disease progression by using such features. We collected and analyzed a series of behavioral features of five representative handwriting tasks used in MMSE, TMT, and CDT from 71 participants including some diagnosed with MCI and AD.

First, although the selected predictive features in our analysis were different depending on the tasks, we found tendencies that features relating to fine motor controls such as velocity, acceleration, and pressure were selected for the MMSE tasks and features relating to attention or cognitive performances such as durations and number of segments were selected for the TMT and the CDT. These results may reflect the characteristics of the different tasks and suggest that exploiting the combined features of multiple tasks may improve the performance of predictive models. We demonstrated that our three-class classification model combining features of multiple tasks improved the accuracy.

Next, we demonstrated that the classification model can also estimate in-clinic cognitive assessment scores via correlation analysis between the model estimated score that can be regarded as a predicted disease progression and the MMSE assessment score. It should be noted that the predicted disease progression scores were obtained just from the labels of disease groups and behavioral features without any progression measures. A more accurate validation of disease progression might require biomarkers such as amyloid beta in the brain and tau in cerebrospinal fluid (CSF), especially when we attempt to build a model for detecting patients at the preclinical AD stage. It would be difficult or impossible to use these biomarkers for training a model, considering the cost and/or invasiveness for assessing positron emission tomography (PET) and CSF. Our approach, which attempts to predict the level of disease progression by using just disease stage information instead of these biomarkers, should reduce the amount of required sample data (e.g., just validation data would be needed).

Some limitations exist in this study. First, since the number of participants was relatively small, generalizability of our results may be limited. Further study with a larger number of participants is our future work. Second, we evaluated the handwriting features using just disease labels and neuropsychological assessment scores. Further study is needed to investigate whether our model for estimating scores can predict known biomarkers for AD such as amyloid beta and tau deposition.

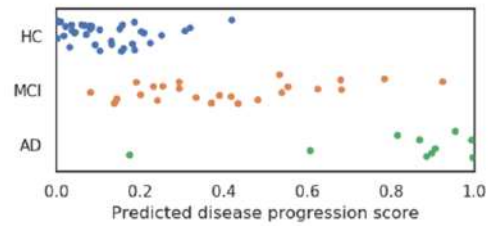

Figure 4 – Strip plot of predicted disease progression scores obtained from model combining multiple tasks.

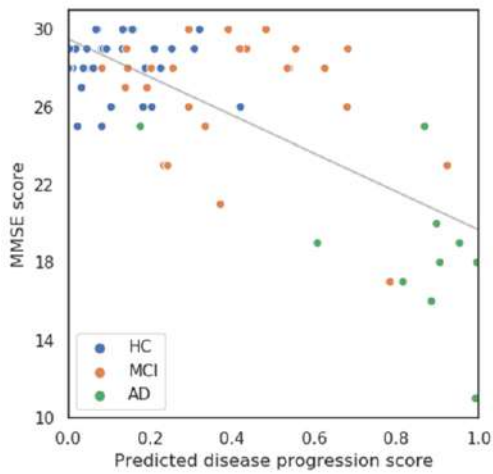

Figure 5 – Scatter plot with the line of best fit between the predicted disease progression scores obtained from the model combining multiple tasks and MMSE score.

Abstract

Frequent utilization of the Intensive Care Unit (ICU) is associated with higher costs and decreased availability for patients who urgently need it. Common risk assessment tool, like the ASA score, lack objectivity and do account only for some influencing parameters. The aim of our study was (1) to develop a reliable machine learning model predicting ICU admission risk after elective surgery, and (2) to implement it in a clinical workflow. We used electronic medical records from more than 61,000 patients for modelling. A random forest model outperformed other methods with an area under the curve of 0.91 in the retrospective test set. In the prospective implementation, the model achieved a sensitivity of 73.3% and a specificity of 80.8%. Further research is essential to determine physicians' attitudes to machine learning models and assess the long term improvement of ICU management.

Electronic health records; Intensive care units; Machine learning

Introduction

In the last decade there has been a distinct increase in life expectancy among the older population that is accompanied by a progression in morbidity rate. For this reason many patients need the specialised health care facility that is offered by an Intensive Care Unit (ICU). Intensive care beds in Austria comprise a higher proportion of total hospital beds in comparison to other European countries. As the availability of this resource varies throughout time, a constant analysis of appropriateness of ICU use is needed [1]. Moreover, frequent utilization of the ICU does not decrease hospital mortality, but is associated with higher costs and decreases the access for those patients who may profit more from the intensivists' expertize [2]. Therefore, patients likely to benefit from ICU admission and those who are at risk for severe postoperative illness have to be identified preventively.

The most common method used to stratify preoperative risk in anaesthesia is the "American Society of Anaesthesiologists – Physical Status (ASA) tool". This world-wide used instrument allows classifying and grading the physical condition of a patient before surgery. It allows estimating possible intraoperative and postoperative anaesthetic complications associated with the patient's preoperative condition. However, one of the disadvantages of the ASA tool is its subjectivity that may lead to only moderate inter-rater reliability when comparing ASA scores estimated by two physicians for the same patient [2].

In a recent published paper, Chan et al. combined the ASA score with electronic medical records (EMR) into the CARES model to predict the need for ICU admission postoperatively [3]. They extracted routinely collected EMR data of more than 90,000 patients and developed a multivariable regression model. The CARES model outperformed the ASA score in the prediction results with an area under the receiver-operating characteristic curve (AUROC) of 0.84 (0.81 - 0.87). However, their final model was based on seven variables only, including the ASA score and a surgical risk classification parameter.

Considering the increasing amount of available health care data, models based on machine learning (ML) are becoming an alternative way for risk prediction. Through ML methods, more variables can be evaluated for the purpose of generating newer, more precise models.

Recently, an ML model predicting major complications and death after surgery was published by Bihorac et al. [4]. One of the analysed complications was an ICU admission greater than 48 hours. The authors used a generalized additive method (GAM) for model development, as this method had outperformed other prior ML methods for anlayses (e.g. logistic regression and support vector machine) [5]. The AUROC for the prediction of ICU admission with GAM was 0.88 (0.87 - 0.89), with a sensitivity of 0.76 and a specificity of 0.83. Utilisation of this prediction model could be beneficial for managing ICU capacities in general, but in routine work it is more crucial to accurately estimate the risk of short term ICU patients.

Several ML-based risk prediction models have been published during the last few years, but only few of them made their way to clinical practice. In order to ensure highest performance of a prediction model and patient safety respectively, research in real clinical settings is needed. Prediction results might differ between validation on retrospectively collected data and prospective validation with real-time prediction.

KAGes (Steiermärkische Krankenanstaltengesellschaft) is the biggest health care provider in Styria, a federal state of Austria. Due to the coverage of more than 90 % of all hospital beds in Styria, KAGes has access to approximately two million longitudinal patient histories. This large amount of clinical data forms a highly valuable basis for modelling and the use of ML methods. KAGes runs several subsidiary hospitals, one of them being the hospital Hochsteiermark – Bruck an der Mur (abbreviated BRU). Hospital BRU has a total of 330 inpatients beds, including twelve beds in the ICU with mechanical ventilation, and eight beds in the intensive monitoring unit without mechanical ventilation. Prior to surgery, patients undergo at least one assessment by an

anaesthesiologist. In 2017, the anaesthesiologits conducted 4,606 preoperative consultations on 3,881 patients. Of these preoperative assessments, 4,370 (94.9 %) cases underwent a surgery, of which 462 (10.6 %) cases were admitted to ICU postoperatively.

During preoperative assessment, anaesthesiologists estimate the patients' risk of ICU admission after surgery, based on patient histories and ASA score classification. This risk estimation is crucial for preoperative anaesthetic management, and ICU bed management respectively. However, due to the subjectivity of the ASA score the accuracy of this assessment may vary between patients. Another problem concerning the accuracy of risk estimation is the large amount of information in some patients' medical histories and having to review all diagnostic findings that were collected in the past.

To overcome this challenge, objective assessment methods are required that support anaesthesiologists in their risk estimation. In clinical practice, such methods will only be helpful when many more variables are integrated than current common surgery risk tools offer. Most of the prediction models published in recent years have shown good results on validation of test data, but little of them have been validated during a real-time scenario. However, a model's usefulness can only be determined through a validation on real-time data. Therefore, our goal in the underlying study was to develop a reliable ML-based model predicting the risk of an ICU admission after an elective surgery and implement the model within a user-friendly interface in the routine clinical workflow.

Methods

The development and implementation of the study received approval from the Ethics Committee of the Medical University of Graz (30-146 ex 17/18). We used the TRIPOD statement [6] as a guideline for the development, validation and reporting. The data process and modelling design of the study are shown in Figure 1.

Data Set

The routine clinical data of KAGes was stored in the Hospital Information System (HIS) openMEDOCS, which was based on IS-H/i.s.h.med information systems, and implemented on SAP platforms. For data analysis, the data warehouse platform SAP HANA was used for controlling and quality issues. All analyses including pre-processing and modelling were performed using the R software environment.

The predicted outcome of our classification model was the admission to ICU within five days after an elective surgery. The time of prediction was defined as the last preoperative assessment of a patient before undergoing the elective surgery.

Cohort Building and Feature Set

For the first step, we extracted a retrospective cohort of hospitalised patients from the hospital BRU and a second KAGes-hospital, the hospital LEO. In this cohort, we included all patients that had undergoe a preoperative assessment in one of the two hospitals between 1st of January, 2010, and 31st of March, 2018. We excluded all patients for whom the elective surgery was not executed after the assessment, as well as patients younger than 18. The final cohort resulted in 61,864 patients.

For the second step, we extracted routinely stored EMR data for the whole cohort. These records included structured information, such as demographic data, ICD-10 diagnosis codes, current Austrian procedures codes, lab data, patient transfer data and nursing protocols. We considered information in lab data from the last 30 days and ICD-10 codes from the last three years. ICD-10 codes for chronic diseases like diabetes, chronic kidney disease, asthma etc. were used without any exclusion. In order to handle rather infrequent ICD-10 codes, we computed groups of related chapters, e.g. the feature ICD_E10_E14 that covered any diabetes code for the patient. This strategy also helped us to handle coding errors for ICD-10 codes which we had detected in our previous research [7]. In addition, we calculated several indices like the Charlson Comorbidity Index [8], length of last inpatient stay or total number of stays. The data extraction and pre-processing resulted in 630 features summarised in Table 1.

In previous studies we had examined the impact of data imputation for EMRs used for modelling [9]. As those studies had shown no improvement in model performance when using imputation methods, we decided against the imputation of values based on population measurements. Instead, we solely performed last-observation-forward imputation for lab data over the last 30 days and for nursing protocols from the last hospital stays.

Table 1 – Modelling Features (n = 630) Extracted from Electronic Medical Records for Prediction of an ICU Admission.

Feature group	Examples	n
Demographic Data	Age, sex, mother tongue, additional private insurance	30
Diagnosis Codes	ICD-10 codes, groups of ICD-10 codes	345
Procedure Codes	X-ray, MRI, physiotherapy, CT, endoprosthesis implantation	103
Laboratory Data	CRP, cholesterol, gamma-GT, haemoglobin,	46
Nursing Protocols	Respiratory problems, sleeping disorder, body mass index	96
Administrative Data, Indices	Transfers, hospital admissions, Charlson comorbidity index	10

Modelling and Calibration

In order to choose the best model for our prediction, we compared various ML methods. We computed all pre-processing and modelling steps in R, using the *caret* package [10] and associated packages for modelling. For a deep learning model we used the *mxnet* package [11]. We split the data set into 75 % training data (n = 46,460) and 25 % test data (n = 15,404). After splitting, we trained all models on the same training data with a five times repeated 10-fold cross validation and used AUROC as a metric to select the optimal model. To overcome the problem of imbalanced data, we applied up- and down-sampling during training. Finally, we calculated model performance parameters for each model (accuracy, sensitivity, specificity and precision) on the remaining test data using the "closest topleft" threshold of the ROC.

The compared models included linear discriminant analysis (LDA), logistic regression (GLM), feed-forward neural networks with single hidden layer (NN), deep neural networks (MXNet), stochastic gradient boosting (GBM) and random forest (RF).

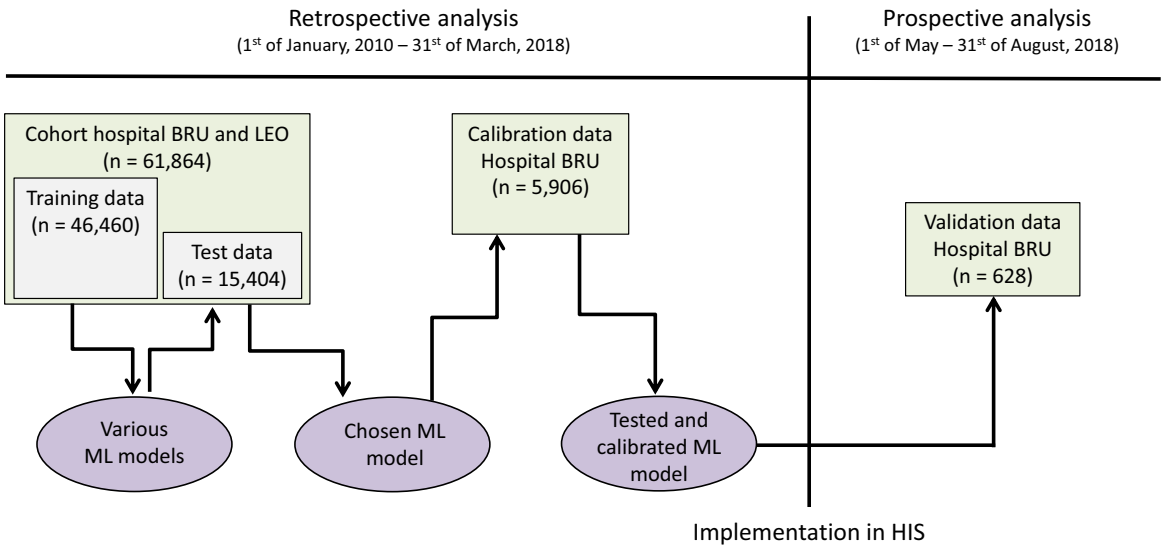

Figure 1 – Data process design for the development of a machine learning (ML) based prediction model for the risk of an ICU admission after surgery, and its prospective validation after an implementation in the HIS.

Based on the results of the area under the receiver operating characteristic curve (AUROC) and accuracy in the test data, we selected the best performing model for further calibration. We chose the thresholds with respect to the characteristics of the department. The aim of the calibration was to avoid over-alerting and to map the patients' risk probabilities to three categories: low risk, high risk and very high risk. In order to determine the best thresholds for these categories, we evaluated the number of available ICU beds and discussed the distributions with the hospital's senior physicians.

Prospective Validation in Clinical Practice

The best performing prediction model was implemented in the HIS during a pilot phase starting on 1st of May, 2018, and ending on 31st of August, 2018. For every patient who underwent a preoperative assessment by an anaesthesiologist, an individual risk of ICU admission was calculated in real-time.

During those four months, the anaesthesiologists were able to review the latest predicted risk for the patients. A traffic light symbol integrated in the HIS represented the patients' risk: high risk presented in yellow and very high risk in red. A click on the symbol revealed details on the prediction. The information integrated in a user interface was designed to support clinical reasoning and highlight the underlying health records that influenced the model's outcome. To increase usability, the presented features were ordered using the calculated variable importance of the model.

After the implementation phase, we analysed the performance of the model in real-time prediction and compared it to the performance in the test data. To calculate the sensitivity and specificity of the validation data, we combined the two categories high risk and very high risk, and defined them as a positive prediction of ICU admission, For every patient we considered the prediction result just before the preoperative assessment. If more than one preoperative assessment was available, only the latest prediction was evaluated.

In addition, the anaesthesiologists in our group examined all patients who were classified into a wrong category. Patients with an ICU stay and a prediction of low risk, as well as patients without ICU stay and a prediction of high risk were defined as incorrectly classified. We analysed their patient histories and further information of the hospital stay including surgical procedures, lab data etc.

Results

The demographic data of the three data sets are presented in Table 2. The percentage of ICU admissions was 7.7 % in the training set and 7.3 % in the test set. For ICU patients, the length of stay was comparable between the two test sets with a median stay of 50 hours and 49 hours, respectively. Distributions of sex and age were comparable between training and test data set, too.

Table 2 – Descriptive Statistics for the Training, Test and Validation Data. (Values of categorical variables are presented in absolute frequencies and column percentages).

	Training (n = 46,460)	**Test (n = 15,404)**	**Validation (n = 628)**
ICU	3,573 (7.7 %)	1,131 (7.3 %)	60 (9.6 %)
Non-ICU	42,887 (92.3 %)	14,273 (92.7 %)	568 (90.4 %)
Length of ICU stay in hours[a]	50.3 (91.9)	49.0 (73.6)	24.5 (24.6)
Male	22,733 (48.9 %)	7,533 (48.9 %)	343 (55.1 %)
Female	23,727 (51.1 %)	7,871 (51.1 %)	280 (44.9 %)

Modelling and Calibration

The model performance of the different ML-based methods on the test data is summarized in Table 3. Comparing the methods, RF with up-sampling performed better than all other models with the highest AUROC (0.911), and accuracy (0.828).

The calibration of the RF model on the test data resulted in two thresholds dividing all predictions into three risk categories. The lowest 82 % of the predicted risk scores were classified to the low risk category, the following 11 % to high risk, and the upper 7 % of all predictions to the very high risk category.

Prospective Validation in Clinical Practice

During the four months of implementation in clinical workflow, 628 patients had an elective surgery with an antecedent preoperative assessment (see Table 4).

The thresholds set during calibration split the predictions accurately into the three risk categories with the category of high risk being slightly bigger for validation than for calibration (17 % compared to 11 %). The AUROC for the validation data was high with 0.843 (0.798 - 0.887), as well as the accuracy with 80.3 %. The sensitivity of the prediction in the validation data was 73.3 %, and the specificity 80.8 %.

We performed qualitative checks on 42 wrongly classified patients. The false negative group consisted of 16 ICU patients with a low risk prediction at the preoperative assessment. For nine patients out of the 16, little information of the patient histories was stored in the HIS. In some cases, there were no ICD-10 codes available at all.

Table 4 – Real-time Prediction of an ICU Admission for All Patients with Preoperative Aassessments

ICU admission	Predicted Risk Category			
	Low	High	Very high	Total
No	459 (80.8)	83 (14.6)	26 (4.6)	568
Yes	16 (26.7)	26 (43.3)	18 (30.0)	60
Total	475 (75.6)	109 (17.4)	44 (7.0)	628

Note: The numbers in parentheses show rounded row percentages.

The false positive group included 26 non-ICU patients with a very high risk prediction. All 26 patients underwent non-severe surgeries, e.g. percutaneous transluminal angioplasty (PTA), shunt procedures, cataract surgeries, or lipoma surgeries. Due to the performed procedures those patients were highly unlikely to be admitted to ICU, although 21 of them were classified as ASA 3, and three of them as ASA 4.

Discussion

In this study, we developed a ML-based classification model to predict an ICU admission after an elective surgery. We used the EMRs of more than 61,000 patients for the modelling process and validated the model on more than 600 patients prospectively during a real-time prediction. In retrospective test data, our model achieved a higher performance than prior published comparable models. Our best performing model, a random forest method, resulted in an AUROC of 0.91, while the previously published multivariable regression model CARES reported an AUROC of 0.84 only [3]. Our literature review revealed only one published ML model predicting a postoperative ICU stay [4]. This model predicted an ICU admission with a stay greater than 48 hours and resulted in an AUROC of 0.88. However, these results are only to some extent comparable to our model, as we focused on any ICU admission independent of the length of stay.

In addition, we offered new insights into the implementation of ML-based prediction models and their performance in prospective settings. During a period of four months, we predicted the risk of ICU admission in real-time just before the preoperative assessment for all patients of one KAGes hospital. The risk for each patient was presented to the anaesthesiologists within the HIS. As expected, in the prospective evaluation the performance of the model decreased compared to the performance in the test data. Nevertheless, the result was satisfying with an AUROC of 0.84 and an accuracy of 80.3 %.

With the goal to improve the prediction model and to find possible deficits in the development, we checked all wrongly classified patients. Interestingly, all patients in the false positive group had surgeries with quite simple procedures, e.g. cataract or lipoma surgery. To overcome this bias in future model development, two additional features should be added: (1) the information of the severity of an elective surgery assessed by an anaesthesiologist, and (2) the type of anaesthesia. This information might improve the prediction for certain groups of patients. One group that might benefit from such an extension is are patients that undergo a severe elective surgery only due to a vital indication. The model assumes that these patients undergo non-severe surgeries only, and therefore have no need for an ICU bed. However, in the

validation data we could not distinguish well between elective surgeries and emergency ones due to missing real-time information, and, thus, might have underestimated the risk for emergency patients with highly severe surgeries. In future work we will need to address this limitation in order to provide the best prediction.

Some other limitations of our study should be considered when interpreting the results. First, all analyses are based on data from a HIS. Although most of the patient histories in the HIS of KAGes are quite comprehensive, the availability of structured information caused some problems in our study. For some of the wrongly classified patients, no coded diagnoses were found in their history, although free-text diagnoses were available in the discharge letters. Future data extraction might include natural language processing methods in order to make use of unstructured information.

Second, we did not consider the length of an ICU stay in our risk prediction, but rather focused on any admission to ICU after surgery. Bihorac et al. [4] had predicted ICU admissions with a stay greater than 48 hours. This prediction is not enough to ensure a precise ICU bed management, as almost 50 % of our ICU patients have a stay with less than 48 hours. It might be useful to combine various prediction models for ICU admission: First, predict any admission to ICU for all patients, and then, predict the length of ICU stay for patients with a previous positive result.

In this study, we focused on the quantitative results of the prediction model. Future work on the model should include an evaluation of the users' experience, especially attitudes and fears towards the use of ML models for prognosis in health care as well as the satisfaction with the results in real-time prediction. In addition, the usability of the implementation in the HIS could be improved through the users' feedback.

Conclusions

We developed a machine learning model that predicts the risk of ICU admission after elective surgery. There is a high need for precise ICU bed management in order to avoid unnecessary costs, improve healthcare for patients, and to support decision makers. We implemented our ML-based prediction model in a clinical workflow to support anaesthesiologists in their clinical reasoning, and prospectively evaluated the model's performance. Further research is essential to determine physicians' attitudes to machine learning based on risk prediction, and to assess the long-term improvement of ICU management and patient outcomes when using ML-based prediction models.

Acknowledgements

This work has been carried out with the K1 COMET Competence Centre CBmed, which is funded by the Austrian Federal Ministry of Transport, Innovation and Technology (BMVIT); the Federal Ministry of Science, Research and Economy (BMWFW); Land Steiermark (Department 12, Business and Innovation); the Styrian Business Promotion Agency (SFG); and the Vienna Business Agency. The COMET program is executed by the FFG. KAGes and SAP provided significant resources, manpower and data as basis for research and innovation.

Abstract

The Electronic Data Interchange (EDI) medical procedure code is the code used for health insurance claims in Korea. We mapped Korean EDI codes to SNOMED CT to explore the global interoperability of health insurance claims data. We developed rules for mapping based on the mapping guideline provided by SNOMED CT International. The first and second authors mapped 726 EDI codes used to claim reimbursement in five specialty areas to SNOMED CT. Eight subject matter experts reviewed the mapping results. Out of 726 procedure codes, 82.5% were exactly or partially mapped to SNOMED CT. An EDI code was mapped to an average of 2.04 SNOMED CT concepts. Twenty-one attributes were identified in the EDI codes mapped to SNOMED CT concepts. We identified strategies to improve the EDI code in this study. They include introducing hierarchical structures, adding inclusion and exclusion criteria for procedure codes, and improving EDI code labels.

Keywords:

Systematized Nomenclature of Medicine, Health insurance reimbursement, Health information interoperability

Introduction

Korea introduced universal health care coverage in 1989. As of 2016, 97.1% of the population is covered by the National Health Insurance (NHI) and 2.9% by Medical Aid [1]. The NHI is managed comprehensively in a form of social insurance, and financed by contributions from the insured and their employers (84.3%), government subsidies (9.2%), and tobacco surcharges and others (6.5%) [2]. A single payer-system was introduced in 2000 and all healthcare providers in the country are required to enroll in the National Health Insurance System (NHIS) to get reimbursed.

The NHIS serves as the insurer, and the Health Insurance Review and Assessment Service (HIRA) as the reviewer of the claims and quality of healthcare services [3]. The reimbursement process starts with the healthcare institutions filing claims for medical fees to HIRA. Most claims (99.7%) are submitted electronically using the Medical Claim Portal Service (MCPoS) or Electronic Data Interchange (EDI) system. HIRA reviews and assesses the claims; it notifies the NHIS of the result for the medical cost payment, and notifies healthcare institutions for verification. Fee-for-service is the main payment system in Korea, covering 99.7% of outpatient care and 80.7% of inpatient care [4].

There are two categories of medical services in the NHIS: 'covered' services in which patients are responsible for only part of the cost and 'uncovered' services in which patients are responsible for the entire cost. Lists of covered and uncovered services are determined by the Ministry of Health and Welfare and maintained by the HIRA. The medical fee schedule is determined by multiplying the resource-based relative value scale (RBRVS) of each medical service by the unit price of the service [3].

As of August 2017, there are 9,252 items of medical services including treatments and surgical procedures, tests, long-term care, medical images, basic treatments, dental services, hospice care, emergency services, anesthesia, traditional medicine, meals, and pharmacy [3]. Out of 9,252 items, 8,759 are covered by the National Health Insurance. The national standard code, also known as the 'EDI code,' was assigned to each medical service. The EDI code is the basic structure for reimbursement claims of medical services in the fee-for-service system, and is used as a major component of patient classification for the DRG-based payment system covering seven groups of diseases or operations.

As use of ICT in healthcare increases, opportunities of sharing and exchanging health information between different healthcare institutions and countries have increased. This led to interest in standard healthcare terminologies and classifications. The Korean Classification of Diseases (KCD), which was modified from the ICD, has been used in Korea for the classification of medical diagnoses since 1952. However, there is no standard classification of medical procedures used in Korea, just as there is no global standard for medical procedures as widely used as the ICD. Even though WHO has been developing the International Classification for Health Interventions (ICHI) for reporting and analysing health interventions for statistical purposes since 2007, there are concerns around some aspects of its operationalization. [5,6].

Even though the EDI medical procedure code has been used for more than 20 years in Korea to file claims for reimbursement, it has a few limitations to be qualified as a classification. For example, the code has no consistent hierarchical structure, even though it contains some medical procedures organized by anatomy. The levels of granularity of the EDI procedure code vary by domain, and sometimes even within the same domain. Thus, it is not easy to use the current EDI code as a means to exchange and share information among the stakeholders. There have been efforts to improve the EDI code as a standardized medical procedure classification interoperable with the global classification by benchmarking ICHI, and ICD-10-PCS in

Korea [7,8]. However, the results of these efforts have not been fully implemented in the EDI procedure code.

SNOMED CT is one of the most widely used standard reference terminologies for information exchange across EHR systems globally [9]. Clinical databases differ in both purpose and design. EHRs are aimed at supporting clinical practice at the point of care, while claims data are built for the insurance reimbursement processes. SNOMED CT as a standard terminology is used to describe clinical conditions and medical procedures in EHRs. SNOMED CT has one of the most extensive coverages among biomedical vocabularies in the world with 340,659 active concepts contained in the July 2018 release [10]. SNOMED CT concepts are defined with the rules called the SNOMED CT concept model with permitted attributes and values that may be applied to each concept. SNOMED CT is used in more than 50 countries and managed by SNOMED International, a non-profit international organization with 35 member countries [11]. Mapping the procedure codes such as CPT and ICD-10-PCS toward SNOMED CT is a useful and rather common exercise [12,13].

In this study, we mapped the EDI medical procedure code to SNOMED CT concepts in order to explore ways to improve the global interoperability of Korean health insurance claims data.

Methods

We developed methods and rules for mapping based on the mapping guideline provided by SNOMED International [14].

Mapping Materials

The source of mapping is the Korean EDI procedure code updated in 2017, and the target of mapping is the SNOMED CT concept within the 'Procedure' top-level hierarchy released by SNOMED International in July 2017. A total of 726 medical procedure codes used to claim reimbursement for treatment and surgery in five specialty areas -- Internal Medicine, Colorectal Surgery, Ophthalmology, Orthopedics and Pediatrics -- were mapped. These specialties were selected due to their broad content coverage and the active participation of the subject matter experts in the use of clinical terminology.

Mapping Procedure

Using the SNOMED International SNOMED CT Browser, the first and second authors searched and identified the SNOMED CT concept that has a synonymous relationship with an EDI medical procedure within the 'Procedure' top-level hierarchy [15]. The identified SNOMED CT concept was used as a lead term for the browse-up and down approaches. In the browse-up approach, parent concept(s) of the identified concept were examined. This helped us to examine if any other children concepts of the parent concept were also relevant and should be included.

For instance, 'Anal sphincteroplasty for obstetrical laceration' was first identified for the EDI medical procedure code 'Sphincteroplasty without levatorplasty'. Browsing up from the SNOMED CT concept 'Anal sphincteroplasty for obstetrical laceration' yields a parent 'Repair of anal sphincter'. Examination of the siblings of 'Anal sphincteroplasty for obstetrical laceration' under 'Repair of anal sphincter' reveals some siblings can be included as a relevant concept of 'Sphincteroplasty limited to anal sphincter', such as 'Post-anal repair', while other siblings such as 'Construction of anal neosphincter' cannot be included.

In the browse-down approach, descendant concepts of the identified concept were examined to see if any of the descendant concepts should be excluded. For instance, for the EDI medical procedure code 'Primary repair of mesentery', the child concepts of 'Repair of mesentery' such as 'Mesentery closure', 'Repair of mesentery of colon' or 'Repair of mesentery of small intestine' can be included. However, 'Mesentery reconstruction' and 'Plication of mesentery' cannot be included.

The browse-up and down sequence of the search was repeated as needed to look for other relevant SNOMED CT concepts. Then, included concepts were numbered from 1 to n. The Boolean logic of the map was provided if necessary. We mapped to concepts with the same meaning, considering use cases. Definition of the EDI medical procedure code, as well as the formal definition, fully specified name and synonyms of the SNOMED CT concept were examined during each mapping.

During the mapping, we identified the attribute relationships of the source concept and the values of the attributes. The attribute relationships will contribute to the definition of the source concept by associating them with the values. We also identified strategies to improve the structure and label of the EDI medical procedure code to improve the global interoperability of the claims data submitted using the EDI code.

Classification of Map

Each map was classified as either an 'exact' or 'partial' map according to the level of correspondence between the EDI medical procedure code and SNOMED CT concept(s). Since the EDI code is used for reimbursement purpose, a single EDI code can have multiple anatomical sites or multiple procedures. An EDI code with more than one site or more than one procedure was dissected to express different meaning of the code and then mapped to multiple SNOMED CT concepts.

For a EDI medical procedure with a single anatomical site and a single procedure, if the identified SNOMED CT concept was equivalent with the EDI medical procedure code, it was classified as an exact map. If the identified SNOMED CT concept was less specific than the EDI code, it was classified as a broad map. For a broad map, post-coordination of SNOMED CT concept can be introduced to represent the EDI code. Otherwise, it was classified as a narrow map.

For a EDI medical procedure with more than one anatomical site or more than one procedure, all of the identified SNOMED CT concepts were equivalent with the dissected EDI medical procedure code, it was classified as an exact map. Otherwise it was classified as a partial map. Partial maps were further classified as a broad, a narrow or a mixed map. If all of the identified SNOMED CT concepts was less specific than the dissected EDI medical procedure code, it was classified as a broad map. For a broad map, post-coordination of SNOMED CT concepts can be introduced to represent the EDI code. If all of the identified SNOMED CT concepts was more specific than the dissected EDI medical procedure code, it was classified as a narrow map. If the identified SNOMED CT concepts were less specific, more specific or equivalent with the dissected EDI medical procedure code, it was classified as a mixed map.

Table 1– Type of Map

Type		Description
Exact		The identified SNOMED CT concept(s) is equivalent with the EDI medical procedure code.
Partial	Broad	The identified SNOMED CT concept(s) is less specific than the EDI medical procedure code.
	Narrow	The identified SNOMED CT concept(s) is more specific than the EDI medical procedure code.
	Mixed	The identified SNOMED CT concepts are either less specific, more specific or equivalent with the dissected EDI medical procedure code.
No map		There is no appropriate SNOMED CT concept to represent the EDI medical procedure code.

For each map, the cardinality of the map between the EDI medical procedure code and SNOMED CT concept(s) was counted. If all descendant concepts of an identified SNOMED CT concept were included as relavant concepts of an EDI medical procedure code, only the parent concept was counted.

Validation of Mapping

Eight subject matter experts from five specialty areas reviewed mapping results to see if SNOMED CT concepts validly represent EDI medical procedure codes. They received five hours of training and education on SNOMED CT before the review. We posed questions to the reviewers based on SNOMED CT concepts and descendants. An example question is 'Should 'Excision of diverticulum from large intestine' or 'Excision of diverticulum of small intestine' be included in 'Diverticulectomy' according to the definition of the EDI code?' If the experts do not agree with the mapping, a consensus building process was introduced. The reviewers were also asked to explore ways to improve global interoperability of the claims data collected using the EDI procedure code during the validation.

Results

Mapping examples of EDI medical procedure codes with SNOMED CT concepts are presented in Table 2.

The mapping rates of 726 EDI medical procedure codes to SNOMED CT concepts are presented in Table 3. Overall, 82.5% of the EDI codes were exactly or partially mapped, ranging from 76.9% to 100% by specialty. The mapping rate of the EDI medical procedure codes in Colorectal surgery was higher than those of other specialties in exact maps (73.8%).

We did not attempt to map 79 EDI codes to SNOMED CT since they are not the codes describing medical procedures. Such examples are EDI codes used to claim reimbursement for objects (dialyser, tubing set, guide wire, IV set, syringe, needle, and catheter) and substances (heparin and normal saline) for extracorporeal dialysis of ascitic fluid.

Out of 726 EDI procedure codes, 48 codes were not mapped since there was no SNOMED CT concept describing these medical procedure codes. For example, the EDI code 'Ultra-Low anterior resection with Intersphincteric Resection' was not mapped. Another example is 'Transaortic approach for transcatheter aortic valve implantation'. SNOMED CT does not have any concept describing this procedure even though there were two SNOMED CT concepts describing transcatheter aortic valve implantation - 'Transapical approach for transcatheter aortic valve implantation' and 'Transfemoral approach for transcatheter aortic value implantation'.

Table 2– Examples of EDI medical procedure code mapped to SNOMED CT concepts with boolean logic

EDI Code	SNOMED CT concepts	#of SNOMED CT concepts	Boolean logic	Type of map
Radio-frequency Ablation of Supra-ventricular Arrhythmia through 3D Mapping	1. Radiofrequency ablation operation for arrhythmia (procedure) 2. Percutaneous transluminal three dimensional electroanatomic mapping of conducting system of heart (procedure)	2	1 AND 2	Broad
Diverti-culectomy	1. Excision of diverticulum from large intestine (procedure) 1.1 Excision of diverticula of colon (procedure) 2. Excision of diverticulum of small intestine (procedure) 2.1 Diverticulectomy of duodenum (procedure) 2.1.1 Excision of diverticulum of ampulla of Vater (procedure) 2.2 Excision of Meckel's diverticulum (procedure)	2	1 OR 2	Exact
Primary Repair of Mesentery	1. Mesentery closure (procedure) 1.1 Suture of mesentery (procedure) 2. Repair of mesentery of colon (procedure) 3. Repair of mesentery of small intestine (procedure)	3	1 OR 2 OR 3	Exact

Table 3– Result of mapping by specialty

Type of map	Internal Medicine	Colo-rectal Surgery	Ophthal-mology	Ortho-pedics	Pedia-trics	Total
Exact	72 (50.3%)	76 (73.8%)	61 (50.4%)	91 (25.9%)	4 (50.0%)	304 (41.9%)
Broad	35 (24.5%)	19 (18.4%)	14 (11.6%)	39 (11.1%)	4 (50.0%)	111 (15.3%)
Narrow	4 (2.8%)	-	25 (20.7%)	140 (39.9%)	-	169 (23.3%)
Mixed	7 (4.9%)	4 (3.9%)	4 (3.3%)	-	-	15 (2.1%)
Not mapped	19 (13.3%)	4 (3.9%)	17 (14.0%)	8 (2.3%)	-	48 (6.6%)
Did not map	6 (4.2%)	-	-	73 (20.8%)	-	79 (10.9%)
Total	143 (100%)	103 (100%)	121 (100%)	351 (100%)	8 (100%)	726 (100%)

In total, 726 EDI codes mapped to 1,481 SNOMED CT concepts with an average of 2.04 SNOMED CT concepts per EDI code. The cardinality of the maps is provided in Table 4. There were 352 EDI codes mapped to one SNOMED CT concept, and 247 EDI codes mapped to more than one SNOMED CT concept with a maximum of 19 concepts. Some of EDI codes do not have a separate code describing surgical procedure with laparoscopic approach such as 'Laparoscopic appendectomy'. Healthcare providers in Korea claim laparoscopic appendectomy using the EDI code for 'Appendectomy with open approach'. Thus, we mapped an EDI surgical procedure which can be performed with an open or laparoscopic approach to two SNOMED CT concepts, one for the open approach and the other for the laparoscopic approach.

Table 4– Cardinality of maps by specialty

Specialty / Cardinality	Internal Medicine	Colorectal Surgery	Ophthal-mology	Ortho-pedics	Pedia-trics	Total
0	25	4	17	81	0	127 (17.5%)
1	70	28	79	167	8	352 (48.5%)
2	23	12	12	62	0	109 (15.0%)
3	5	24	6	19	0	54 (7.4%)
4	9	9	2	14	0	34 (4.7%)
5	4	9	1	5	0	19 (2.6%)
6	0	3	0	1	0	4 (0.6%)
7	0	3	0	1	0	4 (0.6%)
8	7	1	1	1	0	10 (1.4%)
9	0	1	0	0	0	1 (0.1%)
≥10	0	9	3	0	0	12 (1.7%)
Total	143	103	121	351	8	726 (100%)

In total, 21 attribute relationships were identified in Table 5. They are Procedure site, Procedure site - Direct, Procedure site - Indirect, Procedure morphology, Direct morphology, Indirect morphology, Method, Procedure device, Direct device, Indirect device, Using device, Using access device, Access, Surgical approach, Direct substance, Using substance, Priority, Has focus, Has intent, Revision status, Route of administration, and Using energy. For example, the EDI code 'Fusion of joint of lumbar spine with internal fixation by anterior approach' has a 'procedure site - direct' relationship to the concept 'lumbar spine joint structure', 'method' relationship to the concept 'fusion - action', 'surgical approach' relationship to the concept 'anterior approach', and 'using device' relationship to the concept 'Orthopedic internal fixation system, device'. Attribute relationships of the source code identified in this study can be used in the data retrival process where the meaning of a concept is needed to determine whether the EHR record matches the query criteria and advanced analytics.

Table 5– A list of attributes identified in SNOMED CT concepts mapped to EDI codes

Specialty / Cardinality	Internal Medicine	Colorectal Surgery	Ophthal-mology	Ortho-pedics	Pedia-trics
Procedure site	10/3	39/10	20/12	17/8	-
Procedure site - Direct	150/27	515/58	170/40	444/170	4/3
Procedure site - Indirect	121/22	37/22	47/20	92/56	1/1
Procedure morphology	-	6/2	4/1	-	-
Direct morphology	64/12	117/26	66/12	149/26	2/2
Indirect morphology	3/2	14/1	1/1	4/2	-
Method	315/36	590/42	238/51	565/47	5/4
Procedure device	2/2	-	-	-	-
Direct device	110/22	5/4	11/7	81/32	1/1
Using device	70/21	32/5	21/7	66/9	1/1
Using access device	61/14	35/3	-	11/2	-
Access	33/1	5/3	1/1	21/2	2/1
Surgical approach	6/3	63/7	10/5	4/2	-
Direct substance	3/2	19/4	6/5	28/6	-
Using substance	11/3	5/3	2/2	-	-
Priority	-	7/4	-	-	2/1
Has focus	22/2	7/4	34/4	7/2	2/1
Has intent	23/1	-	-	-	3/1
Revision status	2/1	7/2	2/1	53/2	-
Route of administration	-	-	2/1	-	-
Using energy	-	-	1/1	-	-

Table 5 shows the number of attribute relationships identified in the SNOMED CT concepts mapped to EDI codes with the number of unique values for each attribute in each specialty. 'Method' was the most popular attribute, followed by the 'Procedure site - Direct', 'Direct morphology' and 'Procedure site – Indirect' attributes.

Discussion

We attempted to map 726 medical procedure codes in five specialty areas by identifying relevant SNOMED CT concepts using the browser-up and down search sequence. With this approach, we were able to identify all relevant SNOMED CT concepts for eligible medical procedures to claim with a specific EDI code. Thus, it was possible to achieve the similar mapping results to the map of SNOMED CT concepts to EDI medical procedure codes. Overall, 82.5% of the EDI codes were exactly or partially mapped to the SNOMED CT concepts, which is a slightly lower than that of ICD-9-CM Procedure Codes to SNOMED CT map [12].

Out of 726 EDI medical procedure codes, 79 codes used to claim reimbursement for medical procedures with additional comorbidity or accompanying surgeries for higher payment, and materials or drugs used in medical procedures were not mapped. There were 48 medical procedures for which we could not identify appropriate SNOMED CT concepts. They fall broadly into two categories; one category includes EDI medical procedure codes with mismatching body sites or approaches. An example of this is 'Intravenous catheterization for hemodialysis in the subclavian vein and internal jugular vein with cut-down method.' A cut-down approach may be used when inserting an implantable port into the cephalic vein or external jugular vein. The second category includes medical procedures not modelled in SNOMED CT yet. An example of this is 'Repair of nonunion or malunion in fingers or toes'. This procedure can be modelled in SNOMED CT with two concepts: 'Repair of nonunion of phalanges' and 'Repiar of malunion of phalanges'.

During the mapping process, we identified strategies to improve the interoperability of the claims data collected using the EDI medical procedure code. First, we would like to suggest introducing a hierarchical structure to the EDI medical procedure code. We mapped the EDI medical procedure 'Hemorrhoidectomy' to the SNOMED CT concepts 'Closed hemorrhoidectomy', 'Open hemorrhoidectomy' and 'Submucosal hemorrhoidectomy'. However, the EDI code 'Hemorrhoidectomy' is used for a claim for the simultaneous removal of three primary hemorrhoids. There is no EDI code to claim the removal of less than three hemorrhoids. Physicians use the EDI code of 'Excision of thrombosed hemorrhoids' for this claim. This issue can be resolved by introducing a hierarchical structure to distinguish between different types of hemorrhoidectomy. EDI codes used to claim for materials, medication or medical procedures with additional qualifiers such as acuity of patient, co-morbidity or co-treatment can be better organized with the introduction of a hierarchical structure to the EDI code. A list of attributes identified can be used to move the current enumerated EDI medical procedure code to a structured classification.

Second, we would like to suggest revising labels of EDI medical procedure codes to reflect the meaning of the procedure as accurately as possible. 'Enucleation' -- a general surgical technique that removes a mass without cutting into or dissecting it -- was used to describe the removal of an eyeball. 'Enucleation of eyeball' could be a better term to describe this procedure.

Third, we would like to suggest removing EDI medical procedure codes being used rarely for claims. 'Extracoporeal Ascites Dialysis' is being used seven times since 2013 in Korea. This procedure can be removed from the EDI medical procedure code list.

Fourth, we would like to suggest adding examples or synonyms to each EDI medical procedure code as an additional guide to help healthcare providers. For instance, 'Laparoscopic appendectomy' can be added as an example of the EDI code 'Appendectomy'.

We recognize the following limitations in our study. We only focused on EDI medical codes used to claim treatments and surgical procedures in five specialty areas. The EDI code includes other types of medical procedures such as laboratory tests, and imaging studies. Thus, the results may not be generalizable to the medical procedures in other specialties and other type of medical procedures.

Conclusions

The findings of this study will be used to improve the Korean EDI medical procedure code so that global interoperability of health insurance claims data can be improved. The EDI procedure code can be improved by introducing a hierarchical structure, standardizing EDI procedure code labels, and providing better coding reproducibility by clarifying inclusion and exclusion criteria for each procedure code. The global interoperability of health insurance claims data will be improved with the mapping between the EDI medical procedure code and SNOMED CT.

We will extend the mapping project to the EDI codes used in other specialty areas so that claims data can be used for national and international comparison and healthcare research. We hope that this work will trigger the use of SNOMED CT in the EHR system in Korea just as the EDI system had triggered the introduction of health information systems throughout Korea in the early 1990s. If healthcare providers use SNOMED CT when they collect clinical information at different stages of patient care, automated generation of reimbursement claims will be possible with data documented in the EHR system. This will make it possible to monitor the utilization of resources.

In the future, the findings of the mapping between the EDI procedure code and SNOMED CT concepts can be used for linking the EDI procedure code to the ICHI developed by WHO so that we can produce high quality, valid, comparable and sharable health insurance claims data meeting global standards.

Abstract

Background. *Establishing trends of drug overdoses requires the identification of individual drugs in death certificates, not supported by coding with the International Classification of Diseases. However, identifying drug mentions from the literal portion of death certificates remains challenging due to the variability of drug names.* ***Objectives***. *To automatically identify individual drugs in death certificates.* ***Methods***. *We use RxNorm to collect variants for drug names (generic names, synonyms, brand names) and we algorithmically generate common misspellings. We use this automatically compiled list to identify drug mentions from 703,106 death certificates and compare the performance of our automated approach to that of a manually curated list of drug names.* ***Results***. *Our automated approach shows a slight loss in recall (4.3%) compared to the manual approach (for individual drugs), due in part to acronyms.* ***Conclusions***. *Maintenance of a manually curated list of drugs is not sustainable and our approach offers a viable alternative.*

Keywords:
Death Certificates; Drug Overdose; RxNorm

Introduction

Recent mortality trends show a substantial increase in drug overdose death rates in the United States. From 2010 to 2015, the rate of drug overdose death has increased from 12.3 to 16.3 per 100,000 in the U.S. population [1]. Researchers have devoted a significant amount of effort to describing drug overdose trends and to identifying the population at risk, as attempts to address this public health crisis [1–3].

Mortality data are a valuable source of information for establishing drug overdose trends. Causes of death are classified in accordance with the International Classification of Disease, Tenth Revision (ICD-10). ICD-10 codes X40-X49 identify unintentional drug poisoning or overdose deaths, while drug-specific overdose deaths are identified by the contributory causes of death indicated by "T" codes (e.g., T40.1 indicates death due to poisoning by, adverse effect of and underdosing of heroin). ICD-10 codes have been used to facilitate the drug overdose trends analysis [4–6].

While ICD-10 codes support consistent coding of the underlying causes of death, they do not provide enough granularity especially when it comes to reporting drug overdose at the level of individual drugs. While some drugs are assigned a unique ICD-10 code, most of them are not. For example, drug overdose cases caused by heroin and methadone are assigned distinct ICD-10 codes (T40.1 and T40.3 respectively), but drug overdose cases caused by fentanyl and tramadol are clustered together and assigned the same code (T40.4 - poisoning by synthetic narcotics). This issue also affects all the other opioids (T40.2), as well as barbiturates (T42.3) and benzodiazepines (T42.4).

To mitigate the granularity issue, researchers have utilized the literal portion of death certificates (i.e., a short textual description of the cause of death) to identify the contribution of a specific drug to drug overdose cases [7]. The death certificates in which a specific drug is mentioned can be retrieved and used for establishing specific drug overdose trends. Yet, identifying drug mentions in death certificates is not a trivial task as drug entities are often denoted by different terminology variants, including generic names, brand names and synonyms. Moreover, drug names are sometimes misspelled in death certificates. Therefore, it is important to identify these variants in order to have complete and accurate retrieval of death certificates in which drugs are mentioned.

Trinidad et. al. [8] manually inspected death certificates over a 5-year period (2010-2014) and identified a list of search terms for drugs. These search terms were partially populated from Substance Abuse and Mental Health Services Administration's (SAMHSA) Drug Abuse Warning Network (DAWN) Drug Reference Vocabulary (DRV) and complemented by drug mentions identified manually from the literal portion of death certificates. These search terms consist of various terminology variants, including synonyms, abbreviations, brand names, and misspellings. A study team trained in pharmacy and pharmaco-epidemiology then organized these search terms into their corresponding drug entities (around a "principal variant"), as illustrated in Figure 1. We refer to this list as the Manually Curated List (MCL).

This list covers a large number of drugs involved in the death of decedents but requires a significant amount of manual effort from domain experts for its curation. Manual curation is time-consuming and does not constitute a scalable and sustainable approach as new drugs are marketed and new variants appear in death certificates. Moreover, while terminology variants for a given drug entity were grouped together, the type of variant (e.g., brand name, misspelling) was not documented, making it impossible to study the specific contribution of each type of terminology variant.

The objective of this study is to explore an automated approach to generating a list of search terms for drugs to support the identification of individual drugs in death certificates. We assess the performance of our Automatically Compiled List (ACL) against the Manually Curated List (MCL) for the retrieval of death certificates. The main contribution of our work is to address the scalability and sustainability of drug identification in death certificates, by proposing an automated approach to generating the drug list.

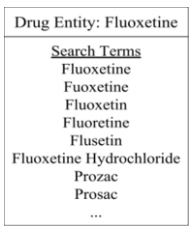

Figure 1 –Example of drug entity in the Manually Curated List with the "principal variant" (top), and the set of terminology variants.

Methods

We use RxNorm to collect variants for drug names (generic names, synonyms, brand names) and we algorithmically generate common misspellings. We use this automatically compiled list (ACL) to identify drug mentions from death certificates and compare the performance of our automated approach to that of the manually curated list (MCL) of drug names. (Figure 2).

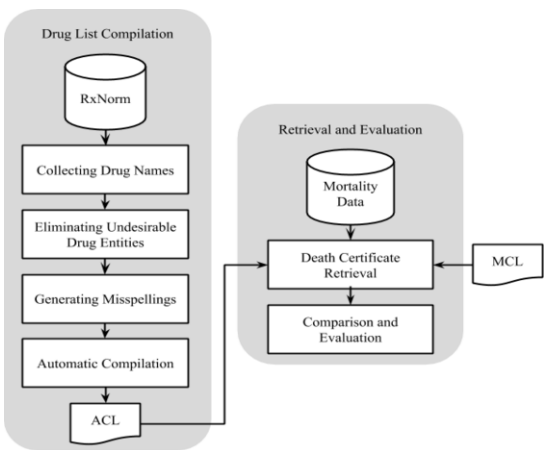

Figure 2 – Overview of the methods.

Drug List Compilation

The first stage focuses on compiling the list of search terms for drugs from RxNorm.

Collecting Drug Names from RxNorm

RxNorm is a normalized naming system for generic and branded drugs from a collection of commonly used public and private drug vocabularies [9]. The present study leverages RxNorm for populating drug names due to its comprehensive coverage of clinical drugs. We collected all names for drug entities from the following three RxNorm categories:

- Ingredients (IN) - a compound or moiety that gives the drug its distinctive clinical properties. Ingredients generally use the United States Adopted Name (USAN), e.g., *Fluoxetine*.
- Precise Ingredient (PIN) - a specified form of the ingredient that may or may not be clinically active. Most precise ingredients are salt or isomer forms, e.g., *Fluoxetine Hydrochloride*.
- Brand Name (BN) - a proprietary name for a family of products containing a specific active ingredient, e.g., *Prozac*.

The rationale for focusing on these three categories is that they are sufficient for identifying drug mentions in death certificates. While brand names generally correspond to prescription drugs (e.g., *oxycontin*), generic names for ingredients in RxNorm may also include substances for which no prescription drugs are available (e.g., *rofecoxib*). Other RxNorm categories, such as 'Semantic Clinical Drug' contain additional information (e.g., dose form and strength), usually not mentioned in death certificates and not essential for the retrieval of death certificates. We collect all synonyms from RxNorm for every drug name.

Eliminating Undesirable Drug Entities

RxNorm includes drug entities that are not of interest for identifying drugs in death certificates and will possibly generate false positives in retrieval, e.g., micro-organisms found in vaccines or used for allergy testing. We utilized semantic categorization (semantic type information) in the Unified Medical Language System (UMLS) [10] for filtering undesirable drug entities. All drug concepts from RxNorm are part of the UMLS Metathesaurus. For the purpose of retrieving death certificates, we only consider RxNorm concepts with the following UMLS semantic types:

- T109 - Organic Chemical
- T116 - Amino acid, peptide or protein
- T121 - Pharmacologic Substance
- T126 - Enzyme

In practice, we search in the UMLS Metathesaurus every RxNorm drug concept collected in the previous step and filter out those for which the semantic type is not one of the four listed above.

Another practical issue in identifying drug mentions in death certificates is that some drugs have brand names that correspond to frequently used English terms (e.g., *Prevail*, *Thrive*, *Today*). When found in death certificates, these terms generally do not denote a drug and will generate false positives in retrieval. In practice, we used the list of the top-5000 words from Word Frequency Data[1] computed from the Corpus of Contemporary American English[2] to filter out from our drug list any brand name that is present in this list.

Generating Misspellings

Some drug names are misspelled in death certificates. These misspellings indicate the mentions of drug entities but are often missed out in retrieval processes. We generated potential misspellings using an algorithm inspired by Pimpalkhute et. al. [11]. There are two phases in the algorithm: generation phase and filtering phase.

We first generated all variants with an edit distance of 1 (i.e., differing from the original by one character through insertion [*bupropion* / *bupropr*ion], deletion [*fluoxetine* / *fuoxetine*] or substitution [*Prozac* / *Prosac*]). We did not generate misspellings for chemical names (e.g., *1,1,2,2-tetrafluoroethane*) or drug names smaller than 5 characters (e.g.

[1] https://www.wordfrequency.info/free.asp

[2] https://corpus.byu.edu/coca/

Agar, *Urea*, *Tums*) to avoid proliferation and ambiguity, respectively.

Misspelling generation has the potential to create a large number of variants. Further filtering (phoneme, lexical and semantic) is needed to select the most relevant misspellings. Phoneme filtering helps to reduce the spelling variants generated to a manageable number. Lexical and semantic filtering helps to avoid generating ambiguous variants that would likely generate false positives in retrieval.

1. ***Phoneme filtering*** helps select misspellings that sound like the original term, which are the most likely to be found in text. We use the metaphone algorithm to identify spelling variants of the original drug name with similar pronunciation (see [11] for details). The other spelling variants generated in previous steps are discarded.
2. ***Lexical filtering*** eliminates existing or potentially ambiguous variants. Short variants are discarded (variants of 4 characters or less) because short words tend to be ambiguous. Variants that correspond to existing English words are discarded because their mention in text most likely denotes an entity other than the drug. Finally, variants that correspond to existing drug names are discarded, because they are already covered by the main drug list.
3. ***Semantic filtering*** eliminates variants that correspond to existing biomedical concepts outside the drug domain for the same reason we eliminate variants that correspond to existing English words. In practice, we use the filter developed for eliminating undesirable drug entities (see above).

Automatically Compiled List of Drug Names

For the purpose of identifying drug mentions in death certificates, we organized the Automatically Compiled List (ACL) of drug names around RxNorm ingredients (IN). In practice, we grouped RxNorm precise ingredients (PIN) and brand names (BN), along with their synonyms and spelling variants, together with their corresponding ingredient. For example, mentions of *Prozac* (brand name for *fluoxetine*) and *fluoxetine hydrochloride* (precise ingredient, salt form of *fluoxetine*) are counted as mentions of *fluoxetine*. However, we keep track of the specific type of terminology variant (e.g., brand name) for each variant.

Evaluation

We use this automatically compiled list to identify drug mentions from death certificates and compare the performance of our automated approach to that of the manually curated list of drug names. We use a corpus of death certificates from Washington State. This corpus spans a period of 14 years (from the year 2003 until 2016) and comprises a total of 703,106 death certificates. After indexing the death certificates with the *Elasticsearch* search engine, we used the automatically compiled list (ACL) and the manually curated list (MCL) to query the corpus of death certificates and retrieved one set for each list. Counts of death certificates are aggregated by ingredient (ACL query) or by principal variant (MCL query). For the purpose of comparing ACL and MCL, we normalized terms from the MCL to RxNorm using the RxNorm API.

Results

Drug List Compilation

Collecting and Filtering Drug Names from RxNorm

A total of 22,161 drug names are collected from RxNorm. After eliminating undesirable drug entities, 21,459 drug names remain (11,396 ingredients, 2714 precise ingredients, 5887 brand names and 1462 synonyms).

The 702 variants eliminated are described below.

- UMLS filtering: 689 RxNorm concepts were eliminated because their UMLS semantic type was outside the drug domain. Examples include *Adenine* (T114 Nucleic acid), *Air* (T167 Substance), *Apple Juice* (T168 Food), *Candida albicans* (T004 Fungus) and *Human poliovirus* (T005 Virus). Additionally, five obsolete drug names could not be mapped to the UMLS and were eliminated.
- Eight brand names corresponding to frequently used English terms (*Legend*, *Prevail*, *React*, *RID*, *Thrive*, *Today*, *Tomorrow* and *Triumph*).

Generating Misspellings

Our algorithm generated a total of 3,255,198 spelling variants, but most of them were eliminated during the filtering phase (Table 1). A total of 903,831 spellings variants was retained.

Table 1 - Number of variants eliminated at each step

Filtering step	Number of variants eliminated	Number of remaining variants	Examples of variants eliminated
Phoneme filtering	2,343,923	911,275	*azciximab, prozaw*
Short variant filtering	7132	904,143	*born, corhd, parox, dylan*
Existing English word filtering	242	903,901	*captain, watery, concert*
Existing drug name filtering	63	903,838	*butabarbital, nexavar, protamine*
Semantic types filtering	7	903,831	*phosphide, ostium, ocular*

Automatically Compiled List of Drug Names

The Automatically Compiled List (ACL) of drug names, after eliminating undesirable drug entities and generating misspellings, comprises 925,290 variants organized around 11,396 main drug entities. Figure 3 shows the terminology variants for the drug entity *diphenhydramine*.

Evaluation

Overall Retrieval of Death Certificates

A total of 37,215 unique death certificates were retrieved with the ACL query and 49,163 with the MCL query. Of these, 35,822 death certificates were retrieved by both queries, leaving 1,393 death certificates retrieved only with the ACL query and 13,341 retrieved only with the MCL query. The total number of death certificates retrieved with any query is 50,556, of which the ACL query retrieved 73.6% and the MCL query 97.2%. The difference in recall between ACL and MCL (23.6%) was expected, since MCL contains non-drug substances and drug classes, while ACL is restricted to drug names by construction.

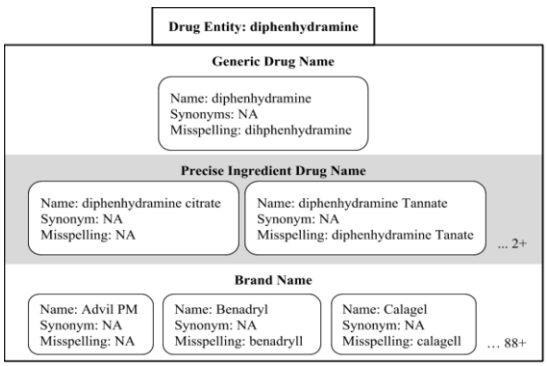

Figure 3 –Example of a drug entity from ACL with different types of variants.

Retrieval of Death Certificates for Individual Drugs

Quantitative evaluation. There are 1654 drug entities present in both MCL and ACL. To assess variant generation in ACL, we specifically compared the number of death certificates retrieved for those drug entities in common between the two lists. A total of 35,674 unique death certificates were retrieved with the ACL query and 37,278 with the MCL query. Of these, 35,633 death certificates were retrieved by both queries, leaving 41 death certificates retrieved only with the ACL query and 1,645 retrieved only with the MCL query. The total number of death certificates retrieved with any query is 37,319, of which the ACL query retrieved 95.6% and the MCL query 99.9%. The difference in recall between both lists, when restricted to individual drugs, is only 4.3% (i.e., much lower than the loss in recall observed overall). Given the significant amount of manual effort involved in curating MCL, the slight loss in recall is indicative of a strong performance for the ACL query. Moreover, the fact that the ACL query retrieved 41 death certificates not retrieved with the MCL query (for variants including *alteplace*, *remicaide*, and *gentamycin*) demonstrates the benefit of a systematic, algorithmic approach to collecting drug names and spelling variants.

Qualitative evaluation. To assess whether ACL and MCL would identify similar trends in drug-related mortality, we compared the top-20 drug entities retrieved by MCL and ACL in death certificates. Table 2 shows that both lists essentially identify the same top-20 drugs. Among the top-20 drug entities in both lists, 19 overlaps. (*Cholesterol* is inappropriately identified as a drug in ACL, but not MCL.) The ranking of these drug entities is also identical in both list, except for the permutation of *Citalopram* and *Alprazolam*, whose frequencies are very close.

Discussion

Specific Contribution of Variant Types

Table 3 shows the overall frequency of death certificates retrieved by each type of terminology variant from the ACL. While ingredient names account for the vast majority of drug mentions, brand names and misspellings also contribute to the retrieval of death certificates.

Table 4 presents the top-5 brand names mentioned in death certificates. Overall, the usage of brand names constitutes 3.6% (1323/37,215) of all drug mentions. One exception is *Coumadin* (926 mentions) , the brand name of *Warfarin* (788 mentions).

Table 2 - Top-20 drug entities identified by MCL and ACL.

MCL		ACL	
Drug entity	**Freq.**	**Drug entity**	**Freq.**
Ethanol	4561	Ethanol	3588
Methadone	3377	Methadone	3375
Methamphetamine	2964	Metamphetamine	2946
Heroin	2456	Heroin	2446
Cocaine	2171	Cocaine	2166
Oxycodone	2100	Oxycodone	2093
Warfarin	1712	Warfarin	1709
Morphine	1412	Morphine	1404
Hydrocodone	1043	Hydrocodone	1037
		Cholesterol	*970*
Diphenhydramine	955	Diphenhydramine	944
Alprazolam	*886*	*Citalopram*	*879*
Citalopram	*884*	*Alprazolam*	*876*
Diazepam	828	Diazepam	827
Oxygen	814	Oxygen	814
Nicotine	685	Nicotine	685
Amitriptyline	623	Amitriptyline	622
Acetaminophen	555	Acetaminophen	552
Iron	533	Iron	533
Hydromorphone	508	Hydromorphone	497
Fentanyl	469	Fentanyl	468

Table 3 - Overall frequency of death certificates retrieved by each type of terminology variant.

Drug category	Variant type	Aggregated number of death certificates*		
Ingredient	Drug Name	35,916	36,007	Total = 37,215
	Synonyms	48		
	Misspellings	398		
Precise Ingredient	Drug Name	122	122	
	Synonyms	0		
	Misspellings	0		
Brand Name	Drug Name	1,299	1,323	
	Synonyms	1		
	Misspellings	25		

** Some death certificates are counted multiple times here when more than one drug is mentioned.*

Table 4 - Top-5 brand names mentioned in death certificates.

Brand name	Generic name	Number of death certificates retrieved
Coumadin	Warfarin	926
Plavix	Clopidogrel	57
Tylenol	Acetaminophen	35
Adriamycin	Doxorubicin	33
Lovenox	Enoxaparin	16

Error Analysis

The error analysis reveals the search terms that lead to loss in recall. Table 5 shows the top-10 drug entities which have the highest difference in retrieval performance. These drug entities explain 61.2% (1007/1645) of the loss in recall. Most of the search terms responsible for the loss in recall are abbreviations (e.g., *ETOH* for *ethanol*). This particular term is responsible for 52.9% (870/1645) of the loss in recall. Adding this one term into ACL would decrease the loss in recall from 4.30% to 1.97%.

Upon inspection of the top-20 drug entities, we observed that some drug entities (from both ACL and MCL) tend to generate

false positive results, i.e., retrieve death certificates for which the drug mentioned is not the cause of death (e.g., *Iron*, mentioned in the context of 'iron deficiency anemia', not iron-related overdose). Most of these drug entities have the semantic type of 'T196 Element' (e.g. *iron*, *oxygen*, *gold*, *helium*) and could easily be eliminated if it is confirmed that they yield false positives.

Table 5 - Top-10 drug entities which have the highest difference in retrieval performance. The search terms are only present in MCL and responsible for the loss in recall. Only the most significant search terms are listed, along with their terminology variant types.

Drug entity	Number of death certificate retrieved		Difference	Search terms (Number of death certificates not retrieved with ACL query)
	MCL	ACL		
Ethanol	4561	3588	973	Abbreviation - *ETOH* (870)
Cannabis Sativa Subsp. Indica Top	107	0	107	Synonym - *Marijuana* (29)
1,1-difluoroethane	78	0	78	Abbreviation - *Difluoroethane* (51)
Alteplase	37	5	32	Abbreviation - *TPA* (32)
Dronabinol	31	3	28	Abbreviation - *THC* (5)
Isopropyl Alcohol	33	7	26	Synonym - *Isopropanol* (10)
Bupropion	271	248	23	Misspelling - *Buproprion* (1)
Cyclobenzaprine	345	326	19	Misspelling - *Cyclobenzapine* (1)
Methamphetamine	2964	2946	18	Abbreviation - *Meth* (7)
Dextromethorphan	213	196	17	Misspelling - *Nyquil* (1)

Sustainability

RxNorm is updated monthly. Since ACL is built programmatically, it can be easily updated when new versions of RxNorm are released. Unlike MCL, the updated ACL will identify mentions of new drugs in death certificates. The algorithm used for generating misspellings is fast and could be run easily on new versions of RxNorm.

Limitations

Our study only focused on drug identification. Assessing whether drug mentions in death certificates actually correspond to drug-related deaths is beyond the scope of this investigation.

Substances mentioned in death certificates are sometimes non-drugs (e.g., *fumes*, *cigarette*, *asbestos*) or drug class names (e.g., *opiates*, *narcotics*, *antipsychotic*, *steroid*) and are not covered by RxNorm. If ICD-10 is not sufficient for coding these substances, other sources can be investigated (e.g., drug classifications systems).

In this preliminary retrieval study, we only included the 184 misspellings that appear in our corpus of death certificates. Restricting misspellings to this small subset would not support the identification of different spelling variants in another corpus of death certificates. However, given the performance of the search engine, using the complete list of misspellings would not be a major issue.

Conclusions

In this study, we explored an automated approach to compiling a list of search terms for identifying drug mentions in death certificates. We showed that the automatically compiled list (ACL) has a competitive retrieval performance for individual drugs compared to the manually curated list (MCL), with only a slight loss in recall, and can reproduce similar drug overdose trend analysis results. Importantly, unlike the manual approach, our automated approach is dynamic, scalable and sustainable.

Pretraining to Recognize PICO Elements from Randomized Controlled Trial Literature

Tian Kang[a], Shirui Zou[b], Chunhua Weng[a]

Abstract

*PICO (**P**opulation/problem, **I**ntervention, **C**omparison, and **O**utcome) is widely adopted for formulating clinical questions to retrieve evidence from the literature. It plays a crucial role in Evidence-Based Medicine (EBM). This paper contributes a scalable deep learning method to extract PICO statements from RCT articles. It was trained on a small set of richly annotated PubMed abstracts using an LSTM-CRF model. By initializing our model with pretrained parameters from a large related corpus, we improved the model performance significantly with a minimal feature set. Our method has advantages in minimizing the need for laborious feature handcrafting and in avoiding the need for large shared annotated data by reusing related corpora in pretraining with a deep neural network.*

Keywords:

Natural Language Processing, Evidence-Based Medicine, Randomized Controlled Trial

Introduction

Evidence-Based Medicine (EBM) is the conscientious, explicit, judicious and reasonable use of modern, best evidence in making decisions about the care of individual patients [1]. However, the evidence base has been growing exponentially. It is practically impossible to catch up with the explosion of the biomedical scientific literature and realize fast and effective evidence retrieval and decision making for EBM practitioners [2; 3]. Evidence adoption at clinical practice remains suboptimal due to poorly formulated clinical questions, ineffective evidence search strategies, and disconnected databases preventing access to the best evidence.

Successfully retrieving relevant evidence begins with a well-structured question. Thus, the ability to question formulation is fundamental to locate and synthesize related resources . PICO (Population/problem, Intervention, Comparison, and Outcome) is widely adopted for formulating clinical questions to retrieve evidence from the literature. PICO stands for :

P *– Population/Problem. What are the most critical characteristics of the enrolled population? What is the primary disease?*
I *– Intervention. What is the primary intervention considered?*
C *– Comparison. To what the intervention is compared?*
O *– Outcome. What are the anticipated measures, improvements or effects?*

The PICO framework is specialized to help break down the need for evidence into searchable keywords and to formulate answerable research questions [4]. A prior study has shown that utilization of the PICO framework can improve evidence search against PubMed [5]. However, due to high demands for technical skills and medical domain knowledge for using PICO, practitioners and the general public who require searching evidence may find it either time consuming to incorporate into their busy clinical workflow, or difficult to learn. Automatic extraction of PICO statements in the biomedical literature is desired to facilitate evidence retrieval, appraisal and synthesis by clinicians and the public [6; 7].

Natural language processing (NLP) in particular promises to help us achieve this goal. Previous work has explored the use of NLP techniques to identify PICO elements in biomedical text. During the last decade, the primary solutions have evolved from knowledge-based to statistical-based such as Support Vector Machine (SVM) and Conditional Random Field (CRF) [8-11]. However, this area has attracted less attention than it should have from the NLP community, primarily caused by the lack of publicly available, annotated corpora [12], and systems almost all heavily rely on laborious handcrafted features including those specifically designed to incorporate domain knowledge.

In practice, there also lacks modularized fundamental NLP tools to support different aspect of evidence synthesis and EBM, such as tools for Named Entity Recognition (NER) to recognize PICO elements and their attributes in literature for indexing, information extraction (IE) systems for parsing and structuring study design and results from free-text literature, as well as information retrieval (IR) tools based on the PICO framework to support effective searching in literature.

With rapid advances in neural network and deep learning, recent state-of-the-art NLP systems have been developed using neural models, including some for the biomedical domain. For the Named Entity Recognition (NER) task, the best performance is achieved by biLSTM-CRF [13-15]. And transfer learning attracts increasing attention to solve high demand of large data for training neural networks [16; 17]. Recently a corpus of 5000 RCT abstracts with multi-level annotations of Patient, Intervention, and Outcomes was published, enabling new NLP application development for EBM research [12].

Compared to prior work, our PICO extraction method makes the following three significant and innovative contributions. First, it is the initial publicly available open-source NLP system for recognizing PICO elements and their attributes/measures in RCT abstracts. PICO elements are normalized with UMLS CUIs (https://github.com/Tian312/PICO_Parser). Second, this tool is developed with the minimum human labor but achieves comparable and even better performance in some categories: only a small size of gold standards is created with high inter-annotator agreement; only word feature, and no laborious handcrafted features, is used. Third, we contribute a method to reuse a large related corpus [12] under annotation guidelines different from ours to improve our model performance.

Methods

Our PICO statement extraction tool processes RCT literature following these steps: 1) Named Entity Recognition for PICO

elements and attributes; 2) UMLS encoding; 3) XML output formatting. An overview of our workflow to develop the model and tool is shown in Figure 1.

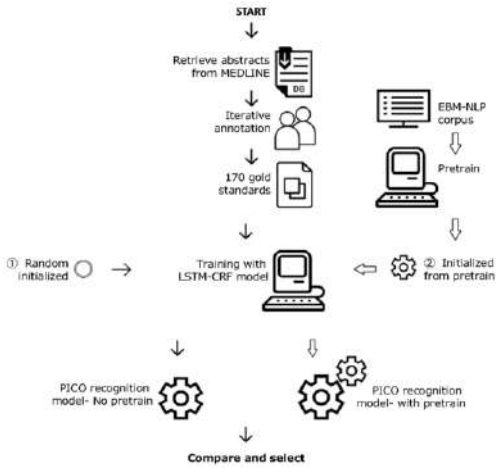

Figure 1 - Overview of the PICO recognition tool development. We compared two optional ways for training the LSTM-CRF model (in blue): 1) with random initialization of model parameters (green, on the left); 2) "pretrain" the model with the same architecture on EBM-NLP corpus, resulting in a better parameter initialization.

Data Collection

Small Size of Gold Standards from Manual Annotation

We randomly retrieved 170 RCT publications using indexed metadata from the MEDLINE database. Abstracts were retrieved from the articles and prepared in brat, a web server based collaborative annotation tool [18]. One medical professional (ZS) and one informatic researcher (TK) designed the annotation guideline for entity and attribution using an iterative process. Entity classes included in the annotation: Population, Intervention (Comparison is merged with Intervention as a subclass), and Outcome, each strictly following standard definition from the PICO framework [4]. The context for PICO elements consists of 2 types of attributes: Qualifier, a qualitative description of PICO elements (e.g., *"difference", "similar", "higher"*), and Measure, a quantitative description of PICO elements (e.g., *"138 +/- 13 mg daily"*). During the annotation process, both annotators followed the guideline for asking answerable research question [19]: each RCT abstract is first classified into one of 5 common clinical question types: Treatment, Prevention. Diagnosis, Prognosis, and Etiology, then annotated with PICO elements based on research type. Attributes are also identified in order to form PICO statements in entity-operator-value triplets. Each abstract is annotated at least twice by two annotators in order to ensure it strictly follows the guideline. As a rule, annotators skip annotating background and implication sections in abstracts since those parts do not usually describe study design or report objective results. An example annotation interface in brat is shown in Figure 2. This step is aimed to create a small size of annotation with a high inter-annotator agreement and high quality, serving as gold standards and core training set.

A Related, Large Publicly Available Corpus

A corpus of 5000 abstracts with multi-level annotation of PIO (C is categorized as a subclass in I as well) has recently been published by a group of EBM researchers [12] (referred as EBM-NLP corpus later in this paper). The annotation was generated primarily by laypersons from Amazon Mechanical Turk (AMT) and a small part by medical professionals. The average inter-annotator agreement is measured by F1 score as 0.3, 0.18, 0.1 in span annotation and 0.5, 0.6, 0.69 in the hierarchical annotation for P, I, O classes, respectively. After reviewing this corpus, we decided that this annotated corpus cannot be directly used for our task for two major reasons. First, the annotation guidelines, primarily in part of defining element boundary and granularity, are different. In the EBM-NLP corpus, identified PICO tend to be the longest description within a sentence. While our guideline is designed to break down abstracts into the most basic elements, which can be used as "building block" for PICO statements and encoded to represent study design and results of each RCT article. For example, "*Seventy-two consecutive anti-HBe-positive chronic hepatitis B patients (59 male and 13 female, median age 41 yr)*" (PMID 10235220) was annotated as one Population element in EBM-NLP. While in our annotation, we recognize "*consecutive anti-HBe-positive chronic hepatitis B*", "*male*", "*female*" and "*median age*" as 4 independent Population entities, and "59", "13", "41yr" as measures. Second, as aforementioned, the EBM-NLP corpus combines measured values descriptive statistics with the PICO terms, while we have separated classes. Instead of directly training on this corpus, we believe it can be helpful for modeling a similar context as a pretrain and guide the next model training on our small gold standards.

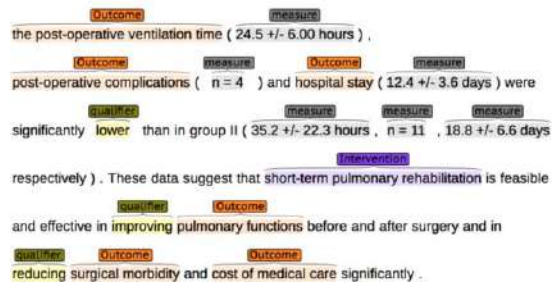

Figure 2 – Example of our annotation in brat

Base model learning and pretraining

We model the task to identify PICO statements, which comprise PICO elements and their attributes in the biomedical literature, as a sequence labeling task for Named Entity Recognition (NER). NER is fundamental in general text mining, as well as in biomedical domain, e.g., recognizing problems, drug names in clinical notes, or protein, gene names in literature. As deep learning based approaches to this tasks have been gaining attention in recent years, NLP researchers now tend to prefer those methods over traditional models alone such as Support Vector Machine (SVM) or Condition Random Field (CRF) since the parameters can be learned end-to-end without the need for hand-engineered features [15]. This is particularly true in biomedical domain where traditional biomedical NLP systems heavily rely on hand-made rules and ontologies in order to reach a good performance. Deep learning methods also start attracting biomedical NLP researchers. However, these approaches are usually built upon large, high-quality labeled data, which is expensive to obtain especially in the biomedical domain because labeling biomedical text requires special medical training.

To address the lack of training corpus, recent researches start focusing on training multi-task models [20], and conducting data augmentation or transfer learning [16; 17]. Inspired by their work, we explore the feasibility and the potential way to overcome such two challenges (i.e., hand-engineered features

and large, high-quality data) in a small training set and simple feature with the help of the public data. We adopt the bidirectional Long short-term memory (LSTM), a kind of recurrent neural network as our base model, and decode with a linear chain CRF in the output layer (biLSTM-CRF). This architecture now achieves state-of-the-art performance in NER tasks. The model details are illustrated in Figure 3. We use classical "BIO" tags to represent the boundary of terms of interest: "O" means it is outside the target terms. "B" represents the beginning word, and "I" tags all the inside words. We compare the results trained with raw tagging to BIO tagging methods. Tagged output for the example in Figure 3 is:

- ***Pre-operative****/B-Intervention* ***short-term****/I-Intervention* ***pulmonary****/I-Intervention* ***rehabilitation****/I-Intervention for patients …*

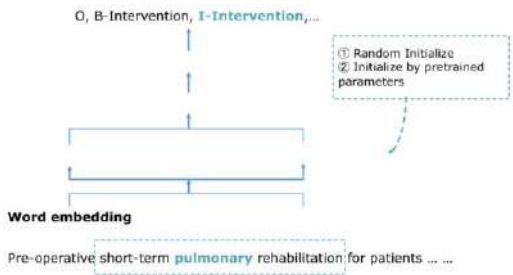

Figure 3 - Base model detailed architecture. It's used to train both PICO recognition model and EBM-NLP corpus.

The base model is similar to [14], and is also used in EBM-NLP corpus paper to generate task baseline for identifying PICO span. The dark green in Fig. 3 represents modules learned during training. While the light green, namely word embedding is pretrained on an entire collection of abstracts on PubMed from 1990-2018 using word2vec toolkit [21]. During the learning phase, the model first generates a character-based representation of each word and concatenate it with pretrained word vectors. In other words, each input word is represented by two concatenated vectors in both word level and character level. In the next step, each sentence as sequenced word vectors is then fed into a bidirectional LSTM to extract the contextual representation of each word.

At this step, we can get a likelihood at word level through a decoder layer. A significant drawback of optimizing by word-level likelihood is that it doesn't consider dependencies between neighboring in the sentence. Thus, a CRF layer is added to model the entire sentence structure. CRF is a log-linear graphical model that additionally considers the transition score from one tag to the next. This characteristic makes it a classic model in traditional NER tasks. After decoding by CRF, the log likelihood is maximized for the entire sentence in order to select the best tag for the target word. Like in Figure 3, when the target word is "pulmonary", all the neighbor words in a window are considered to generate the tag. Only word features, i.e., word vectors and character vectors, are used in this model, without any feature engineering.

Without pretraining, biLSTM in the base model is randomly initialized and then optimized using the Adam optimizer. For pretraining, we use the entire 5000 abstracts in EBM-NLP corpus with "starting span" annotation (only in PICO level, no further hierarchical labeling) in the same model architecture, and then transfer the learned weights to the PICO recognition model. Next, we fine-tune the PICO recognition model to reach the best performance. All models are trained using TensorFlow (https://www.tensorflow.org/).

Concept Normalization and Output Structuring

We select the best model as the backend support of our PICO recognition tool. Given one or a set of free text abstracts as input, the tool automatically recognizes Patient, Intervention (including Comparison), Outcome elements and corresponding attributes. In order to support further computational tasks, the recognized PICO elements are encoded with the Unified Medical Language System (UMLS, https://www.nlm.nih.gov/research/umls/), an integrated biomedical terminology, by applying a UMLS concept extraction tool QuickUMLS [22]. Extracted semantics are further organized into a structured format. The default output format is XML, while users can also choose JSON, as more recently published APIs use JSON as standard data format.

Results

Descriptive Statistics of the Annotated Corpus

We created a sharable, finely annotated corpus for PICO extraction with its descriptive statistics provided in Table 1.

Table 1. Descriptive statistics of the annotated corpora

	Entity class			Attribute class	
	P.	**I. (+C.)**	**O.**	**Qualifier**	**Measure**
Count	1185	2027	2140	766	904
Agreement	0.916	0.844	0.727	0.955	0.954

The inter-annotator agreement is evaluated by cohen's κ statistic. The overall agreement between the two annotators for 5 categories is 0.83. The category-specific κ measures is reported in Table 1. Our goal in this step is to create a corpus of high-quality annotation with high agreement. Thus, our annotation team spent much time on iterative annotation guideline design and test run in sample corpus for multiple rounds to resolve discrepancies between annotators and arrive at consensus understandings for each class and required granularity. Compared to the related NLP work, we have a relatively small corpus to minimize human labors. We plan to achieve satisfactory performance with such small corpus.

Model Performance

For evaluation purpose, 6-fold cross-validation is applied. 170 abstracts are equally divided into 6 groups. Among each run of model learning and testing, 4/6 of the data used as training set, 1/6 as validation set and 1/6 as test set. We report the performance on test sets.

Classic evaluation metrics are generated for evaluating NER tasks: precision, recall and, F1 score, to evaluate model performance in two different levels: word level and token level and use represent the two by *span* and *trunk*. In word level or span evaluation, the basic unit is the word, while in trunk evaluation, basic unit is a token. Using an intervention element with BIO tagging as an example, "*short-term/B-Intervention pulmonary/I-Intervention rehabilitation/I-Intervention*", in span evaluation, there are 3 predictions for each word. A true positive is counted when both BI tag and class are predicted correctly. There are 3 true positives at most. While in trunk evaluation, "short-term pulmonary rehabilitation" is counted as one token, 1 true positive is counted only if both boundary and class of this token are correctly predicted.

The model performance is reported based on the test set in Table 2. We test performance with different tagging methods (raw/BIO tagging) and pretrain or not. For each model setting, we report the best evaluation among 6 sets for cross-validation

and also averaged measures. In summary, using BIO tagging and pretrain can both improve model performance. In word-level, span evaluation, the best performance comes from the model using pretrain and raw tagging with 0.78 in averaged F1 score, and the best F1 in the subset is 0.89. Compared to the model setting with raw tagging as well but using no pretrain, the F1 score has been improved about 10%. With pretrain and BIO tagging, the performance is also improved, but not as much as using raw tagging. It's a reasonable result as in BIO tagging a word is counted as true positive requiring both BI tags and class are correct while raw tagging only require class prediction. On the other hand, BIO tagging provides more information for learning to help identify the boundary of each element. This is reflected by the evaluation in trunks/token level. The best performance in token level is generated by model with pretrain and BIO tagging (average F1 score 0.62, best 0.64). Compared to the two model only trained on 170 abstracts (0.52/0.54 for average F1), pretraining on EBM-NLP corpus and transferring learned parameters also help improve the model performance significantly by 10%. Therefore, applying pretrain and BIO tagging can best improve the recognition of PICO elements boundaries and predicting PICO classes.

Table 2. Model performance in different training settings.

		No Pre + Raw		No Pre + BIO		Pre + Raw		Pre + BIO	
		Best	**Ave.**	**Best**	**Ave.**	**Best**	**Ave.**	**Best**	**Ave.**
Test set (Span)	**Precision**	0.78	0.76	0.84	0.85	0.93	0.87	0.86	0.83
	Recall	0.62	0.63	0.68	0.66	0.80	0.70	0.71	0.7
	F1 score	0.69	0.66	0.75	0.74	**0.89**	**0.78**	0.78	0.73
Test set (Trunk)	**Precision**	0.54	0.52	0.58	0.53	0.74	0.61	0.63	0.63
	Recall	0.53	0.51	0.56	0.52	0.74	0.56	0.64	0.61
	F1 score	0.53	0.52	0.57	0.54	0.74	0.58	**0.64**	**0.62**

We further analyzed the individual performance from one of the 6 sets using the best model setting (Pre+BIO). The details are shown in Table 3. As evaluated by F1 score, entities with B tags are generally better than I tags, indicating the model is better at predicting if there is an entity, but need to be improved to predict the span of it. I tag prediction is especially poor in evaluation for Modifier, with F1 score only 0.25. We retrieved raw prediction results for Modifier class. We found due to the fact that we have a small gold standard set, and only 1/6 used for testing, there are only 166 Modifier tokens in the test set, among which only 6 are not unigram (have I tags). Modifiers are usually one-word token such as "higher", "rise", and "similar". Among 6 modifiers with I tags in the test set, the model predicts 2 I-modifier tags and 1 of them is correct. Thus, precision/recall is 0.5/0.16 and F1 is calculated as low as 0.25, but actually caused by its small total number in entire corpus.

Table 3. Detailed evaluation for one set in PICO/attribute

	B-Pop.	**I-Pop.**	**B-Int.**	**I-Int.**	**B-Out.**	**I-Out.**
Precision	0.82	0.84	0.82	0.78	0.88	0.85
Recall	0.68	0.65	0.70	0.50	0.75	0.42
F1 score	0.75	0.74	0.75	0.61	0.81	0.56
	B-Mea.	**I-Mea.**	**B-Qua.**	**I-Qua.**		
Precision	0.77	0.85	0.91	0.5		
Recall	0.65	0.65	0.60	0.17		
F1 score	0.71	0.74	0.72	0.25		

Sample output

The models are trained with following parameters: mini batch (size of 5) and Adam optimizer are selected for training; the dimensions of the word and character vectors are 200 and 100; the learning rate is set as 0.001with a decay of 0.9. Pretrain converges within 50 epochs and the training on 170 abstracts within 10 epochs. A sample recognition result in XML format is shown in Figure 4 It contains rich parsed semantic and positional information that can support further computational tasks such as relation extraction and information retrieval. Sample JSON output can be found in our github repository.

Figure 4 - Sample output for our PICO extraction method

Discussion

Error Analysis

The most common error happens when multiple PICO terms appear in conjunction. For example, an RCT paper titled "Perioperative enteral nutrition and quality of life of severely malnourished head and neck cancer patients: a randomized clinical trial", and one Population entity recognition result is:

<entity class=Population UMLS='C0278996:head and neck cancer,C0162429:malnourished,C0205082:severely' index='T3' start='8'> severely malnourished head and neck cancer </entity>

Although we define the PICO elements to be the annotated as the most basic concepts (should be "*malnourished*" and "*head and neck cancer*" the two P entities in this case), there was

variance in what annotators considered, also causing inconsistency when calculating inter-annotator agreement.

Comparative Performance Evaluation Results

In the EBM-NLP corpus, the best performance for the baseline model trained on 5000 abstracts for P, I, O classes are 0.71, 0.65 and 0.63 by F1 score respectively (mathematical mean: 0.66) at the word level. In contrast, with a small gold standard set (170 abstracts) and without any hand-engineered features, our model reaches 0.78 for the best average F1 score at word level and 0.62 at the token level. Our results prove the effectiveness of pretraining in minimizing human efforts in annotation and features engineering while reaching satisfactory performance.

Future Work

We have not yet related the attributes to their PICO elements nor distinguished PICO elements by arms. To further complete the structured information, negation and semantic relations need to be identified. We will progressively complete the functions of this tool, and eventually turn it to comprehensive information extraction system to computationally represent abstracts describing RCTs.

Conclusions

In this study, we demonstrate the early promise of pretraining to improve model performance tuned on a small training set, with only word feature, and we achieve better performance than conventional machine learning models trained on a larger corpus. This result is significant in showing the feasibility of overcoming the challenges in the dearth of annotated data and laborious feature handcrafts in biomedical NLP. We also contribute an open source NLP tool to automatically recognize PICO elements and their attributes from RCT abstracts. This tool, can be used to structure study design and results and can further enhance evidence retrieval and synthesis from biomedical literature to facilitate evidence-based medicine.

Abstract

This study focuses on the extraction of medical problems mentioned in electric health records to support disease management. We experimented with a variety of information extraction methods based on rules, on knowledge bases, and on machine learning, and combined them in an ensemble method approach. A new dataset drawn from cancer patient medical records at the University of Utah Healthcare was manually annotated for all mentions of a selection of the most frequent medical problems in this institution. Our experimental results show that a medical knowledge base can improve shallow and deep learning-based sequence labeling methods. The voting ensemble method combining information extraction models outperformed individual models and yielded more precise extraction of medical problems. As an example of applications benefiting from acurate medical problems extraction, we compared document-level cancer type classifiers and demonstrated that using only medical concepts yielded more accurate classification than using all the words in a clinical note.

Medical Informatics, Natural Language Processing, Neural Networks

Introduction

Computerized physician order-entry systems with decision support have been implemented as a solution to reduce medical errors, but these systems rely on structured and coded information in the electronic health record (EHR). Unfortunately, a substantial proportion of the information available in the EHR is only mentioned in narrative clinical notes. Electronic lists of problems are available in most EHRs, but they require manual management and consequently are often incomplete, inaccurate, and out of date.

To improve the completeness, correctness, and timeliness of electronic lists of medical problems and allergies, we are building on earlier efforts [26] and developing a system based on natural language processing (NLP) to continually extract relevant information from EHR notes with high accuracy [27]. This system is integrated with the EHR system and helps ensure the majority of medical problems and allergies of a patient are known by their healthcare providers, and are available for decision support and quality improvement.

In this study, we focus on medical problem extraction (MPE) to identify medical problem concepts, such as disease, sign, symptom, and other abnormalities mentioned in EHR text notes. MPE makes relevant patient information available to improve patient data quality and disease management. The challenge of this task is in limited access to shared data, unstructured narrative text format, and heterogeneous contents across various healthcare providers.

For this research, we employ a variety of information extraction (IE) methods including rule-based and machine-learning based methods. Early clinical NLP applications used rule-based approaches combining syntax analysis and semantic lexicons to identify and encode medical information [6; 10; 30]. MetaMap [1] is a prominent rule-based system example we also used for this research. It maps terms found in biomedical or clinical text with Unified Medical Language System (UMLS) [2; 21] Metathesaurus concepts.

Most current clinical IE systems use statistical machine learning approaches that often achieve better performance than rule-based approaches. The MPE task is closely related to named entity recognition (NER). Over the past two decades, NER has applied a variety of machine learning algorithms [8; 17; 24]. Clinical NER has advanced from general text or biomedical literature NER by sharing the algorithms and features. More recently, NER based on deep neural networks [7; 18; 22] has reached even higher accuracy than previous machine learning-based approaches. We also adopted these recent advances and trained long-short-term memory (LSTM) recurrent neural networks (RNN) [12] with the output of rule-based systems.

Machine learning-based approaches have been effective in information extraction because of their ability to automatically capture lexical, syntactic, or morphological patterns in the terms of interest and their local surroundings. However, when focused only on certain types of information with small amounts of labeled text for training, supervised learning methods tend to only allow for reduced accuracy. They tend to miss information that does not appear in training data, or extract false positive information that is not of interest.

We investigate information extraction methods to identify only commonly recorded medical problems in EHRs. We present a new clinical text corpus from the EHR of patients with breast, lung, or gastrointestinal cancer. We focused on the 168 medical problems most frequently recorded at the University of Utah Healthcare in 2013. We annotated all mentions of the selected medical problems and of all directly related medical problems (i.e., parent or children such as "*Hypertensive crisis*" or "*Systolic hypertension*" with "*Hypertensive disease*").

First, we create four different MPE applications implementing different methods and evaluate performance with our new corpus. Next, we show that augmenting features derived from a medical knowledge-base allows for better performance, and using a combination of various MPE methods can yield more precise extraction of medical problems.

As another contribution of our study, we examine whether the MPE methods can help with document classification. We trained multi-class classifiers using the words contained in the documents and medical problem concepts identified by the MPE applications. We demonstrate that cancer type classifiers using only medical concepts can lead to more accurate classification.

Methods

In the following paragraphs, we present an NLP system that extracts medical problems from clinical notes. We describe how we created a new clinical text corpus and examine how we developed four different MPE applications.

Data Description

For this study, we randomly selected a cohort of 154 patients treated at the Huntsman Cancer Institute (Salt Lake City, Utah) for breast, lung, or gastrointestinal cancer. For each patient, five most recent clinical notes of select types were used. To create a reference standard, nine medical experts annotated all mentions of the selected medical problems (i.e., 168 most frequently recorded medical problems at the University of Utah Healthcare in 2013) found in the clinical notes. The inter-annotator agreement was good with an F_1 score of 70% or even 90% if not considering detailed modifiers (e.g., negation, temporality, subject), allowing for a good quality reference standard.

Our corpus was randomly split in a training subset of 495 notes and a test subset of 275 notes. The training subset contains 9,337 annotated medical problem concepts and the test subset contains 5,360 concepts. Table 1 shows the ten most prevalent medical problems in each text collection categorized by cancer type. Some medical concepts, such as '*dyspneas*' and '*swollen lymph nodes*', are common across all texts. However, the prevalence of most medical concepts varies greatly. For example, '*colon cancers*' is far more common in the medical records of gastrointestinal cancer patients (not surprisingly).

Medical Problem Extraction Applications

We describe how medical problems were recognized using a variety of information extraction methods, including knowledge base, rule-based, and machine learning models.

MetaMap

We used MetaMapLite [9], a knowledge-based system that identifies UMLS Metathesaurus concepts in free text. We used the CUIs (Concept Unique Identifiers) assigned by MetaMap to select concepts of interest for our task. Once we collected all of MetaMap's findings, we chose the MetaMap concepts with CUIs listed in our terminology subset of 16,384 UMLS concepts described below.

Rule-based Application

The rule-based system used dictionary lookup with a custom medical problem terminology subset. We used a modified version of ConceptMapper [31], an easily configurable dictionary annotator. We identified the longest phrase of contiguous word tokens that matched one of the dictionary entries.

We created a medical problem terminology subset based on the Clinical Observations Recordings and Encoding (CORE) Problem List Subset of SNOMED CT [11]. For the 168 most frequently recorded problems, the parent and all children (i.e., more detailed concepts) were also included. As a result, our dictionary included 57,624 medical problem concepts. For each concept, the corresponding UMLS CUI was recorded. A CUI was often linked with multiple terms. For example, '*renal fibrosis*', '*kidney fibrosis*' and '*fibrosis kidney*' were all linked with '*C0151650*'.

Conditional Random Fields (CRF) Application

We created sequential models using linear chain CRFs [17]. We applied the Stanford CoreNLP tool [23] to our datasets for tokenization, sentence annotation, lemmatization, part-of-speech (POS) tagging, and named entity recognition (NER). To train the CRF models, we used Wapiti [20], a simple and fast discriminative sequence labeling software.

The training data was reformatted with BIO token tags (B: at the beginning, I: inside, or O: outside of a concept). The feature set was based on our previous medical concept extraction studies [14; 15]. We defined features for the targeted word's lexical string, lemma, POS tag, affix(es), orthographic features (e.g., alphanumeric, InitCaps), named entity tag (e.g., PERSON, LOCATION, DATE, TIME), word skip-grams, word embedding features, and the predictions of *MetaMap* and the *Rule-based application*. We used the orthographic features defined in McDonald and Pereira [25] with a slight modification. For example, "`[A-Z].*`" is a regular expression to capture whether the first letter of a word is capitalized (InitCaps). We performed K-means clustering for word embedding using word2Vec [28]. We created 1,000 clusters of semantically related words in the 2014 English Wikipedia data with word2Vec default parameters. We used the cluster identifier of each word in a sentence as a feature.

We implemented four different CRF variations: without external system output (CRF), with MetaMap output (CRF+M), with the Rule-based application output (CRF+R), and with the outputs of both systems (CRF+M+R) as features. To fine tune

Table 1– Ten Most Frequent Medical Problems in the Training Set

CUI	Examples	Count			
		Total	brCA	giCA	lgCA
C0006142	*breast cancer, malignant tumor of breast*	360	350	4	6
C0027497	*nausea, feeling queasy*	353	90	192	71
C0007102	*colon cancers, malignant colon tumor*	326	17	300	9
C0013404	*dyspneas, short of breath*	309	102	99	108
C0015967	*high body temperature, fevers*	296	93	149	54
C0000737	*abdominal pains, bellyache*	288	69	202	17
C0042963	*vomiting symptom, throwing up*	227	60	128	39
C0011991	*diarrheas, loose stools*	223	38	119	66
C0497156	*lymphadenopathy, swollen lymph nodes*	216	62	85	69
C0015672	*fatigue, tiredness*	194	37	80	77

brCA: breast cancer, giCA: gastrointestinal cancer, lgCA: lung cancer

the parameters of machine learning-based classifiers, we randomly selected 100 documents (about 20% of the training set) from the training set as held-out data. Parameters were tuned to maximize the F_1 score with the held-out data. We observed that CRF models performed very well with the parameter settings used in our medical concept extraction studies [14; 15]. We set the size of the interval for the stopping criterion to be $e = 0.001$. For regularization, *L1* and *L2* penalties were set to 0.005 and 0.4, respectively.

RNN Application

We trained RNN-based deep neural network models proposed by Ma and Hovy [22]. To build BLSTM-CNN-CRF models, the combination of bidirectional LSTM network, character-level CNN (convolutional neural network) and CRF decoding, we employed the NER system of Reimers and Gurevych [29]. Similarly to CRF models, we trained RNN models with or without the outputs of two external systems. Words and the output of the MetaMap and Rule-based application were used as inputs. We used *RMSProp* gradient descent method to produce more stable results than other optimizers. The RMSProp gradient descent is an adaptive learning rate method proposed by Tieleman and Hinton [32] and keeps the gradient relatively small and consistent during iterations. After experimenting with different values on the development data, we set the learning rate at 0.0001 and the models were trained within fifty epochs.

As demonstrated by the experimental results of Reimers and Gurevych [29], non-deterministic approaches, such as LSTM network with random weight initialization and a random shuffling of the training data, can lead to statistically significant differences between multiple runs, even with the same hyperparameters. To obtain the most representative or consistent model among the various models, we applied the model selection method based on the pairwise comparison. We trained five different RNN models with the same hyperparameters and extracted medical concepts from the test set. We then calculated the similarity (i.e., pairwise F_1 score) between the results of five trials and selected the model with the highest F_1 score on average.

Voting Ensemble Method

A voting ensemble can provide a convenient and effective way to combine multiple applications without retraining the new model. It has been applied to several NLP tasks and has shown that it can outperform individual applications [4; 5; 16]. We created an ensemble method combining all MPE applications with voting from the predictions of the individual application. We used the ensemble method with voting that we successfully applied to our previous research on medical concept extraction [14; 15] or text de-identification [13]. The ensemble method collects all concept predictions from the individual MPE applications.

The voting ensemble selects a concept candidate when having one vote for each component to determine whether the candidate is a medical concept. When two different concepts have overlapping text spans, the concept that receives more votes is selected. For overlapping concepts with identical vote counts, the one produced by the highest ranked MPE application is selected. To determine the ranking of the applications, we measured how an MPE application agreed with the others for medical concepts extraction. Similarly to the model selection method applied to the RNN, an application ranking was based on the F_1 scores measured with the other applications. The higher the average F_1 score, the higher the application was ranked.

Cancer Type Classification

To confirm that our MPE applications could benefit other high-level tasks, we tackled the cancer type classification problem. This task involves recognizing three types of cancer: *breast cancer*, *gastrointestinal cancer*, and *lung cancer*. The classifier assigns one of the three cancer categories to a clinical note using its textual content.

We created a multi-class OGD (online gradient descent) [3] classifier with words and medical problem concepts. We used the Vowpal Wabbit [19] online learning library to train one-against-all models. For each word contained in the document, we defined 3-skip-trigrams that allow for words to be skipped. These lexical features were also captured for each word contained in the medical problem term. The number of training passes was set to 100 after trials with default Vowpal Wabbit parameters.

Results

We present experimental results for each MPE application and for the voting ensemble method. We measured recall, precision, and the F_1 score (harmonic mean of recall and precision with equal weight). We present the results of exact and partial text span matching. With exact matching, the text span must exactly match the reference annotation. With partial matching, any overlap between the reference standard text span and the concept detected by the system is considered a match. We also assess the classification of the document for patient cancer types. We report the accuracy of how our multi-class model correctly identifies the type of cancer in each patient note.

Evaluation of MPE Methods

Table 2 shows the results measured with individual MPE applications and the voting ensemble method. MetaMap showed moderate performance. Filtering with the list of CUIs of interest allowed for a precision of 94.3%, but a relatively low recall of 79.7% with partial matches. Our dictionary lookup (Rule-based application) reached good performance with a recall of 87.8% and 91.6% with exact and partial matching respectively. It produced higher recall and F_1 score than the CRF and RNN MPE applications.

Table 2– Problem Extraction Result of Each Method

Methods	Exact			Partial		
	P	**R**	**F**	**P**	**R**	**F**
MetaMap (M)	87.4	73.8	80.0	94.3	79.7	86.4
Rules (R)	88.8	87.8	88.3	92.7	91.6	92.2
CRF	90.3	81.7	85.8	95.3	86.3	90.6
CRF+M	91.5	86.8	89.1	95.4	90.5	92.9
CRF+R	93.0	91.8	92.4	95.5	94.2	94.8
CRF+M+R	93.4	91.8	92.6	95.9	94.2	95.0
RNN	86.3	85.3	85.8	91.5	90.5	91.0
RNN+M	89.6	88.7	89.2	93.8	92.9	93.3
RNN+R	92.9	91.4	92.1	95.5	94.0	94.7
RNN+M+R	92.3	**92.7**	92.5	94.7	**95.0**	94.9
Vote	**93.8**	92.1	**92.9**	**96.0**	94.3	**95.1**

P = Precision, R = Recall, and F = F_1 score

CRF with MetaMap (CRF+M) and Rule-based (CRF+R) outputs increased F_1 scores by 3.3 (= 89.1% − 85.8%) and 6.6 (= 92.4% − 85.8%) respectively. Among the four CRF models, the CRF+M+R system obtained the best results with an F_1 score of 92.6% with exact matching and 95.0% with partial matching.

In general, RNN models achieved higher recall than corresponding CRF models. The RNN model with MetaMap and Rule-based outputs (RNN+M+R) produced the best recall at 92.9% and 95.0% with exact and partial matching, respectively.

We evaluated the performance of the ensemble method with voting combining ten MPE application versions. The last row in Table 2 shows the results with a voting threshold of five (i.e. five votes are needed to annotate a concept). This voting ensemble method achieved higher precision than any of the individual classifiers, with 96.0% precision, 94.3% recall, and 95.1% F_1 score with partial matching. Using a paired t-test to compare F_1 scores demonstrated that the voting ensemble method reached significantly higher accuracy than all other approaches at the 95% significance level with exact matching, but not significantly better than the CRF+R, CRF+M+R, and RNN+M+R models with partial matching.

Evaluation of Cancer Type Classification

We examined the impact of the various MPE approaches and how they contributed to cancer type classification. Table 3 shows the results produced with the multi-class models using the combination of all words and medical problem concepts extracted from the clinical notes. For comparison, we also created two additional models with reference standard medical concepts.

Table 3– Cancer Type Classification at Note Level

Features	Accuracy (%)
Words	75.6
Problems (given)	90.2
Problems (system)	88.7
Words + Problems (given)	87.9
Words + Problems (system)	87.3

The model trained with only words (first row in Table 3) achieved 75.6% accuracy. The models with only problem concepts outperformed the models with the combined features from words and problems. The model trained with system detected problems (third row) reached an accuracy of 88.7%. This demonstrates that our MPE task has the potential to efficiently acquire relevant patient information for improved data quality and decision making.

Discussion

Figure 1 shows the recall, precision and F_1 score measured with the voting ensemble method and 10 different MPE application versions. Note that the y-axis scale in each graph does not start at zero to focus on the value ranges of interest.

Partial matching results with voting thresholds ranging from one to ten are presented. The voting threshold had a significant impact on performance. The curves show that the higher the threshold, the higher the precision but the lower the recall. When the voting threshold was set to four or five, the voting ensemble achieved the highest F_1 score at 95.1%.

We analyzed false negatives from the voting ensemble method. Table 4 shows false negative examples with the number of occurrences in the training data. When contextual differences in the words surrounding the medical concept terms were found, they were misclassified, although they often appeared in the training data. We also witnessed some false negatives written in a similar way to medical concept terms that are not our interest. Some abbreviated concepts were missed when they never or rarely appeared in the training data. For example, CVA (cerebrovascular accident) occurred only two times and SVT (supraventricular tachycardia) never appeared in the training data.

Figure 1– Voting Ensemble Method Results

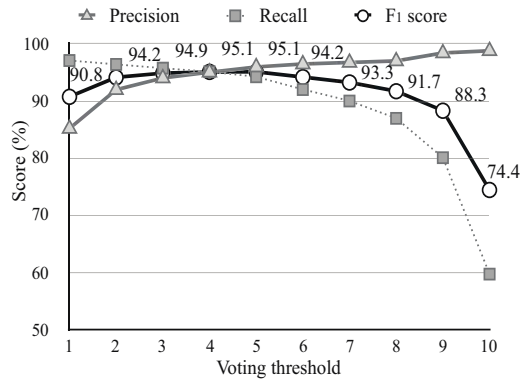

Table 4– False Negative Examples

Occurrences	Examples
More than 50 times	*vomiting, chest pain, JVD*
Less than 5 times	*CVA, N&V*
Unseen	*T2DM, SVT*

Conclusions

We demonstrated that a medical knowledge-base can improve information extraction when labeled data is not sufficient. Both CRF and RNN MPE applications benefited from a list of medical problems compiled from the UMLS Metathesaurus. Our voting ensemble outperformed individual models and its outputs contributed most to classifying patient cancer types.

One avenue for further study would be applying semi-supervised learning that exploits large amounts of unlabeled clinical texts. New models can be trained through the acquisition of clinical notes where there are medical problems of our interest but not mentioned in the labeled data.

Acknowledgments

This research was supported in part by the National Cancer Institute (R41CA180190). We thank Paul Heider for organizing the corpus.

Abstract

Although a number of foundational natural language processing (NLP) tasks like text segmentation are considered a simple problem in the general English domain dominated by well-formed text, complexities of clinical documentation lead to poor performance of existing solutions designed for the general English domain. We present an alternative solution that relies on a convolutional neural network layer followed by a bidirectional long short-term memory layer (CNN-Bi-LSTM) for the task of sentence boundary disambiguation and describe an ensemble approach for domain adaptation using two training corpora. Implementations using the Keras neural-networks API are available at https://github.com/NLPIE/clinical-sentences.

Natural Language Processing, Machine Learning, Neural Networks (Computer)

Introduction

In contrast to general English, clinical notes have significant differences in structure and content. For instance, clinical text often contains units of thought that fit the technical definition of sentences that are not terminated by the standard sentence boundary symbols or any symbols in many cases. Structures such as labels, section headers, text arranged in tables, and lists are examples of clinical text that do not follow general English rules for sentence termination. Furthermore, clinical text contains a disproportionately high number of acronyms, abbreviations, and ordinal numbers frequently decorated with punctuation symbols and containing variable capitalization. Segmentation errors caused by these ambiguities are magnified in downstream processing.

Previous research has shown that transfer learning in deep networks can improve generalization to tasks of related problems with small data sets [1]. Ensemble methods that engage in meta-learning through weighted voting models such as boosting, bagging, and stacking also reduce the generalization error over standard models [2]. We utilize transfer learning both in the use of word embeddings, and in our method for domain adaptation of models trained on one corpus to a different, but related corpus of clinical text.

Sentence boundary disambiguation (SBD), also known as sentence segmentation or sentence boundary detection, is a well-understood and explored problem in the domain of general English text. In well-formed general English text, most sentences are terminated by sentence boundary symbols. Ambiguities caused by acronyms, abbreviations, quotations, and ordinal numbers are handled by further rules, or by statistical methods such as maximum entropy classification of boundaries. Using these methods on general English text results in accuracy performance above 95% [3]. Relying on sentence boundary symbols for SBD on the entire text of a clinical document leads to errors in detecting non-terminated sentence boundaries [4]. Although deep learning is the prevailing approach for many machine learning problems, it remains underutilized in clinical applications, and the generalizability of clinical applications using current approaches is limited [5].

In this paper we report on applying deep neural network methods with the use case of sequence labeling to the SBD problem on the entire text of clinical notes with no preprocessing or cleaning. We show that an architecture consisting of word embeddings enriched with character information run through a bi-LSTM have high accuracy in detecting sentence boundaries. We also explore the generalization problem of using a trained model for SBD on previously unseen text using several implementations, including combining training data, resuming training with data from the new corpus, and a stacking method where the hidden layer results of two models trained separately on both corpora are summed before prediction using a shared prediction layer. We show that the stacking method has the lowest generalization error with 96% F1 score for beginning of sentence tags.

Methods

Sentence Segmentation

SBD is often the first step in solving any problem using natural language processing (NLP). Availability of sentence boundaries is necessary both for many general language tasks, such as part-of-speech tagging and parsing, and for domain-specific analytical tasks such as document classification. Errors in sentence detection tend to propagate to many other areas in a system making sentence accuracy critical for any downstream tasks in a text analysis system.

In Table 1, some examples of text from Fairview Medical Services notes where sentences are not terminated with sentence boundary symbols are shown.

Table 1 – Examples of sentences without termination

There are several existing commonly used implementations of SBD that rely on or expect sentence boundary symbols and perform poorly in their absence. Stanford CoreNLP [6] provides a rule-based algorithm, which makes decisions based on the results of a tokenizer to disambiguate whether sentence boundary symbols indicate sentence splits. Natural Language Toolkit (NLTK) [7] implements SBD using a method that combines rules for sentence boundaries with an unsupervised algorithm for the detection of acronyms and abbreviations, a common source of errors in SBD [8]. The Apache OpenNLP toolkit [9] and Apache cTAKES [10] provide SBD based on the maximum entropy method described in Reynar, et. al [3]. Previous evaluations have looked at the performance of SBD and have noted the difficulty of the task in the domain of clinical notes and have noted the performance issues on non-terminated sentences [4].

Approaches to the NLP problem of sequence tagging are well-suited for the SBD problem—which can be expressed as a tagging task where words beginning sentences are tagged 'B' and words internal to sentences are tagged 'I'. The architecture for sequence tagging involving recurrent neural networks (RNNs) has shown good results when applied to the tasks of part-of-speech (PoS) tagging and named entity recognition (NER) [11], and improvements were shown when character information is combined with word embeddings via a convolutional neural network (CNN) [12].

Dataset

Source Corpora

We created two source corpora for the sentence detection task. The first dataset was drawn from the MIMIC-III (Medical Information Mart for Intensive Care) corpus [13], which is a de-identified corpus of notes associated with 40,000 intensive care unit patients at the Beth Israel Deaconess Medical Center between 2001 and 2012. Our MIMIC corpus consisted of 749 randomly sampled notes. A second, target dataset was drawn from the Fairview Health Services (FV) EHR system. We used a stratified sampling strategy, in which we created batches of 56 notes made up of 16 inpatient notes and 40 outpatient notes. The inpatient notes were selected proportional to the distribution of note type (Table 2) and the outpatient notes were selected proportional to the distribution of department (Table 3). A total of 952 notes from FV were used, 17 complete batches. MIMIC notes were in plaintext while FV notes were converted from RTF to plaintext using the BioMedICUS system [14]. The MIMIC corpus used in this study contains a total of 315,797 tokens, and the FV corpus contained 415,112 tokens.

Table 2 – Inpatient note types per FV batch

Note Type	Number

Cardiovascular Disease	3
13 other departments	1 each

Manual Annotation of Sentences

The manual annotation of sentences was performed in the BRAT Rapid Annotation Tool [15] by a pair of trained annotators. Annotators were instructed to label all complete thoughts, section headers, item labels, list items, and fragments using a "Sentence" annotation. For any data that was not groupable into sentence-like units (e.g., purely numeric tables, lists of laboratory data, lines of vital signs measures, and metadata tables such as those in header information), or for any other areas of text for which annotators had low confidence in their ability to correctly label sentences, annotators were instructed to use an "Unsure" annotation. After sentences were manually annotated, the documents were tokenized and converted to tagged sequences where 'B' was applied to the first token in every sentence, 'I' was applied to the rest of the tokens in the sentence, and 'O' was applied to all the tokens in the "Unsure" category.

Cross-validation structure

To evaluate generalization error, a cross-validation structure was used where 100% of the MIMIC data was used for cross-validation with 80% as a training split and 20% as a validation split; for the FV data 50% was used for cross-validation (again using an 80-20 training-validation split) and 50% was held out as an unseen test corpus. For architecture and hyper-parameter tuning, the MIMIC validation split was used. The FV cross-validation set was used for training models alone or augmenting MIMIC-trained models. During training, the validation data was used to provide validation loss as an estimation of generalization error to determine when the model has stopped improving and training could be halted.

Model Architecture

Words were tokenized according to rules that split whenever any whitespace, any symbols, or any digits are encountered. Words were represented using a 300-dimension word embedding trained using the Facebook fastText software package [16] on the entire MIMIC-III corpus preprocessed to replace any symbols with spaces, to replace digits with their English names in separate words, i.e. "1.23" to "one two three", and to lowercase all letters. These word embeddings are enriched by summing with the results of a convolutional neural network (CNN) on 30-dimension character embeddings which are learned during training on the SBD tagging task. The CNN is made up of one convolutional layer with 300 filters, each looking at the sequences of the embeddings of four characters, followed by global max pooling. The results of the CNN func-

tion as an adjustment vector to the original word vector for the sentence tagging task. The input of the character CNN is all characters of the word (including symbols and whitespace) along with a context of up to seven characters between the previous word and the word; and up to seven characters between the word and the next word. Special characters were inserted for the end of the previous word, the beginning of the next word, the beginning and end of the word, as well as the beginning and end of the document if those fell into the context. Using all the original characters, including whitespace, allows structural information about the document's formatting to be used for SBD decisions. After the word representation is constructed the results are batch-normalized before passing to the next layer. The architecture of the word representation layer is shown in Figure 1.

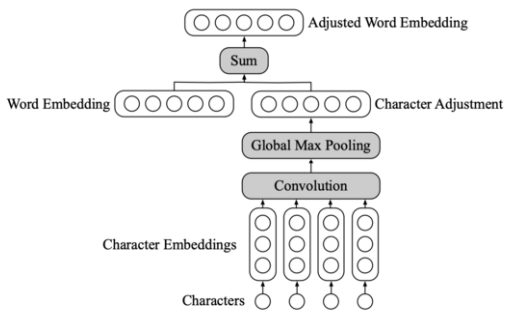

Figure 1 – Word Representation Layer

To encode contextual word representations, we use a bi-directional long short-term memory (LSTM) layer. LSTM units are iteratively run on time-series data (sequences of words in the case of text), maintaining an internal cell state as it moves from one input to the next. LSTMs are optimized during training to learn what information is important to remember from previous inputs to the cell. A LSTM layer is parameterized by the number of LSTM units, each contributing one output dimension. In a bi-directional LSTM layer, the inputs are run both ways through the layer, with one set of LSTM units responsible for seeing the data in order and one set responsible for seeing the data in reverse. Dropout and recurrent dropout [17] were used to provide regularization of the learned weights and prevent overfitting. The results of the bi-LSTM layer are batch-normalized before being passed to the inference layer. In Figure 2, computation of a bi-LSTM on time series data is shown, each node labeled LSTM-F and LSTM-R is the same set of units at different points in the time series, and the lines drawn between nodes represent the propagation of internal memory states to the next item in the time series. The outputs from the forward and backward LSTMs are concatenated to a single contextual word representation, an embedding of the word and surrounding words.

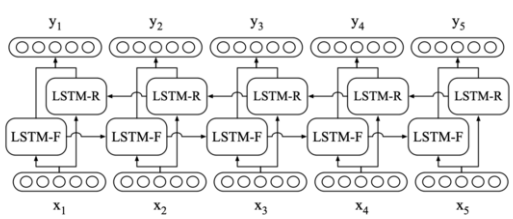

Figure 2 – Bi-directional LSTM

After the bi-directional LSTM layer, a sigmoid-activated dense NN prediction layer is used on each contextual word embedding to output the log-probability that the word is the beginning of a sentence. Lasso or L1-norm regularization was used on the weights of the prediction layer to prevent overfitting. The complete graph of our architecture is shown in Figure 3.

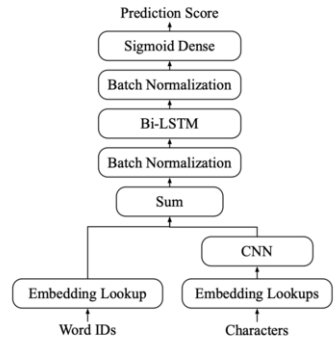

Figure 3 – Complete Model Graph

Domain Adaptation

In addition to using models trained on each individual corpus, we evaluated three methods for domain adaptation of models trained on MIMIC to the FV hold-out test set. First, we looked at merging the cross-validation data from both corpora. Second, we looked at resuming training of the network trained on the MIMIC cross-validation data with the FV cross-validation data. Third, we looked at using an ensemble stacking method for transfer learning where the hidden-layer contextual word representations of the network trained on MIMIC were summed with the contextual word representations of a new network before the sigmoid dense NN prediction layer. In this architecture the output of the second network functions as corrections to the first network for the FV training data. This stacked network architecture is shown in Figure 4.

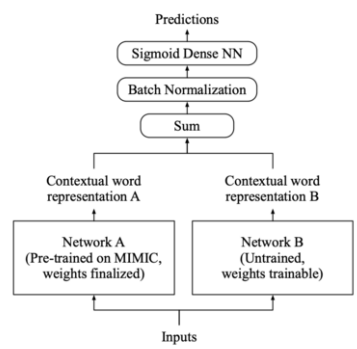

Figure 4 – Ensemble of Two Networks

Training

Based on the results of tuning using CV on the MIMIC corpus, we selected the gradient descent variant ADAM (Adaptive Moment Estimation) [18] as the optimizer of network weights. During training, only models that were improvements on validation loss were saved, and after 5 epochs with no im-

provement training was terminated. Binary cross-entropy loss was used for training, and loss values were weighted by the ratio between the target tag probability and an equal distribution of tags, shown in the equation in Figure 5. Mini-batching was used for training, sequences of 32 words were batched into groups of 32 for gradient optimization.

$$weight_{class} = \frac{samples_{total}}{n_{classes} \times samples_{class}}$$

Figure 5 – Weighting of classes

Results

Manually Annotated Corpora

On an overlap of 100 MIMIC notes annotated by both annotators, ignoring "Unsure" annotations, the Cohen's kappa of Sentence annotations was computed as 0.957 using the irr library in R version 3.4.4. The agreement between annotators on "Unsure" annotations was 0.646. After conversion, on the subset of 100 notes labeled by both annotators Cohen's kappa was 0.71 for all tags and 0.95 after excluding items labeled as 'O' by either annotator. Tables 4 and 5 describe the distribution of 'B', 'I', and 'O' tags after this conversion.

Table 4 – Distribution of Tags in MIMIC

Tag	Count	Percentage
B	23,648	7.5%
I	200,272	63.4%
O	91,877	29.1%

Table 5 – Distribution of Tags in FV

Tag	Count	Percentage
B	43,636	10.5%
I	336,018	80.9%
O	35,458	8.5%

In both source corpora, sentences not terminated by sentence boundary symbols are highly prevalent. Section headers and text labels were common and often ended by the colon sentence boundary symbol. Table 6 shows the quantity of sentences terminated by each symbol.

Table 6 – Sentence Termination Type

Type	MIMIC	FV
Period	12,698 (53.7%)	13,619 (31.2%)
Exclamation Point	4	19
Question Mark	24 (0.1%)	261 (0.6%)
Semi-colon	48 (0.2%)	10
Colon	4,855 (20.5%)	6,180 (14.2%)
Quotation	4	58 (0.1%)
No symbol	6,018 (25.4%)	23,506 (53.8%)

Evaluation of SBD Approaches

For our evaluation we ignored all tags that were labeled as 'O' both during training and during evaluation. Thus, the recall, precision, and F1 for 'B' and 'I' are symmetric, every false positive 'B' is a false negative 'I' and every false negative 'B' is a false positive 'I'. We've reported only the 'B' scores as they are directly proportional to the overall accuracy of detected sentences. The best architecture and hyper-parameter tuned models from cross validation achieved 98.6% F1 on both 'B' and 'I' tags on the MIMIC validation set and 99.2% F1 on 'B' and 'I' tags in the FV validation set.

We evaluated our implementation of SBD against the 50% FV hold-out data set (476 notes). In addition to the architecture described above, we evaluated a maximum entropy / logistic regression classifier (listed as LR) using optimization of a sigmoid-activated dense NN layer on an input of 7 characters before, at the beginning, at the end, and following every word. This is an approach like, but not as tuned as individual implementations of maximum entropy SBD. The primary metrics used for evaluation were the precision, recall, and F1-score for the beginning of sentence class tag.

In addition to models trained on MIMIC and FV individually, we evaluated three methods to test generalizability against the FV test corpus. The models trained solely against one corpus are listed as "MIMIC" and "FV." The results of a model trained on a both corpora's cross-validation set combined are listed as "MIMIC+FV." The continued training of one network is listed as "MIMIC then FV" and the ensemble model is listed as "Ensemble." Results of these evaluations are show in Table 7 with best results in bold.

Table 7 – 'B' Tag Accuracy Against FV Hold-out

Method	Precision	Recall	F1
LR-MIMIC	0.511	0.840	0.636
LR-FV	0.650	0.948	0.771
MIMIC	0.829	0.971	0.895
FV	0.923	0.991	0.956
MIMIC+FV	0.919	**0.995**	0.956
MIMIC then FV	0.910	0.992	0.949
Ensemble	**0.933**	0.989	**0.96**

Discussion

The complexity, grammatic idiosyncrasies, and domain variability of clinical text lead to significant hurdles in designing and training generalizable models for NLP tasks. This common challenge necessitates the use high-capacity, complex machine learning models such as the deep neural network approach described here. Leveraging transfer learning and domain adaptation, such as the ensemble method used here, is an important tool to regularize models created from smaller domain-specific corpora with data from external corpora. In the SBD task, the clinical-specific structuring of sentences in our target corpus led us to applying these approaches.

In all experiments, recall was higher than precision, which can be explained by the class weighting structure. Models are penalized much higher for missing a 'B' tag than for replacing an 'I' with a 'B' tag, leading to models being overeager in splitting sentences. Adaptation of models trained on one corpus to another corpus of text show clear but relatively small losses in performance—we can see that the MIMIC trained model has an F1-score approximately 0.06 lower than the FV trained model.

The ensemble method slightly improves the F1 score against the other domain adaptation methods, increasing precision at a slight cost to recall. The ensemble method was the best performing overall with a 0.96 F1 score on B-tags. This F1-score is on par with the 0.957 Cohen's Kappa inter-rater agreement on the MIMIC data that represents a "ceiling" for performance of SBD algorithms. As shown in the information about our corpora, the FV corpus has different distribution of sentence 'B', 'I', and 'O' tags than the MIMIC corpus, demonstrating that these methods are successful in adapting to a corpus with significant syntactic differences.

There is a loss in performance in the continued training method versus the MIMIC+FV method. In this method, weights may not be able to recover from sub-optimal positions for predicting FV data from the training on MIMIC data. The gradient descent may not be able to find a path from the current position of the weights to the more optimal position of weights found by the FV-only and the MIMIC+FV trained models.

Conclusions

Our study shows that there are improvements in SBD using deep networks over using traditional classification methods, and that these networks can perform well even against different corpora and against corpora with large proportions of sentences that are not terminated by sentence boundary symbols. We've also shown that transfer learning approaches for domain adaptation such as the ensemble model have lower generalization error than combining training sets or continued training.

Further Work

The generalization performance gains from using a two-network ensemble indicate further exploration into meta-learning and ensemble approaches may be fruitful. Furthermore, usage of this or other transfer learning ensemble methods with general-domain English corpora included as training data for base models remains an unexplored possibility.

The accuracy of automatically detected sentences can have substantial consequences on downstream components in a processing pipeline. These benefits are significant on face but have not been formally quantified, and these effects are a potential target for future research.

Abstract

We devised annotation guidelines for the de-identification of German clinical documents and assembled a corpus of 1,106 discharge summaries and transfer letters with 44K annotated protected health information (PHI) items. After three iteration rounds, our annotation team finally reached an inter-annotator agreement of 0.96 on the instance level and 0.97 on the token level of annotation (averaged pair-wise F1 score). To establish a baseline for automatic de-identification on our corpus, we trained a recurrent neural network (RNN) and achieved F1 scores greater than 0.9 on most major PHI categories.

Introduction

Natural Language Processing (NLP) research, in general, has greatly benefited from sharing software resources (tools) and datasets (corpora, lexical repositories, etc.), as well as organizing challenge competitions to evaluate this research infrastructure [1]. This role model has also been adopted by biomedical NLP [2], including clinical NLP [3]. The i2b2 series of competitions[1] mark the cornerstone for the development of numerous clinical datasets[2] and the offspring of specialized software solutions[3] that shape the current state-of-the-art in clinical NLP–yet, for the English clinical language only. Still, almost all of these (de-identified) datasets are accessible to the international research community under the legal conditions of Data Use Agreements (DUA) building on less restrictive data privacy law in the US than in many other parts of the world.

National privacy law in Europe and the General Data Protection Regulation (EU) 2016/679 pose a number of obstacles on the way to extramural sharing clinical corpora. Yet, the minimal prerequisite for all shared clinical corpora is de-identification, i.e., the removal of any patient-identifying information from clinical data. In Germany, one of the top representatives of a particularly restrictive data privacy legislation, the heavily funded Medical Informatics research Initative (MII)[4] was launched recently whose goal is, among others, to empower interoperability of and transparent access to data (including clinical document corpora) and software resources within and across different clinical sites at the national level, in conformance with valid data privacy regulations. Our team heads the NLP acitivities within one of the four funded consortia, *Smart Medical Information Technology for Healthcare* (SMITH)[5] [4]. One of the early outcomes of these efforts is 3000PA [5], a German-language clinical corpus made of 3,000 discharge summaries and transfer notes from three national university hospitals located in Jena, Leipzig and Aachen. Moreover, we are also involved in developing automated workflows for *Healthcare Integrated Biobanking* (STAKI^{2}B^2) where de-identification of clinical corpora is a prerequisite when it comes to workflow validation across different biobanks. In this paper, we report on the de-identification of a list of protected health information (PHI) categories reflecting US law criteria (Health Insurance Portability and Accountability Act (HIPAA)),[6] and their adaptation to national requirements and clinical particularities in German hospitals.

Related Work

Many systems for automatic de-identification have been developed, especially for the English language, but only a few large de-identification gold-standard corpora are reported in the literature–even fewer are publicly available, typically protected by DUAs. In this paper, we report on our efforts in creating a de-identification gold-standard corpus for the German language. To put this work in perspective, we focus on previous work on the creation of corpora annotated with PHI categories.

For clinical English, several corpora have been compiled and annotated for the purpose of de-identification. Building on manual de-identification work by Douglass et al. [6; 7], Neamatullah et al. [8] assembled an automatically de-identified gold-standard corpus of 2,434 nursing progress notes of patients from intensive care units collected in the MIMIC II project [9]. The final corpus consists of almost 340K tokens, contains 1,779 instances of PHI and is available on PhysioNet.[7]

Two different gold-standard corpora for de-identification were assembled for the i2b2 de-identification challenges in 2006 and 2014. For the first challenge [10], 889 medical discharge summaries consisting of almost 550K tokens were annotated semi-automatically, with almost 20K instances of PHI. For the second challenge [11], a corpus of 1,304 longitudinal medical records consisting of more than 800K tokens was annotated, with more than 28K PHI items. The authors report an averaged token-based F1 score of 0.927 between the annotators and the gold standard. For the CEGS N-GRID shared task on de-identification [12], a corpus of 1,000 psychiatric intake records

[7] https://www.physionet.org/

consisting of more than 1,8M tokens was annotated, with more than 34K PHI instances. Token-level agreement of 0.91 F1 score between the annotators and the gold standard was slightly worse than for the i2b2 annotation campaign in 2014. After surrogate replacement, all three challenge corpora were made publicly available via DUAs. The 2006 i2b2 corpus (training set) and a carefully genre-balanced corpus from the Veterans Health Administration (800 documents, with 5.5K PHI items; test set) formed the basis for an "out-of-the-box" evaluation of five operational text de-identification systems [13].

Deléger et al. [14; 15] annotated 3,503 clinical notes of more than 22 different types (more than 1M tokens) with about 30K PHI. They report an inter-annotator agreement of 0.92 F1 score. In a later publication [16] they modify the corpus such that it can be shared for research purposes. Similar annotated corpora (albeit not always publicly available) exist for a few other languages, such as French [17] and Swedish [18; 19]; synthetic (fictional) data were created for Japanese [20].

Unfortunately, no shareable de-identified corpus exists for the German language–in general, there has been only little work on the de-identification of German clinical data. Seuss et al. evaluate a commercial de-identification tool on German clinical reports [21] and to this end assemble a large semi-automatically annotated corpus. They manually correct the output of the tool on 1,400 documents consisting of 5M tokens, identifying more than 23K PHI items (in nine categories pre-defined by the tool), and report high recall values for the system. However, the manual annotation process is tightly coupled with the tool and there is no evaluation of inter-annotator agreement between the three human annotators. Recently, Richter-Pechanski et al. [22] presented a de-identification tool that combines an off-the-shelf named entity recognizer (German Stanford NER tool, retrained on non-medical data), regular expressions and gazetteers with spelling variation detection. For evaluation purposes, they annotated a set of 15 notes (~ 14K tokens) with ten different categories, identifying 680 PHI entities overall.

Manual Annotation

In this section, we describe in detail the manual annotation campaign we conducted: our data, annotation guidelines, evaluation measures, the rationale for several annotation iterations, and the final annotated corpus. All annotations were created using the *Brat Rapid Annotation Tool* (BRAT) [23].

Data

Annotations were based on the Jena slice of the 3000PA corpus [5], a collection of 1,106 discharge summaries, short summaries and transfer letters. All documents were extracted from EPRs of deceased patients (due to privacy concerns) who were treated in either internistic or ICU units for at least five days between 2010 and 2015. The extraction included a conversion from a proprietary data format to plain text (for details see [24]). Our work on this data was approved by the local ethics committee (4639-12/15) and the Data Protection Officer of the Jena University Hospital.

Annotation Guidelines

Our annotation guidelines are based on the 18 PHI categories defined in HIPAA and subsequent manual and automatic annotations of these PHI types, most notably as part of the i2b2 de-identification challenges [10-12; 25]. We iteratively developed and updated our guidelines in three preliminary annotation rounds, adjusting them to our data, common clinical requirements and the particularities of the German language. The final guidelines define eight broad categories, three of which are further divided into more specific annotation types:

- **Age:** age of patient or relative (any age)
- **Contact**: URL, IP address, email, phone or fax number
- **Date:** any date (excluding single days of the week and times of the day)
  - **Birthdate:** date of birth
- **ID:** any ID or code (patient id, medical record number, codes with unknown semantics that might be PHI)
  - **Typist:** shorthand symbols for medical typists
- **Location:** place names (mainly addresses, including street, house number, zip code, city, district, state)
- **MedicalUnit:** medical units (hospital names, names of hospital departments and ambulant medical units)
- **Person:** names of persons
  - **Patient:** patient names
  - **Relative:** names of relatives
  - **Staff:** names of medical staff
- **Other:** any remaining PHI

Each category is also an annotation type by default; thus, we come up with 13 annotation types. Annotators were required to select only the most specific applicable type for each entity. For instance, if they found the name of a physician, they were instructed to assign it the type *Staff*, not *Person*. Only if the context was unclear about whether a name belongs to a patient, a relative or a member of staff, or if the person denoted by a name belongs to neither of these three groups, the annotators were instructed to assign it the generic *Person* type.

Our scheme collapses several of the HIPAA-defined types of PHI because they are infrequent or indistinguishable in our data: *ID* comprises social security, medical record, account, certificate/license, patient-related serial numbers, and any numbers or codes that may directly or indirectly identify a patient or member of staff. Since we work with plain texts, we dropped the category for photographic images. On the other hand, we introduced some more fine-grained distinctions, e.g., between names of patients, relatives and staff. The *Typist* category was introduced after the second pre-iteration (see below) to resolve systematic disagreement among annotators.

Evaluation Measures

In the following, we report inter-annotator agreement (IAA) as pair-wise averaged F1 score [26], both on instance level and on token level. An instance is a single annotation, possibly spanning multiple tokens, e.g., "*Jane Smith"* denotes one instance of a patient's name comprised of two tokens. Tokens are based on the tokenization script of the TreeTagger[8] with minor post-processing. To obtain token-based agreement, we annotate each token overlapping with an annotation with the annotation's type, sub-token annotations are expanded to full tokens. Due to missing spaces, we got two annotation types per token in 13 cases–we kept both annotation types for each of these tokens when calculating agreement, but used only one as input to the classifier described in the second part of this paper.

Annotation Iterations

We ran three preliminary annotation iterations (summarized in Table 1) before we started the final annotation project. Iterated annotation rounds for building de-identification gold standard corpora have also been suggested by Browne et al. [27] as a strategy to cope with the complexities of this task that are

[8] http://www.cis.uni-muenchen.de/~schmid/tools/TreeTagger/

meticulously described in their paper. The number of annotations in this table includes redundant annotations from different annotators on the same documents. In the first iteration, eight medical students and two physicians worked on the full set of 1,106 documents, covering all protected health information with generic annotations according to a first set of guidelines based on the list of PHI items defined in HIPAA and the i2b2 de-identification challenges [11; 25]. We automatically pre-annotated dates with a regular expression covering standard numerical date representations. Annotators at this stage could focus on finding PHI items in the text and were not supposed to categorize them. These first annotations were intended to serve as pre-annotations for later iterations (ensuring that each document was checked for false negatives at least twice) and formed the empirical basis for a refined set of annotation guidelines. After a qualitative analysis of the results, we further specified the extent of each annotation type, defined a list of 12 types of PHI (the types listed in the previous section, excluding *Typist*) and added illustrative examples for each category.

Table 1 – Annotation iteration setups and results

Annotation	Pre-1	Pre-2	Pre-3	Final
# documents	1,106	25	12	1,106
# agr. docs	0	25	12	50
# annotators	10	4	4	5
# ann. types	1	12	13	13
# annotations	40,664	4,347	2,556	51,814
Avg. F1 (token)	-	0.91	0.96	0.97
Avg. F1 (inst.)	-	0.87	0.92	0.96

Using simple patterns and keywords, the generic annotations from the first iteration were automatically categorized according to the new guidelines. These data served as pre-annotations for the second iteration in which four medical students each worked on the same set of 25 pre-annotated documents. Their task was to identify missing PHI items and correct both extent and type of the existing annotations. They achieved an inter-annotator agreement of 0.87 ($\sigma = 0.02$) on instance level and 0.91 ($\sigma = 0.02$) on token level.

To further train our annotators and achieve even higher agreement values, a third pre-iteration was conducted with four annotators (one of the previous annotators had to leave the team temporarily and was replaced by a new annotator). We defined an additional category, *Typist*, for shorthand symbols identifying medical typists to resolve the ambiguity between *ID* and *Person*[9] and added more examples to the annotation guidelines to resolve cases of systematic disagreement among annotators. Each annotator was provided with six documents with annotations he or she had created in the previous iteration[10] and six documents with semi-automatically generated pre-annotations. Inter-annotator agreement improved on both the old and the new documents. For the full set of documents, the averaged pair-wise F1 score reached 0.92 ($\sigma = 0.04$) on instance level and 0.96 ($\sigma = 0.02$) on token level.

For the main annotation, five annotators worked on the 1,106 Jena documents of 3000PA. A subset of 50 documents (cf. Table 1, '# agr. docs') was annotated by all five annotators and served as the basis for the computation of IAA which improved further to 0.97 ($\sigma = 0.01$) on token level and 0.96 ($\sigma = 0.01$) on instance level. We also noticed an increase in IAA within the final annotation hinting towards a training effect over time.

Final Corpus

The final corpus consists of roughly 1.4M tokens for which our annotators created more than 44K annotations, excluding redundant agreement annotations.[11] Table 2 gives an overview of instance and token frequencies by annotation type for the entire corpus, as well as instance- and token-level agreement by annotation type on 50 multiply annotated agreement documents. Looking at the instance frequencies, we notice that almost half of the PHI items in our corpus are dates, followed by medical units, locations and staff names, each accounting for more than ten percent of all annotations. The large share of dates is partially a consequence of our broad definition of *Date* which only excludes days of the week without month or year and times of the day. At the other end of the frequency spectrum, we find the generic types *Person* and *Relative*. The fact that only few instances fall under the *Person* category indicates that most names could be assigned unambiguously to either *Patient, Relative* or *Staff*. The low frequency of *Relative* is probably an artifact of our data sampling criteria–most of the deceased patients were elderly people for which family history is less important, hence names of relatives occur rarely. The frequency distribution of tokens mirrors that of instances and gives information about the average length of each annotation type. The share of *Date*s is lower as they usually consist of only one token, whereas instances of the types *Location*, *MedicalUnit* and *Staff* often span multiple tokens, raising their relative frequency at the token level.

Table 2 – Number of instances and tokens per annotation type in the final corpus. Instance-level and token-level agreement (Avg. F1) on 50 multiply annotated agreement documents.

Category	Type	Instances		Tokens	
		Frequency	Avg. F1	Frequency	Avg. F1
Age	Age	498	1.00	500	1.00
Contact	Contact	613	0.97	2,009	0.98
Date	Date	20,603	0.98	24,277	0.99
	Birthdate	1,103	1.00	1,103	1.00
ID	ID	398	0.81	424	0.82
	Typist	655	0.86	1,418	0.93
Location	Location	5,429	0.98	11,286	0.99
MedicalUnit	MedicalUnit	6,189	0.90	12,499	0.95
Person	Person	14	-	23	-
	Patient	3,180	0.99	5,167	1.00
	Relative	36	0.80	62	0.88
	Staff	5,231	0.95	10,003	0.97
Other	Other	218	0.28	271	0.26
Total	*	44,167	0.96	69,042	0.97

[9] Shorthand symbols or initials denote persons but are different from typical person names.

[10] The fourth annotator received 12 new documents.

[11] Of all annotations created for the 50 multiply annotated agreement documents, the final corpus only contains those created by the annotator who achieved the highest IAA.

Instance and token-level agreement lie between 0.8 and 1 for most annotation types. However, for *Relative, Other*, and *ID* each annotator found 11 or less instances on average. These values thus cannot be considered reliable. *Person* occurred 14 times in the whole corpus, none of these occurrences are in the 50 agreement documents. Low agreement for *Other* does not come as a surprise (independent of IAA reliability problems), as annotators were supposed to assign this category whenever they found information that they considered confidential, but could not match with any other annotation type. This vague definition led to a number of varying subjective judgements. For many annotation types (especially *MedicalUnit, Typist,* and *Staff*), token-level agreement is higher than instance-level agreement, indicating that there is disagreement about the exact extent of some annotations: partially overlapping annotations raise agreement on token level, but not on instance level. We also observe cases where one annotator decided to create one long annotation while another one created two short ones covering the same tokens. For the task of de-identification, the latter kind of disagreement is less severe, as we are mainly interested in covering all sensitive information.

Automatic De-Identification

In order to provide a first baseline for automatic de-identification on our annotated data and to submit the quality of our annotations to an empirical test, we trained and evaluated a neural network for named entity recognition (NER) designed by Sterbak [28] on the final corpus.

Methods

We randomly sampled 80% of the documents for training and used the remaining 20% as test set. Splitting the corpus on documents rather than sentences ensures a representative share of out-of-vocabulary (OOV) tokens. We provide only tokens and characters as input. The network employs a unidirectional LSTM [29] to learn word representations based on character embeddings. These character-based representations are concatenated with word embeddings (all embeddings were initialized randomly). The resulting complex word representations serve as input to a bidirectional LSTM. At each timestep, the output of the bidirectional LSTM is fed into a densely connected layer of units with a softmax activation function. Each unit of the last layer represents one possible classification result (the annotation types and an additional outside tag, *O*, for non-PHI data). The softmax function provides a probability distribution over these possible results. For each token, we predict the type with maximal probability.

To obtain reliable results despite randomly initialized weights, we train five different models on the same train-test split. We compute standard NER evaluation measures for each model and report averages over all five models. Additionally, we determine the percentage of OOV tokens for an annotation type *T*, that is, tokens that occur in the test set labeled as *T,* but do not occur in the training set with the same annotation type *T*.

Results

Table 3 yields the classifier's precision, recall and F1 score on the test set, as well as the support (the number of expected occurrences) and the percentage of OOV tokens for each annotation type and the outside tag (*O*). Totals are averages over all types weighted by support. For most annotation types, we achieve F1 scores between 0.88 and 0.98. 14% of all PHI tokens are OOV, whereas only 4% of all tokens are OOV. Disregarding confusions between different PHI types and only considering the binary distinction between PHI and non-PHI, the classifier achieves a precision of 0.98 and a recall of 0.96.

Table 3 – Automatic de-identification results on the test set: token-level precision, recall, and F1 score, support and percentage of out-of-vocabulary tokens per annotation type.

Type	Prec	Rec	F1	Supp	OOV
Age	0.885	0.910	0.897	89	25%
Birthdate	0.959	0.992	0.975	222	68%
Contact	0.966	0.945	0.956	435	7%
Date	0.959	0.970	0.964	4,969	15%
ID	0.693	0.385	0.480	95	91%
Location	0.977	0.940	0.958	2,188	11%
MedicalUnit	0.967	0.938	0.952	2,424	4%
O	0.998	0.999	0.999	269,337	3%
Other	0.592	0.384	0.463	63	46%
Patient	0.952	0.962	0.957	990	35%
Person	0.000	0.000	0.000	5	80%
Relative	0.000	0.000	0.000	16	100%
Staff	0.975	0.961	0.968	2,015	7%
Typist	0.898	0.862	0.879	245	12%
Total	0.996	0.996	0.996	283,093	4%
Total w/o O	0.959	0.947	0.952	13,756	14%

Discussion

We observe a clear drop in performance for smaller classes, especially *ID*, *Other, Person*, and *Relative*. The latter two together contribute only 85 tokens in the whole corpus, 21 of which are in the test set. So, we cannot expect the network to learn these rather difficult types. The confusion matrix reveals that, on average, around 43 out of 95 *ID* tokens were misclassified as *Date*s which suggests that the internal representations learned by the network are rather shallow–combinations of digits and punctuation marks may be *ID*s or *Date*s depending on the context–and to a large extent explains the low recall for *ID*. Furthermore, we find that low IAA scores are reflected in the classifier's performance for *Other* and *ID.* The overall F1 score (without the outside tag *O*) is slightly below the token-level results reported by Stubbs et al. [25] where the best system achieves an F1 score of 0.961 for the i2b2-PHI categories and 0.976 for the HIPAA-PHI categories. However, this comparison has to be taken with a grain of salt since both our annotation types and the data are different. The percentage of OOV tokens in the last column of Table 3 gives an idea about the recall a lazy learner might achieve by just remembering tokens occurring in the training set. Since our dataset stems from two units of a single hospital, the percentage of OOV tokens for *MedicalUnit* and *Staff* is low which puts the results for these types into perspective. For *Patient*, we observe a high percentage of OOV tokens, but for this type of PHI we sometimes find clear contextual cues (e.g., German equivalents of *Mr.* or *Ms./Mrs.*) which facilitate automatic recognition.

Conclusions

We annotated 13 PHI categories on the Jena slice of the German-language 3000PA corpus (1,106 documents) based on annotation guidelines that evolved over three annotation pre-iterations. The annotation process ensured that each document was checked twice for PHI and high inter-annotator agreement scores suggest that the resulting annotations are of very good quality. The neural baseline model we trained on the final annotated corpus achieved promising results, indicating that the annotation types defined in our guidelines lend themselves well to a data-driven approach to automatic de-identification. Future work will be directed at incorporating the 1,000 document

slices from the other two clinical sites, Leipzig and Aachen. With these more heterogeneous data, the classifier will be further tuned to maximize recall while ensuring generalizability to provide reasonable input for the planned pseudonymization engine as a resilient basis for the DUA-controlled distribution of a large corpus of German clinical documents.

Creating a Queer Ontology: The Gender, Sex, and Sexual Orientation (GSSO) Ontology

Clair Kronk[a], Giao Q. Tran, PhD[b], Danny T.Y. Wu, PhD, MSI[a]

[a] Department of Biomedical Informatics, University of Cincinnati, Cincinnati, Ohio, United States,

Abstract

Cultural attitudes, linguistic variation, and historical pathology have led to a plethora of terms concerning gender, sex, and sexual orientation that have caused confusion and uneasiness among both lay people and relevant professionals. For members of the LGBTQIA+ community, these negative reactions are compounded by identities which have historically and contemporarily been mistreated by medical professionals. In an effort to provide a reliable resource for patients and clinicians, we have created the Gender, Sex, and Sexual Orientation (GSSO) ontology, which currently includes over 4,000 entities from multiple disciplines. The GSSO is a manually curated resource utilizing related glossaries from biology, medicine, psychology, sociology, and gender studies. With links to over 20 other ontology resources such as SNOMED-CT and MedDRA, the GSSO aims for accessibility and interoperability with existing systems. It is also open-source and features an easy-to-use web interface (https://github.com/Superraptor/GSSO). Future work involves multiple language support efforts and empirical evaluation.

Keywords:
Linguistic, Sexual and Gender Minorities; Social Determinants of Health

Introduction

An ontology is a description of a common, shared, or otherwise controlled vocabulary used to explain information in a particular domain, such as linguistics or medicine. More often than not, due in part to advances in biomedical informatics and the rise of big data, ontologies are usually designed primarily to be machine-interpretable, rather than strictly human-readable [1].

Noy and McGuinness point out several reasons why ontology development is crucial in a general sense, including reuse of domain knowledge, analysis of that knowledge, and creating explicitness within that domain. This explicitness is especially important for scientific communication, namely helping the public understand the importance of such communication, especially when such communication concerns health outcomes. As Markides put so well in 2014 "[c]ommunication is the most important component of our work with patients. It is the cornerstone of our interaction with people" [2].

Clear communication is even more crucial when it concerns people belonging to groups that have historically and contemporarily experienced discrimination in healthcare and mistreatment by medical practitioners. If communication is unclear, disparaging, or otherwise offensive, patient outcomes can be affected [3–6]. Various forms of discrimination or perceived discrimination, many of which include linguistic components, have been strongly linked to suicide and other areas of mental health [7–15].

One such group that experiences such discrimination are LGBTQIA+ (lesbian, gay, bisexual, transgender, queer/questioning, intersex, agender/asexual, and other umbrella gender and sexual identity minorities) populations. For example, it is well documented that LGBTQIA+ populations have significantly higher risk of suicide than general population. The differences in suicidality have been variously attributed to social determinants of health (SDOH) including anti-LGBTQIA+ government policies, medicalization of gender and sexual nonconformity, and unemployment linked to LGBTQIA+ status [16–18].

Unfortunately, the chasm between healthcare providers and the LGBTQIA+ community persists, with one study suggesting 23% of transgender respondents did not see a doctor when they needed due to fear of mistreatment [19]. Even well-intentioned providers can find reliable information difficult to access. As one clinician explained [20]:

> [D]espite trying to find ways to improve my expertise, I just didn't know where to go or who to talk to, or where to get the information, and I felt really bad because some of my initial attempts to help these people—I sent them to people I wish I hadn't sent them to.

Here, we present preliminary efforts to structure information about gender, sex, and sexual orientation into a comprehensive ontology for use by healthcare professionals and patients alike, with potential to help mitigate communication issues and provide reliable, trustworthy information on LGBTQIA+ terminology and medical needs.

Methods

Ontology Development

An iterative approach was used to manually create and expand the Gender, Sex, and Sexual Orientation (GSSO) ontology, following the procedures outlined by Corcho et al. for annotation [21]. These include four main steps: 1) marking, 2) exploring, 3) mapping, and 4) abstracting.

First, the subject area was clearly marked as including gender-, sex-, and sexual orientation-related knowledge, helping to exclude materials in psychiatry, psychology, and other fields outside the purview of those fields. Second, current lists of terminology and vocabulary regarding these content areas were explored primarily using PubMed, Google Books and Scholar,

and the HathiTrust Digital Library, supplemented by wiki-based sites featuring specific slang and media styleguides (such as those provided by LGBTQIA+ organizations like GLAAD and PFLAG) to provide necessary context. Examples of exploratory sources included *The International Encyclopedia of Human Sexuality* (2015), *Encyclopedia of Gender and Society* (2009), *The Wiley Blackwell Encyclopedia of Gender and Sexuality Studies* (2016), and several editions of the *Diagnostic and Statistical Manual of Mental Disorders* (1952, 1968, 1980, 1987, 1994, 2013).

Third, once a group of terms was identified, they were mapped onto existing terminologies available via the NCBO (National Center for Biomedical Ontology) BioPortal where appropriate (a summary of these mappings is shown in Table 1). Originally, terms mappings were performed automatically using full-string matching or near-string matching, but this process introduced significant false positive matching and addition of inaccurate, incomplete, and entirely missing annotations. Therefore, mapping was supplemented by a manual process to approve any automatic matching. Finally, these terms were "mapped up" using existing ontologies, moving toward higher abstractions (eventually running into the basic formal ontology's [BFO] *entity* concept) [22]. Often when searching resources, web-related documents and print periodicals would be consulted to approximate leveraging clinical definitions and more colloquial definitions. During this process, new terms appeared, necessitating beginning the approach from the first step.

Table 1. Cross-references to various other ontologies. Despite over 1,200 mappings, over 2,000 terms are entirely new.

Acronym	Full Name	# Terms
BFO	Basic Formal Ontology	19
ChEBI	Chemical Entities and Biological Interest	4

TE	Terminologia Embryologica	30
TH	Terminologia Histologica	2
UBERON	Uber-anatomy Ontology	22
	Total:	**1416**

Construction of the GSSO is ongoing using a combination of this methodology and user feedback concerning necessary additions and terms considered missing or in need of editing.

Ontology Evaluation

The GSSO was evaluated using three techniques derived from Brank et al. [23]. These methods included comparisons and mappings to other ontologies (which was folded into the "mapping up" done during construction), usage of the MIMIC-III database for finding patients based on GSSO terminology versus ICD-9-CM (automated matching/classification as part of an application), and preliminary feedback from experts in different fields affected by the GSSO. Several more comprehensive validation techniques are in development and outside the scope of the current study.

Results

The GSSO includes over 4,000 classes, with over 1,000 definitions and more than 1,400 external biomedical ontology references (not including links to wiki-based sources, which would bring the total of external links to over 3,300). Over 70 scholarly articles and 80 books are fully cited and sourced, covering a range of topics, from Perry M. Lichtenstein's infamous "The 'Fairy' and the Lady Lover" (1922) to "Induced Lactation in a Transgender Woman" (2018). A list of all sources (as of 11 November 2018) is included as a Microsoft Excel spreadsheet on the project's GitHub (https://github.com/Superraptor/GSSO/blob/master/docs/gsso_sources_11.15.2018_v1.xlsx). In addition, as of the time of writing, the GSSO is the only known ontology to include its sources as classes in the ontology itself, a unique feature which allows one to analyze concept shift over time, and to drill down to original definitions. Generally speaking, highly connected relationships were prioritized, meaning terms that appeared more often in source materials usually ended up with more detailed annotations (such as *transgender*, visualized as a map in Figure 1).

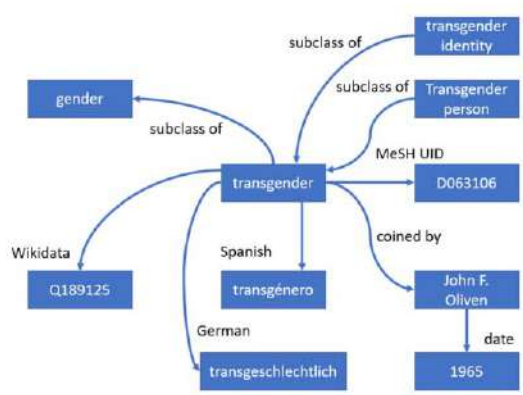

Figure 1. Visualization of Highly-Connected Relationships in the GSSO (emphasizing database cross-references and translations) Highly-connected networks allow for more complicated annotations and queries which are more reflective of complicated relationships in reality.

More than 200 usage notes are included, discussing reclaimed terms (such as *dyke*), terms that are considered problematic in certain contexts (*transsexual*), and terms that are obsolete

(*transgenderism*). An sample entry, the term *homosexual*, is shown with such notes in Figure 2.

Because some of these terms are slang, taboo, or only used within select groups, online sources played a large part in tracing word origins and sentiment. All of these sources were archived using the Wayback Machine provided by the Internet Archive, ensuring that they will be available in their original state for the foreseeable future (this includes nearly 100 online sources captured from the early days of Usenet to present).

Many terms did not appear in any of the 600+ available biomedical ontologies, especially those relating to transgender health care: gender expression, non-binary gender identities, gender passing, and cultural gender roles (*hijra*, *māhū*, two-spirit, etc.) were all unaccounted for.

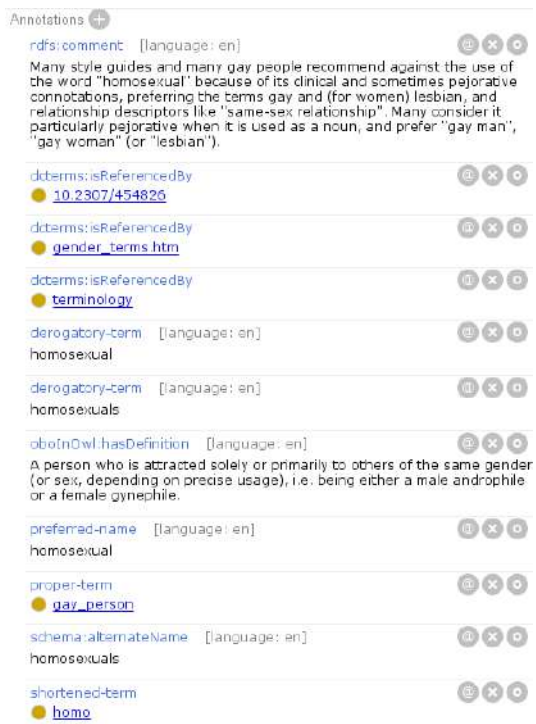

Figure 2. Example Annotation Showcasing Usage Notes. Displayed using Protégé, a free, open-source ontology editing framework.

Validation efforts are ongoing, as the ontology itself is still growing. Exploratory efforts showed promising results. Preliminary feedback from experts regarding the ontology's content, subject area, and resourcing has been positive based on discussion at the University of Cincinnati Graduate Student Research Forum (GSRF), the American Medical Informatics Association (AMIA) 2018 Annual Symposium, and the GLBT Museum and Archives in San Francisco, California. A mailing list sent by the GLBT Archives to various archivists and librarians across the United States yielded similar positive feedback. High facial validity was also shown in the comparison and mapping of GSSO to other ontologies. When identifying transgender patients in the MIMIC-III clinical notes database [24], only six verified transgender patients could be identified using ICD-9 codes alone. However, when using the ontology within unstructured clinical notes, the GSSO allowed for detection of those six, along with seven others. Additionally, six of these patients had an incorrect sex assigned at birth noted, which could only be detected after using the ontology to analyze the clinician's notes specifically. Use in a wider clinical dataset is underway.

Discussion

In this project, we developed the GSSO ontology and demonstrated preliminary evaluation results. As previously stated, over 2,000 terms within the ontology are entirely new, having been unaccounted for in other biomedical ontologies. Ultimately, we hope that this ontology can be layered in with existing electronic health record technologies to educate medical professionals, without requiring additional separate trainings (problematic terms could be underlined and indicated as such without being interruptive, providing extra information about why a certain term is derogatory, for instance).

Using such a system could help orient and educate patients and clinicians approaches biomedical ontologies from an uncommon perspective, building from a human readability standpoint first. Of course, the ontology could be used in machine learning or natural language processing applications, but having a very human readable focus is not particularly common among other ontology systems. For this reason, the paired automatic and manual approaches towards validation are considered especially crucial.

LGBTQIA+ specific forums present on Reddit (https://www.reddit.com/) and Usenet (archived here: https://groups.google.com) are being analyzed to provide online contexts, and to see if similar results can be obtained on more chaotic, unstructured text present on the internet. Such an approach parallels that of the previously constructed Vaccine Misinformation Ontology (VAXMO), which aimed to collect misunderstandings about vaccines [25]. In the VAXMO paper, suggested use cases included producing datasets for machine learning and semantic-driven approach for misinformation detection, both of which the GSSO could handle in its own respective domain. For example, the GSSO could be used to identify positive and negative connotations in the LGBTQIA+ entity space as well as looking for information that could be considered medically misinformed (such as incorrect information regarding hormone replacement therapy or sexually transmitted infections). The GSSO has great potential to produce information that could be used to better inform clinicians and thereby facilitate effective patient communication, which is a critical first step to solve social and political issues faced by this underserved patient population.

In addition to these automated approaches, we are also designing inclusive protocols for both patients and providers to evaluate the ontology in a more subjective manner, including the ontology's presentation, usefulness, and potential missing entries. As such, the ontology is publicly available for comment at https://github.com/Superraptor/GSSO, with a simple search interface available at http://homepages.uc.edu/~kronkcj/gsso/ (Figure 3).

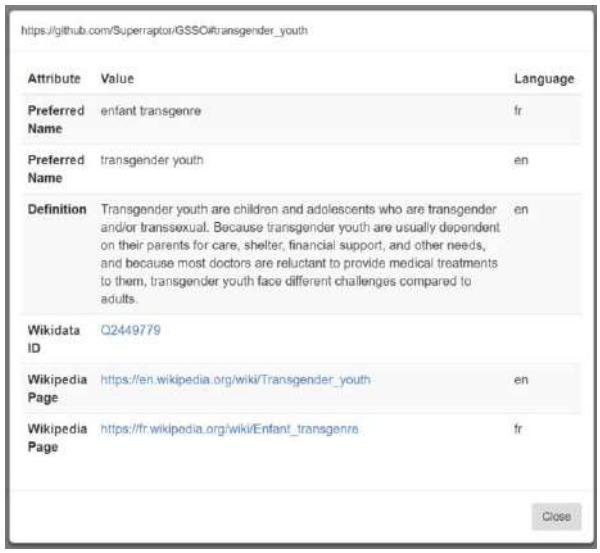

Figure 3. Modal Displaying Annotations for the Term, Transgender Youth*. Interface was built entirely using JavaScript and provides accessibility to those not necessarily familiar with ontologies.*

Conclusions

Language has more power in medicine and outside of medical environments than people realize. As one activist put so well: "To omit specific labels… is to deny the existence of the labelled" [26]. Since Ralph Werther became the first transgender person to publish an autobiography in the United States in 1918, it was clear that abusive language affected mental well-being [27,28]:

> Mean-spirited boys would call me a girl in derision, and twit me about my conduct of early childhood, thus awakening a violent desire to commit suicide.

One hundred years later, despite over coming many significant hurdles, the National Transgender Discrimination Survey still reported that 50% of transgender patients sampled had to teach their medical provider about transgender care—and 19% reported being refused care because of their gender status [29]. Using ontologies as a baseline to educate both patients and providers helps attack the problem at both ends, potentially leading to better health outcomes for LGBTQIA+ patients in general as communication and understanding between groups improves.

Acknowledgements

In addition to thanking my mentors Drs. Danny T. Y. Wu and Giao Q. Tran, I would like to thank Jonathan Ned Katz, Randall Sell, and Susan Stryker for their help in determining historical contextualization which helped facilitate the development of the GSSO. I would also like to thank Nalini Elias and Patricia Delara of the GLBT Historical Society Museum & Archives.

Abstract

Medical terminologies are the basis of interoperability in medicine. They allow connecting the various systems and data and facilitate searches in databases. An example is the MedDRA terminology, used in particular for coding drug adverse events. However, these terminologies are often complex and involve a huge number of terms. Consequently, it is difficult to browse them or find the desired terms. Traditional approaches consist of lexical search, with the problems of synonymy and polysemy, or tree-based navigation, but the user often gets "lost" in the tree.

Here, we propose a new approach for browsing medical terminologies: the use of pictograms and icons, for formulating the query in complement to a textual search box, and for displaying the search results. We applied this approach to the MedDRA terminology. We present both the methods and search algorithms and the resulting browsing interface, as well as the qualitative opinions of two pharmacovigilance experts.

Keywords:
Terminology as Topic, Pharmacovigilance, Nonverbal Communication.

Introduction

Medical terminologies are the basis of interoperability in medicine [1]. They allow connecting the various systems and data, and facilitate searches in databases [2]. An example is the MedDRA terminology, used in particular for coding drug adverse events. Traditional search approaches are either based on lexical search or on the navigation in a hierarchy [3]. However, lexical searches suffer from synonymy, polysemy and metonymy, e.g. a search with "auricular" return terms related to both heart and ear. Navigation in a tree is usually complex and the user often gets "lost" in the tree [4]. Brown [5] described the various difficulties encountered when performing searches in MedDRA-coded pharmacovigilance database.

In the literature, several authors suggest the use of pre-coordination for defining terms in terminologies, i.e. the decomposition of disorders into anatomic location and morphology, e.g. "nephritis," defined as an inflammation of the kidney, and post-coordination for selecting terms [6]. Bakhshi-Raiez et al. [7] proposed to take advantage of the compositional aspect of the SNOMED CT terminology to facilitate the searches in the terminology. Lee et al. [8] proposed the use of post-coordinated expressions to retrieve ICD codes. Third-generation, knowledge-based terminologies, aim at formalizing semantic relations and decompositions between terms, which can help with searches [9]. The use of semantic web standards such as RDF has also been proposed to facilitate data retrieval from MedDRA [10].

In previous works [11], we proposed an iconic compositional language for medical concepts. In this paper, we propose an iconic approach to the browsing of medical terminologies. Our approach uses icons at two levels: (1) for formulating the query, in combination with a traditional textual search box, and (2) for displaying the search results, by grouping similar terms using icons. This work is part of the Pegase project, which aims at helping pharmacovigilance experts with the use of the MedDRA terminology.

Methods

MedDRA is a medical classification often used for coding drug adverse effects and events. It has 5 levels, from the more general to the more specific: system organ class (SOC), high-level group terms (HLGT), high-level terms (HLT), preferred terms (PT) and low-level terms (LLT). The classification is multi-axial: a term can have more than one parent. We worked on the French translation of MedDRA 19.

VCM [11] is an iconic language for representing the patient main clinical conditions, including symptoms, diseases, physiological states (*e.g.* age class or pregnancy), risks and history of diseases, drug and non-drug treatments, lab tests and follow-up procedures. VCM includes a set of graphical primitives (colors and pictograms) and a grammar to combine these elements for creating icons.

For representing clinical signs and disorders, a VCM icon is made of a color, a basic shape, a central pictogram and a set of modifier pictograms. The color indicates the temporal aspect of the icon: red for current states of the patient, orange for risk of future states, and brown for past states. The basic shape is a circle for physiological states or a square for pathological states (diseases or symptoms). The central pictogram indicates the anatomico-functional location (e.g. endocrine system) or the patient characteristic (*e.g.* pregnancy) involved; and special pictograms are available for a few specific disorders associated with a specific anatomico-functional location (*e.g.*

```
function lexico_icono_hierarchical_search(keywords, pictograms, selected_levels):
    if only keywords (i.e. pictograms = ∅ ):
        terms = { t such that MedDRA(t) and match(t.label, keyword) and t.levels ∈ selected_levels }

Figure 2– Algorithm performing the lexico-icono-hierarchical search in pseudo-code. The search takes three input parameters: a set of lexical keywords, a set of pictograms, and a set of selected levels in the hierarchy (e.g. {PT, LLT}). It returns two values: the set of icons and the set of MedDRA terms to display. We used a first-order logic syntax in the algorithm, i.e. classes are unary predicates and properties are two-argument predicates, e.g. "MedDRA(t)" means that it is a MedDRA term and "has_icon(t, i)" means that it has icon i. Finally, match() is a function that performs keyword-based string comparisons.

diabetes for the endocrine system). Modifier pictograms can be added to specify (a) a general pathological process (*e.g.* tumor or infection), and (b) a "transversal" anatomical structure that can be present in many anatomico-functional locations (*e.g.* blood vessels and nerves are present in most organs).

The VCM ontology has been designed for formalizing the semantics of VCM icons [12]. This ontology includes 3 parts: (1) graphical concepts corresponding to VCM graphical primitives (*i.e.* the various shapes, colors and pictograms), (2) medical concepts (*i.e.* the main anatomical structures, biological functions, pathological processes, *e.g.* liver, hepatic function and inflammation, but *not* the various disorders, such as hepatitis), and (3) relations between the graphical and the medical concepts (*e.g.* the "liver" central pictogram is associated with both the liver anatomic structure and the hepatic biological function). In a previous work [13], we started to design a mapping between MedDRA and VCM.

Model

We designed an OWL ontology including: (1) all MedDRA terms with their codes, labels and parent-child relations, (2) MedDRA to VCM mapping and (3) decomposition of VCM icons in pictograms. Figure 1 shows the general model of the resulting ontology.

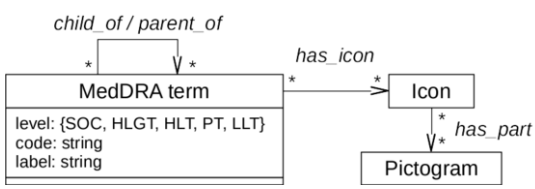

Figure 1– General model of the ontology, as a UML class diagram.

We used PyMedTermino [14] to extract the MedDRA terminology and to deal with VCM icons. The resulting OWL ontology includes 531,095 RDF triples (46 Mb) and belongs to the $\mathcal{ALH}(D)$ family of description logics. The ontology was stored in an optimized quadstore based on a SQLite3 database, using the Owlready ontology-oriented programming module [15, 16] for Python. Owlready was used because it allows an object-oriented access to ontologies with performances similar to SQL databases. It also supports a full-text search.

Search Approaches

The proposed interface combines three approaches for searching terms; they are detailed in the following paragraphs.

The **full-text search** approach consists of searching for one or more keywords in the labels of the MedDRA terms. Each keyword has to match the beginning of one word of the term, *e.g.* keyword "Abs" match term "Renal abscess" but not "Bile acid malabsorption". We used Owlready2 to perform the search, which relies on the FTS5 implementation of Sqlite3. In the interface, keywords are entered into a search bar.

The **iconic approach** consists of selecting one or more pictograms and searching for all terms that are associated with icons that include all the selected pictograms. To facilitate the selection of pictograms, we organized them on a schematic anatomical sketch, called "Mister VCM". It shows 37 pictograms, grouped in 6 regions: the head, the hat (for social medicine), the thoughts (for psychology and addictions), the trunk, the arm (only one limb is detailed) and the etiologies. The entire VCM language has more than 150 pictograms, however, many of them are specialized versions of a more general pictogram, and "Mister VCM" shows only the general pictograms. The user can click on a pictogram to select it, and the gray pictogram is replaced by a red icon. By clicking the same pictogram again, the user can deselect it. When several pictograms are selected, we consider their intersection, *i.e.* the terms have to match all the selected pictograms.

The **hierarchical approach** considers the hierarchical structure of medical terminologies. In the present work, we limited this approach to the ability to filter MedDRA terms according to their depth level in the terminology, *e.g.* search only for PT, or for both PT and LLT, ... The interface includes 5 checkboxes, one per MedDRA level; they allow the user to select the desired levels.

The output of the search is a set of MedDRA terms, but also a set of VCM icons. The set of icons are be used to display the search results in a synthetic and visual way. Figure 2 gives the algorithm that combines the three search approaches. If only keywords are present in the query, we search for the terms of

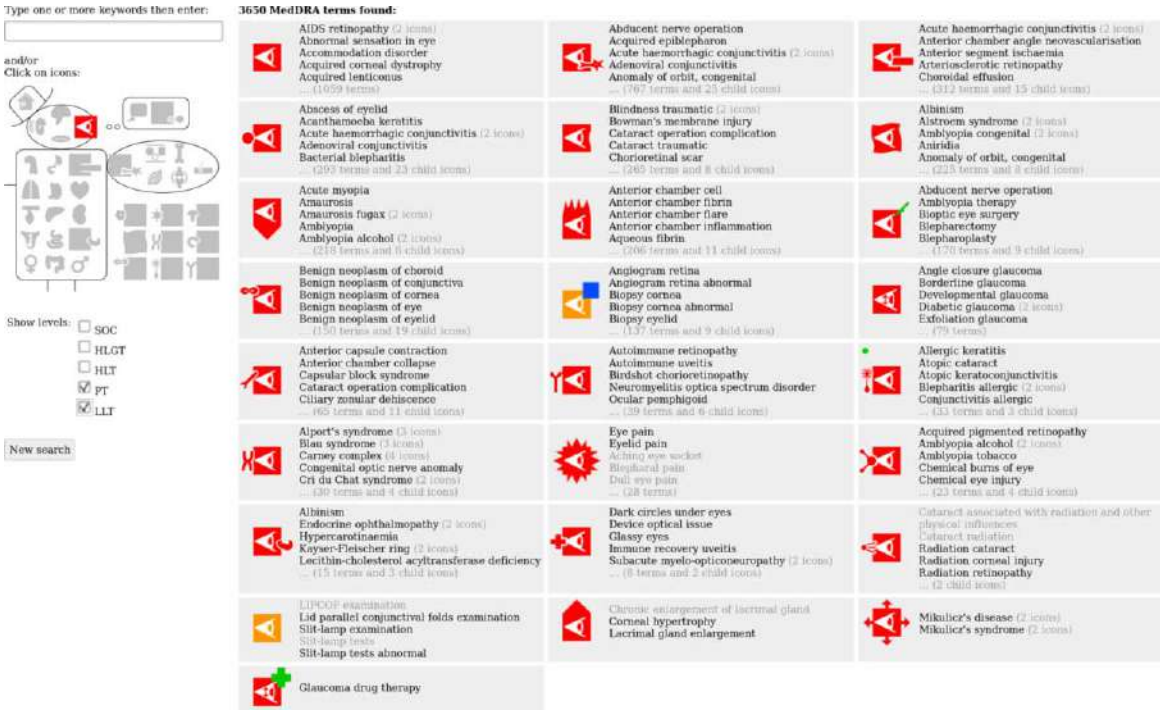

Figure 3– Screenshot of the results of an iconic search for PT and LLT with the "eye" pictogram.

the desired levels whose label matches the keywords; then we search for their icons. If only pictograms are present, we search for the icons having these pictograms; then we search for the terms of the desired levels that have at least one of these icons; finally, we filter the set of icons to those associated with at least one term in the resulting set of terms (due to the filtering on hierarchical levels, some icons can be associated with no terms). When both keywords and icons are present, we search for terms (taking into account keywords and levels) and for icons (taking into account pictograms) independently, and then we restrict both resulting sets to the elements associated with at least one element in the other set. In addition, the proposed algorithm is designed so that each step involves at the most two classes out of the three in the model (*i.e.* MedDRA terms, Icons, and Pictogram). This improves performances of the search.

Displaying the Search Results

Search results can be numerous; therefore, we use icons to organize them. Icons are sorted by the number of associated terms. For each icon, we display a panel with the icon on the left and the list of the corresponding MedDRA terms on the right. LLT are displayed in gray and other levels in black. When more than 6 terms are present, we display only the first 5 ones (in alphabetical order) and the total number of terms; the entire list of terms can be obtained by clicking on the panel. Whenever a given term is associated with more than one icon in the resulting set of icons, the term appears in several panels (one per icon), with a gray label indicating the number of icons (*e.g.* "2 icons"). By mouse-hovering this label, the user can see a popup bubble showing all the icons.

Moreover, when there are more than 10 icons, we reduce the list of icons by removing all icons that are more specific than another. In fact, the VCM ontology defines is-a relation between icons. For example, the icon "renal infection" is more specific than "renal disorder" and "infection". The terms associated with the removed icons are re-associated with their parent icon (if several parents are present, the terms are associated with all of them and will be displayed in several panels, as previously). When the panel of the parent icon is clicked, the terms initially associated with the parent icon are displayed, as well as other panels for the child icons.

Preliminary Evaluation

As a preliminary evaluation, we showed the proposed interface to two pharmacovigilance experts working daily with the MedDRA terminology. We gathered their opinions and their comments using a qualitative form including the following 7 general questions: Is the interface useful for finding MedDRA terms when coding a new case? when gathering codes for performing an exhaustive search in a pharmacovigilance database? Do you search mainly at the PT level or the LLT level? Is the iconic search interesting? alone? in combination with the lexical search? Is a training necessary for using VCM icons?

Results

Iconic Interface for Browsing MedDRA

Figure 3 shows a screenshot of the proposed interface. On the left, the user can enter keywords, click pictograms on "Mister VCM" and select the desired MedDRA levels. These three

operations can be done in the order of his choice. The proposed system has a good performance: even when searching over the largest part of MedDRA (the tumor pictogram), the response time does not exceed 0.6 seconds.

Figure 3 shows the results of an iconic search with the "eye" pictogram. 3,650 terms were found and grouped according to 25 icons (more specific, children, icons exist but are not shown). When clicking on an icon panel, the entire list of associated terms is shown, as well as more specific icons. Figure 4 shows an example of such a panel, obtained after clicking on the "allergic inflammation of eye" icon on Figure 3 (it is the icon marked with a green dot). The panel shows 2 more specific child icons: "allergic inflammation of the optic nerve" and "allergic edema of eye".

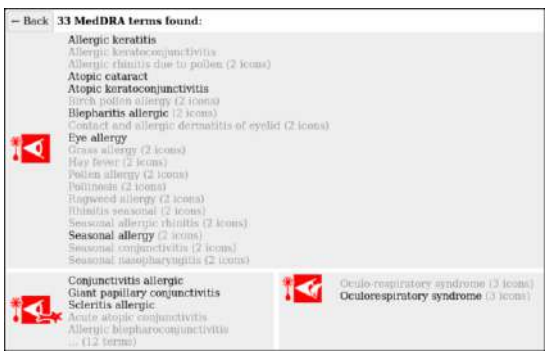

Figure 4– Screenshot of the panel shown when clicking the "allergic inflammation of eye" icon in Figure 3 (the one marked with a green dot).

Figure 5 shows an example of a search mixing lexical and iconic queries. We wanted to search for abscess in the urinary tract. "Abscess" is a clearly defined and specific keyword, so we typed it into the lexical search box. On the contrary, "urinary tract" is more general: many synonyms exist, and it also includes several subparts (*e.g.* ureter). Thus, we clicked on the "kidney" pictogram that represents the urinary system. The results show 2 icons with 17 terms.

When a term is clicked, it is displayed on a page with its label, its MedDRA code, its icons and its position in the MedDRA hierarchy, including ancestors and children terms. Ancestors and children can be clicked. As a consequence, the proposed interface also allows a classical tree-based navigation in the terminology.

Expert Opinions

The purely iconic search was not found very interesting by the two experts. On the contrary, the combination of the lexical and iconic search was described by them as very interesting, for example when dealing with synonymy (*e.g.* "auricular" keyword + heart pictogram to avoid auricular terms referring to ear) or for increasing the sensibility of the search, since most pictograms are rather general. This second point makes our interface particularly appealing to them when gathering codes for performing an exhaustive search. Moreover, the ability to select the depth level allows starting at a high level and then going down to lower levels if there is no result on the higher level.

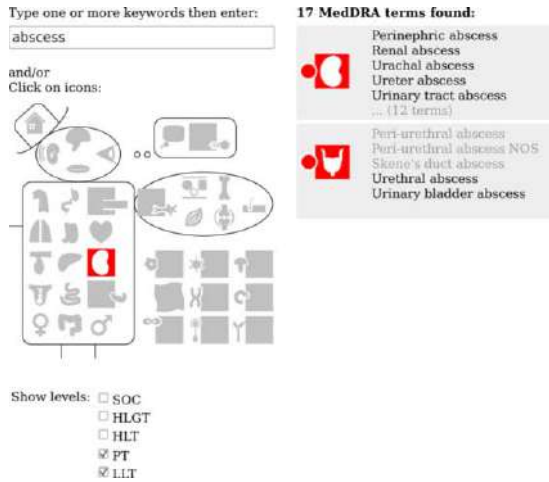

Figure 5– Screenshot of a lexico-iconic search: we searched for PT and LLT in MedDRA with the keyword "abscess" and pictogram "urinary".

On the contrary, when coding a new case, experts have to "stick" to the diagnostic mentioned in the case, and thus a lexical search through LLT is more appropriate. The iconic interface is thus less interesting for them. However, one expert qualified VCM icons as an "Esperanto of medical language". She considered that the iconic interface would be very useful for clinical research associates in the industry, because they are often non-specialists (*i.e.* not a physician or pharmacist) and could benefit from the guidance of icons: they may help to clearly identify the anatomic location or the morphology of a complex pathology, *e.g.* VCM icons explicitly represent "glomerulonephritis" as an inflammation of a part of the kidney while it may not be obvious to a non-specialist. In addition, many of them have to use MedDRA in English, even if it is not their native language.

Finally, both experts considered that training is needed before using VCM icons.

Discussion

In this paper, we proposed an original approach for browsing and searching medical terminologies, using pictograms and icons in addition to lexical keywords and terms. We applied this new approach to MedDRA. The resulting tool was found interesting by pharmacovigilance experts, in particular for gathering terms before performing an exhaustive search in a pharmacovigilance database, and for non-specialist users.

"Mister VCM" was initially designed to gather and organize a small set (5-50) of VCM icons. Here, we used it in a very different way, for allowing the selection of one or more pictograms in order to formulate a query in a visual way. This is the first time we use VCM for a querying purpose.

The icon enables a semantic search in the terminology. For example, the heart pictogram allows searching for all cardiac-related terms, without having to deal with the problems of synonymy or polysemy, while a lexical search would have to consider the many existing synonyms: "heart", "cardiac",

"card-", but also parts of the heart, such as "ventricular" or "coronary", and polysemy, *e.g.* "cardia" is not related to the heart but to the stomach, despite its short lexical distance which "cardiac" would suggest.

Some medical terminologies have an ontological structure that could be used for performing a semantic search. For instance, SNOMED CT relates all disorders to their finding site. These relations could be used to find all disorders related to the heart (including the heart subparts). However, the huge number of concepts in SNOMED CT makes this approach difficult and tedious to use. Moreover, ontological definitions are usually stricter than a human expert would expect, especially when performing broad search: *e.g.* in SNOMED CT, pericardium is not included in the heart because, strictly speaking, it is not a part of the heart. On the contrary, VCM pictograms are far less numerous, and they have a broader definition: *e.g.* the heart pictogram also covers the heart-related structure such as pericardium.

In the literature, Massari et al. [17] proposed meta-terms based on medical specialties to enrich terminologies and facilitate searches. Meta-terms can be combined with other types of searches. This approach is similar to the one we proposed here, but neither iconic nor visual.

Conclusions

Icons are a new, promising approach for browsing and searching medical terminologies. The perspectives of this work are twofold. First, the proposed interface will be properly evaluated in pharmacovigilance settings, using quantitative methods. Second, it could also be adapted to other medical terminologies such as ICD10 or SNOMED CT and used for helping physicians associate coded terms to their patients. Applications in medical education are also possible.

An Empirical Test of GRUs and Deep Contextualized Word Representations on De-Identification

Kahyun Lee, Michele Filannino, Özlem Uzuner

Department of Information Science and Technology, George Mason University, Fairfax, VA, United States

Abstract

De-identification aims to remove 18 categories of protected health information from electronic health records. Ideally, de-identification systems should be reliable and generalizable. Previous research has focused on improving performance but has not examined generalizability. This paper investigates both performance and generalizability. To improve current state-of-the-art performance based on long short-term memory (LSTM) units, we introduce a system that uses gated recurrent units (GRUs) and deep contextualized word representations, both of which have never been applied to de-identification. We measure performance and generalizability of each system using the 2014 i2b2/UTHealth and 2016 CEGS N-GRID de-identification datasets. We show that deep contextualized word representations improve state-of-the-art performance, while the benefit of switching LSTM units with GRUs is not significant. The generalizability of de-identification system significantly improved with deep contextualized word representations; in addition, LSTM units-based system is more generalizable than the GRUs-based system.

Introduction

Removing identifiable information from personal data is important for protecting privacy. The General Data Protection Regulation (GDPR) in the European Union (EU) prohibits processing of personal data without obtaining explicit consent unless identifiable information is first removed from the data. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) requires removal of 18 categories of protected health information (PHI) from electronic health records (EHRs) in order to protect the privacy of patients. The task of removing such information is often referred to as de-identification. This task is often the first step that must be performed before EHRs can be shared. In this paper, we focus on the de-identification of EHRs for HIPAA compliance. This task can be accomplished both manually and automatically. However, manual de-identification is non-reusable, time-consuming, and costly. For example, Dorr et al.[1] assessed the difficulty and time costs of manual de-identification in clinical notes. On average, manual de-identification of a clinical note, with an average note length of 261 ± 352 words, required 87.3 ± 61 seconds. Douglass et al.[2] found that each human annotator could read 16,000 to 20,000 words hourly and was paid $50 per hour. Given the vast amount of EHRs and the time and financial cost of manual de-identification, fully manual de-identification is not feasible and must benefit from automated methods.

The earliest automated de-identification systems were primarily rule-based [3–5]. Researchers utilized external knowledge resources, such as lists of personal names and addresses, as well as medical term dictionaries. They also implemented regular expressions to capture morpho-lexical features of PHI.

Recently, machine-learning systems have made significant contributions to de-identification. Most machine learning models interpret de-identification as a sequence-labeling problem [6–11]. These models can handle sequences of characters, words, or sentences. For the 2014 i2b2/UTHealth shared task on de-identification [12], Yang and Garibaldi [7] earned the highest F1-score among participants using a sequence-labeling classifier based on conditional random fields (CRFs) which were complemented with customized rules. All the systems that ranked among the top five in this shared task were based on CRFs. More recently, artificial neural networks (ANNs), which are also sequence labelers, have been used for de-identification. Among various architectures of ANNs, recurrent neural networks (RNNs) have been the most common. A type of RNNs, referred to as long short-term memory (LSTM) units combined with CRFs along with manually encoded rules [11] have displayed the best performance in the 2016 CEGS N-GRID de-identification shared task [13]. Interestingly, the best systems in both shared tasks complemented their machine learning solutions with hand-crafted rules that were optimized to their datasets. Independently of these shared tasks, Dernoncourt et al. [14] built NeuroNER, and achieved state-of-the-art performance on the 2014 i2b2/UTHealth dataset. NeuroNER is also based on bi-directional LSTM (bi-LSTM) units and CRFs but includes no hand-crafted features or external resources other than GloVe word embeddings [15]. NeuroNER implements the bi-LSTM units on a character-level input to get character embeddings and concatenates character embeddings with pre-trained token embeddings. The resulting character-enhanced token embeddings are fed into the bi-LSTM units again and the sequence of probabilities are then tuned with the CRF sequence optimizer to produce the system output.

The success of NeuroNER prompts some follow up questions. The first concerns the use of different recurrent units. Although RNN with traditional neural units could handle sequence-based problems such as de-identification, they cannot effectively handle tasks that contain long-term dependencies. This is often referred to as the vanishing gradient problem. To mitigate the vanishing gradient problem, researchers have devised either enhanced learning algorithms [16] or more sophisticated activation functions [17, 18]. Among these activation functions, LSTM units are the most popular. However, in 2014, Cho et al. [18] proposed a different type of gating mechanism, namely the gated recurrent units (GRUs). Like LSTM units, GRUs can address the vanishing gradient problem, but they also have simpler structure relative to LSTM units. While LSTM units contain “forget,” “update,” and “output” gates, GRUs merely have “reset” and “update” gates. Despite this structural advantage and comparable performance [19], GRUs have not

been evaluated in de-identification.

The second question entails the benefit of incorporating different combinations of embeddings. Although basic word representations such as GloVe [15] and Word2Vec [20] have become the core of most recent natural language-processing (NLP) research, they face challenges when handling out-of-vocabulary (OOV) words and ambiguity, i.e., words that do not have an embedding (such as misspellings, dates, telephone numbers, and ID numbers) and words that are ambiguous (such as the word 'can' as a modal in the sentence "I can do it" and the same word as a noun in the sentence "this is a trash can"). Character embeddings could compensate for some of the weaknesses of these representations providing character-level information that can encapsulate the semantics of words. In their ablation test to investigate the contribution of each component to the performance of NeuroNER, Dernoncourt et al. [14] determined that their system performed reasonably well using only character-level embeddings (i.e., without word embeddings). However, both word embeddings and character embeddings contain limited or no information about context, which can be pivotal for capturing the true semantics of words. Recently, Peters et al. [21] devised word representations that can incorporate context into token embeddings. These "deep contextualized word embeddings" are calculated from a bi-directional language model (biLM) and are evaluated in our experiments.

Finally, despite the high performance of existing machine-learning-based de-identification systems, these systems do not generalize well to new types of data. The result of the 2016 CEGS N-GRID shared task on "sight unseen" data supports this observation. This task tested the performance of existing, unmodified de-identification systems on new types of data consisting of psychiatry records and was the first shared task of its type that utilized psychiatry data. Nine teams participated in this task. Each team could train their system on any data of their choosing. All systems were evaluated on the same previously unseen test data. The highest-performing team on this task could not reach 0.80 in terms of strict entity-based F1-score [13].

To reliably remove PHI from EHRs in practice, however, de-identification systems should generalize to new types of data that are different from what they trained on. Systems tested on the 2016 CEGS N-GRID shared task on "sight unseen" data were each trained on different sets of data, which rendered comparison of generalizability of their models impossible. Here, we present a systematic evaluation of generalizability of our systems. To the best of our knowledge, this is the first use of GRUs and deep contextualized word representations in de-identification and provides a systematic assessment of generalizability of discussed solutions.

Methods

State-of-the-art in de-identification was developed by Dernoncourt et al. [14]. This system, NeuroNER, consists of four layers, including a character-embedding layer, a token-embedding layer, a label-prediction layer, and a label-sequence-optimization layer. NeuroNER utilizes bi-LSTM units on character-level input to get character embeddings and concatenates character embeddings with pre-trained token embeddings. The resulting character-enhanced token embeddings are fed into bi-LSTM units again, and the resulting sequence of probabilities are then tuned with a CRF label sequence optimizer.

We selected NeuroNER as our baseline model. We maintained its overall pipeline, and modified its components (as described in the following experiments) to evaluate GRUs and deep contextualized word representations in de-identification, and to assess generalizability of the resulting models.

Datasets

We evaluated de-identification performance on the 2014 i2b2/UTHealth and the 2016 CEGS N-GRID de-identification data. The 2014 i2b2/UTHealth de-identification dataset (henceforth, the 2014 dataset) consists of 1,304 medical records, including discharge summaries, progress notes, doctor's notes, doctor-patient communications from 296 diabetic patients. These records contain 28,872 PHI entities in 28 types (including subtypes for some HIPAA PHI categories) [12]. The 2016 CEGS N-GRID de-identification dataset (henceforth, the 2016 dataset) includes 1,000 psychiatric intake records containing 34,364 PHI entities with the same types [13]. Table 1 summarizes the statistics of each dataset. As indicated in the table, the 2016 dataset contains more tokens and PHI per record. Considering the ratio between the average token per document and the average PHI per document, the 2014 dataset is denser than the 2016 dataset.

Both the 2014 and 2016 datasets consisted of training (60%) and test (40%) sets. We divided each of the training sets into training (40%) and validation (20%) sets. We used the training and validation sets for system development. We report results on the test sets.

Table 1 – Overview of the 2014 and 2016 Datasets

	2014 Dataset	2016 Dataset
Records	1,304	1,000
Total # of tokens	805,118	1,862,452
Average # of tokens per record	617	1,862
Total # of PHI entities	28,872	34,364
Average # of PHI per record	22	34

Evaluation Metrics

For evaluation, we used micro-averaged precision, recall, and F1-score computed using the following equations:

- Precision (P) = true positives / (true positives + false positives)
- Recall (R) = true positives / (true positives + false negatives)
- F1-score (F1) = 2*P*R / (P+R)

Organizers of the 2014 and 2016 de-identification shared tasks measured multiple versions of these metrics (strict/relaxed/overlap with token-based/entity-based matching) over two sets of PHI types (i2b2 PHI vs. HIPAA PHI). Strict, relaxed, and overlap measurements differ in terms of their acceptance of exact or inexact textual spans corresponding to PHI. Token-based versus entity-based evaluation refers to whether the complete string or individual words in the string are considered for de-identification. i2b2 PHI and HIPAA PHI differ in terms of granularity of PHI. i2b2 categories classify the 18 HIPAA categories into sub-types (e.g., a location HIPAA PHI type can be classified into street, city, state, zip i2b2 types). In this paper, we evaluate performance with the strictest settings—strict entity-based matching over i2b2 PHI.

System Structure

NeuroNER serves as both the starting point and the benchmark for the experiments presented in this paper. Our goal is to improve performance of this state-of-the-art system on de-identification and to assess its generalizability under different conditions. We experiment with different RNNs and

embeddings in order to evaluate the contribution of each to system performance and generalizability.

Our system accepts tokenized narrative text as input. For this, the narratives are first pre-processed using spaCy [22] for sentence detection and tokenization. Given the pre-processed narratives and NeuroNER, we experimented with bi-LSTM units and bi-GRUs. LSTM units and GRUs are alike in that they both incorporate history into their predictions. But as previously mentioned, GRUs have simpler structure than LSTM units. As a result, GRUs have fewer parameters than LSTM units, and can converge faster [19]. In terms of their performance, the superiority or inferiority of either LSTM units or GRUs remains a matter of debate [19, 23], while the merits of both units relative to the traditional RNNs units (for example, tanh) are undeniable [24,25].

In order to evaluate the performance of these units, we tested three different types of embeddings with them. Pre-trained word embeddings [12,17] are widely used and have become a core element in recent machine-learning-based NLP research; however, they can fall short on OOV and ambiguous words. One way of resolving these cases would entail the use of character-enhanced token embeddings or deriving from deep contextualized word representations. Rather than training a word vector for each token, deep contextualized word representations train a context function that is based on two-layer biLMs with character convolutions and that returns a flexible word vector [21]. This function assigns a different vector to each word based on its morphological features and context; even the same two words in the same sentence can have different word vectors. Deep contextualized word representations can mitigate both OOV and ambiguous word problems. We used 1,024-dimensional deep contextualized word representations in addition to character embeddings and word embeddings. We processed our datasets (using only the training and validation portions) with a pre-trained model (which is a context function trained on the 1B Word Benchmark [26]) to extract deep contextualized word representations.

To investigate the contribution of different embeddings to different RNNs on de-identification, we experimented with all possible combinations of items within the four layers of NeuroNER architecture. The layers are summarized in Table 2.

Table 2 – Experiment Items in Each Architectural Layer of NeuroNER

Location	Experiment items
4th layer	CRF label sequence optimizer
3rd layer	bi-LSTM units vs. bi-GRUs
2nd layer	word embeddings (WEs) and/or deep contextualized word representations (DEs)
1st layer	character embeddings (CEs)

Training and Hyperparameters

We tuned our hyperparameters using the training set of each dataset. NeuroNER accomplished its optimal performance on both datasets with these parameters:

- character-embedding dimension: 25
- character-based token-embedding dimension: 25
- token-embedding dimension: 100
- label-prediction dimension: 100
- dropout probability: 0.5

In addition to the above hyperparameters, the dimension of the deep contextualized word representations was 1,024. Therefore, the inputs to the label-prediction layer entail a minimum of 25 dimensions (in the case that only character embeddings are tested) and a maximum of 1,149 dimensions (in the case that all three embeddings are tested). When training, iteration was stopped if there was no improvement in the F1-score on the validation set for 10 epochs.

Results

Performances of both LSTM units-based and GRUs-based RNNs are presented in Tables 3 and 4. The statistical significance of F1-score difference from the baseline model was tested using approximate randomization [27] with 9,999 shuffles. Statistically significant F1-score differences at the level of 0.01 are asterisked.

Table 3 indicates the performance of LSTM units-based RNNs with different combinations of embeddings. The baseline performance of NeuroNER is underlined, and the precision, recall, and F1-score of the highest-performing combination for each dataset is in bold font. In the 2014 dataset, the role of character embeddings was pivotal. Without word embeddings, LSTM units-based RNNs accomplished 89.70 for F1-score. Any combinations that included deep contextualized word representations significantly outperformed the combination of character embeddings and word embeddings, which were our baseline, in F1-score. Even the system that used deep contextualized word representations alone could outperform this baseline in F1-score. The highest F1-score achieved with LSTM units-based RNNs was 92.82, which is 1.15 higher than the baseline. In the 2016 dataset, the system with only character embeddings underperformed relative to the system with only word embeddings. Deep contextualized word representations worked effectively on the 2016 dataset as well, but it did not surpass the baseline system until it was combined with the other two embeddings. The highest F1-score was 89.00. In both the 2014 and 2016 datasets, the optimal performances were observed when all three embeddings were combined.

Table 3 – Performance of LSTM Units-Based RNNs

Embeddings	2014 Dataset			2016 Dataset		
	P	R	F1	P	R	F1
CEs	92.83	86.77	89.70*	84.96	78.58	81.65*
WEs	85.46	79.09	82.15*	85.92	79.99	82.85*
DEs	93.50	90.79	92.13*	88.23	86.56	87.39*
CEs+WEs	92.39	90.97	91.67	89.15	87.09	88.11
CEs+DEs	93.14	90.84	91.98*	88.65	86.95	87.79
WEs+DEs	93.34	90.91	92.11*	87.99	87.92	87.95
All three	94.33	91.36	92.82*	90.88	87.20	89.00*

Table 4 – Performance of GRUs-Based RNNs

Embeddings	2014 Dataset			2016 Dataset		
	P	R	F1	P	R	F1
CEs	91.98	87.30	89.58*	84.77	77.20	80.81*
WEs	86.86	77.81	82.09*	84.66	78.73	81.59*
DEs	93.04	91.23	92.13*	88.48	85.99	87.22*
CEs+WEs	93.77	90.49	92.10*	89.66	86.39	87.99*
CEs+DEs	93.63	90.33	91.95*	90.57	86.58	88.53*
WEs+DEs	94.07	90.74	92.37*	89.97	87.51	88.72*
All three	93.59	91.65	92.61*	89.11	87.10	88.09

Table 4 indicates the performance of the GRUs-based RNNs. Here, character embeddings were pivotal in the 2014 dataset but not on the 2016 dataset. The combination of GRUs with deep contextualized word representations achieved a good performance. The optimal F1-score in the 2014 dataset was received when all three embeddings were combined, while the combination of word embeddings and deep contextualized

word representations exhibited the second highest performance. The differences in F1-score are statistically significant at P=.008. Regarding the 2016 dataset, the optimal performance was produced when word embeddings and deep contextualized word representations were combined; combining character embeddings with these two embeddings deteriorated the performance of the system.

Comparing Tables 3 and 4, we see that GRUs demonstrated a comparable performance relative to the LSTM units and even outperformed the LSTM units in some combinations. Notably, the F1-score increased by 0.43 merely as a result of substituting the LSTM units with the GRUs for the 2014 dataset (which does not occur in the 2016 dataset). The differences in F1-score are statistically significant at P=0.002. However, the highest performance with the GRUs-based RNNs could not surpass that of the LSTM units-based RNNs for both datasets. The differences in F1-scores are statistically significant at P=0.004.

We also investigated the generalizability of both LSTM units-based and GRUs-based RNNs systems. To test the generalizability of each combinatio, we evaluated the performance of the model trained using the 2014 training set on the 2016 test set.

Table 5 – Generalizability of LSTM Units-Based RNNs

Embeddings	2014→2016			2016→2014		
	P	R	F1	P	R	F1
CEs	67.25	55.17	60.61*	57.67	62.76	60.11*
WEs	57.57	59.81	58.67*	57.08	42.65	48.82*
DEs	74.56	69.97	72.19*	70.95	69.51	70.22*
CEs+WEs	70.62	66.01	68.24	68.62	67.09	67.85
CEs+DEs	75.95	70.96	73.37*	69.37	70.84	70.10*
WEs+DEs	74.97	70.79	72.82*	70.92	70.42	70.67*
All three	77.51	68.30	72.61*	71.98	70.90	71.44*

Table 6 – Generalizability of GRUs-Based RNNs

Embeddings	2014→2016			2016→2014		
	P	R	F1	P	R	F1
CEs	72.85	54.02	62.04*	64.24	63.46	63.85*
WEs	61.08	58.87	59.95*	50.62	44.36	47.28*
DEs	71.78	70.17	70.97*	68.76	66.11	67.40*
CEs+WEs	76.68	66.82	71.41*	66.95	66.20	66.57*
CEs+DEs	74.55	71.04	72.75*	70.81	69.09	69.94*
WEs+DEs	76.82	69.19	72.81*	69.58	69.37	69.47*
All three	72.75	71.72	71.93*	73.18	69.12	71.09*

As Tables 5 and 6 demonstrate, combinations that performed effectively on training data also work effectively on new types of data. In addition, the introduction of deep contextualized word representations significantly increased the generalizability of both LSTM units and GRUs-based systems on both datasets. The differences in F1-score of the baseline and the models that include deep contextualized word representations are statistically significant at P<0.001. The gain in generalizability over the baseline is more significant than the gain in performance. The performance increase from the baseline to the highest F1-score of LSTM units-based system within the 2014 dataset was 1.15, while the increase in the performance while going across datasets was 5.13.

Discussion

Error Analysis

The distribution of PHI found by each RNN is shown in Table 7. Overall, both RNNs succeeded in finding 9,871 entities from the 2014 test set and 9,950 entities from the 2016 test set. In contrast, both units missed 1,302 entities in the 2014 test set and 3,339 entities in the 2016 test set. To investigate the strengths and weaknesses of each RNN, the number of entities found by only one of the units were counted. For example, "only GRUs found" indicates the number of PHI entities that all embeddings combinations with LSTM units failed to detect, but all embeddings combinations with the GRUs could find. These entities can be only found by GRUs regardless of embedding types, and they may reveal the empirical difference between LSTM units and GRUs.

Table 7 – Distribution of PHI by RNNs

	2014 Dataset	2016 Dataset
Total PHI in the test set	11,462	13,519
Both found	9,871	9,950
Both failed	1,302	3,339
Only GRUs found	243	104
Only LSTM units found	46	126

We extracted the sentences that include "only LSTM units found" and "only GRUs found" PHI entities and manually reviewed their characteristics. In many "only GRUs found" PHIs, the entities were directly adjacent to special characters such as slashes (/), colons (:), commas (,), and hyphens (-). For example, 102 DOCTOR entities, which are typically in the form of 'initial/name1/name2' or 'initial:name', could be found only by GRUs-based systems. It appears that GRUs are less sensitive to directly adjacent tokens in predicting the label of the current token. In contrast, PHI only found by LSTM units contain more contextually complex sentences. For example, in 41 cases, seasons and years (both are in DATE category) in sentences such as "healthy until spring of 0314 2126," "in the spring of 2128," and "in the summer of 2096" could not be found by GRUs, but they were detected by LSTM units. However, these findings need to be taken with a grain of salt given the small sample size.

Table 8 – Distribution of PHI by Embeddings

	2014 Dataset	2016 Dataset
Total PHI in the test set	11,462	13,519
Found only without CEs	347	175
Found only with CEs	131	249

Table 8 indicates the distribution of PHI for deep contextualized word representations with both RNNs. A total of 380 PHI entities were additionally found with these embeddings. These PHI entities were primarily centered around several entity types, such as PROFESSION (19%), HOSPITAL (15%), ORGANIZATION (15%), PATIENT (12%), and DOCTOR (11%). This distribution differs from the original PHI distribution of the test set: PROFESSION (5%), HOSPITAL (9%), ORGANIZATION (3%), PATIENT (7%), and DOCTOR (14%). From a practical perspective, 'PATIENT-DOCTOR' and 'HOSPITAL-ORGANIZATION' pairs are difficult to be differentiated from each other because of the semantic similarity between these PHI categories. Through manual review, we found these PHI entities were in complete sentences in most cases. This illustrates that a pre-trained context function returns better word representations when inputs are lengthy and sufficiently informative to make a machine understand context. Gains in the 2016 dataset are nearly twice as abundant as those in the 2014 dataset perhaps because EHRs in the 2016 dataset are more organized and structured than those in the 2014 dataset. As a result, the sentence detector worked more effectively on the 2016 dataset, providing cleaner input to the RNNs.

Miscellaneous

On average, GRUs show higher per-category F1-score on entity types CITY, COUNTRY, DOCTOR, HOSPITAL, IDNUM, PHONE, PROFESSION, and STATE whereas LSTM units perform better on AGE, DATE, MEDICALRECORD, ORGANIZATION, PATIENT, STREET, USERNAME, and ZIP. Interestingly, deep contextualized embeddings achieve higher per-category F1-score than both character and word embeddings regardless of entity types. Theoretically, the convergence of GRUs-based systems should be faster than LSTM units-based systems because GRUs have simpler structure and fewer parameters than LSTM units. This was confirmed by the experiments. For the 2014 dataset, convergence required an average of 37 epochs for the LSTM units-based systems, whereas for GRUs-based systems, convergence required an average of 28 epochs. Similarly, in the 2016 dataset, LSTM units required an average of 32 epochs, whereas GRUs required 30 epochs.

Conclusions

To automate de-identification tasks, de-identification must be highly accurate and generalizable. State-of-the-art de-identification systems are based on RNNs with bi-LSTM units. This study investigated avenues for improving the state-of-the-art by modifying types of recurrent units and embeddings. It also investigated how these modifications affect generalizability. We found that substituting LSTM units with the GRUs cannot significantly improve performance or generalizability. However, this does not imply the inferiority of GRUs relative to LSTM units on de-identification. GRUs outperformed LSTM units in some PHI types and could complement LSTM units in an ensemble. They could also converge to optimal parameters faster than LSTM units. The introduction of deep contextualized word representations on top of character embeddings and word embeddings was certainly helpful in increasing both the state-of-the-art performance and generalizability.

Abstract

We tested the value of adding data from the operating room to models predicting in-hospital death. We assessed model performance using two metrics, the area under the receiver operating characteristic curve (AUROC) and the area under the precision-recall curve (AUPRC), to illustrate the differences in information they convey in the setting of class imbalance. Data was collected on 74,147 patients who underwent major noncardiac surgery and 112 unique features were extracted from electronic health records. Sets of features were incrementally added to models using logistic regression, naïve Bayes, random forest, and gradient boosted machine methods. AUROC increased as more features were added, but changes were small for some modeling approaches. In contrast, AUPRC, which reflects positive predicted value, exhibited improvements across all models. Using AUPRC highlighted the added value of intraoperative data, not seen consistently with AUROC, and that with class imbalance AUPRC may serve as the more clinically relevant criterion.

Keywords:
Medical Informatics; Hospital Mortality; Risk Assessment

Introduction

Clinicians routinely use data from various sources to make diagnostic assessments and treatment decisions. However, recent insights from behavioral economics and psychology highlight the limits of human decision-making, particularly with respect to synthesizing vast amounts of data with high variety and velocity [1-3]. The advent of big data science and predictive analytics holds the potential to improve key clinical tasks such as risk-stratifying patients at risk of poor outcomes. Doing so, however, will require careful alignment between methods and clinical use of predictions.

One key area of high clinical interest for predictive analytics is risk-stratification of patients for an outcome of death, particularly after surgery. There is expansive literature on this because of the frequency of noncardiac surgery. In 2010 alone, more than 25 million major noncardiac procedures were performed in the United States [4]. Though rates of postoperative mortality can be as low as 2%, postoperative mortality rates increase beyond 10% in high-risk subgroups [5-7]. Clinicians and researchers have thus developed various approaches to risk-stratify patients for postoperative mortality risk. The most widely used system is the American Society of Anesthesiologist (ASA) physical status classification score, which represents a clinician's assessment of a patient's risk of postoperative mortality based on data available before surgery starts [8]. However, the human decision-making element presents major inter-rater reliability issues with respect to accuracy and consistency of scores [9]. There are several other clinical risk scores that use data and patient characteristics before surgery, such as POSPOM, Risk Stratification Index (RSI) and Risk Quantification Index (RQI). [5; 10]. Such models obtain very high area under the receiver operating characteristic curve (AUROC) values ranging from 0.8 to 0.94. The Surgical Apgar Score takes a simpler approach and uses three intraoperative variables: estimated blood loss, lowest mean arterial pressure, and lowest heart rate measured during surgery to predict major postoperative complications [11]. The Surgical Apgar Score performs variably across studies with AUROC values from 0.6 to 0.86 [12-14]. One study added Surgical Apgar Score variables to RQI variables, but found little improvement in predicting postoperative death versus RQI itself [14]. This may be an indication that intraoperative information does not add value to postoperative mortality risk. However, there are two outstanding issues. First, it is still unclear whether and to what extent intraoperative data can improve the prediction of postoperative mortality. Second, assessing model performance with AUROC may be problematic because it is not aligned with the information clinicians seek, and thus other metrics need to be tested in assessing the value of intra-operative data.

Although AUROC serves as an important indicator for model performance, it is not necessarily aligned with how clinicians would use a prediction model in some settings. In the context of noncardiac surgery, death is a relatively rare outcome, so the importance of identifying high-risk patients who may die during their admission is more critical than identifying patients who do not die (the majority class). AUROC is immune to changes in class distribution because it is calculated only using sensitivity (i.e., recall, true positive rate) and specificity (i.e., false positive rate) [15] and therefore cannot distinguish between models that have equal sensitivity but different precision (i.e., positive predictive value (PPV)). In our clinical context, the precision--the probability of correctly identifying patient death out of all predicted deaths--is a more clinically meaningful measure than AUROC.

In this paper, we examine how adding intraoperative data to baseline (pre-hospitalization) and preoperative data can improve prediction of postoperative mortality using AUROC

and AUPRC to assess performance. We first show that AUROC metrics are very high even when using just baseline and preoperative data, which may lead to the conclusion that adding intraoperative data does not add any predictive information. We then use AUPRC, which reflects PPV as used in clinical decision-making, and demonstrate that adding intraoperative data results in improved predictions. These improvements are robust in multiple predictive modeling approaches. Lastly, we utilize clinician assessments of risk, specifically the ASA physical status score, to show that the AUPRC in models with intraoperative data contains substantial information that covers most of clinician assessment information.

Methods

Data Sources and Collection

Data was extracted from various databases across the University of Pennsylvania Health System (UPHS) and integrated into a comprehensive perioperative dataset (data containing administrative, preoperative, intraoperative, and postoperative information related surgeries). Administrative and clinical data were collected from a clinical data warehouse, Penn Data Store, and an electronic health record (EHR) (Epic Systems, USA). Intraoperative data was extracted from a perioperative data repository constructed from a set of transformation scripts run on EPIC's Clarity databases developed by the Multicenter Perioperative Outcomes Group who work to standardize perioperative information for academic research [16]. The study design and data access were approved by the University of Pennsylvania Institutional Review Board Protocol 824057.

Patient Inclusion and Exclusion Criteria

Patients 18 years or older who underwent major noncardiac surgery across four academic medical centers within the University of Pennsylvania Health System in Pennsylvania, United States between June 2012 to June 2017 were included in the sample. Patients who underwent multiple major surgeries during the same visit were excluded.

Major Noncardiac Surgery

Noncardiac surgery was identified using Current Procedural Terminology (CPT®) codes specification ranges for noncardiac surgeries 10021-32999 and 34001-69990 [17]. The Agency for Healthcare Research Quality Healthcare Cost Utilization Project (AHRQ HCUP) Surgery Flag Software was used to identify surgeries classified as major therapeutic procedures [18].

In-Hospital Mortality

The primary outcome for the predictive models was all-cause, in-hospital mortality, represented as a binary variable.

Model Performance

Cohort data was randomly split by the patient into training (60%), validation (20%), and test (20%) sets as defined by Hastie et al [4], with similar incidence of in-hospital mortality in the resulting sets. All models were assessed on test data. DeLongs and Wilcoxon-Mann Whitney tests were used to test for significant differences on 1000 Bootstrap samples for each model.

Imbalanced Outcome Class

Death is clearly a very important and clinically relevant postoperative complication and is quite infrequent for patients undergoing major noncardiac surgeries. This class imbalance may result in challenges in assessing model performance. We used two metrics to help assess overall model performance.

Area under the Receiver Operating Characteristic Curve (AUROC)

The AUROC metric represents model discrimination across various thresholds for a classification problem. The AUROC depends on sensitivity (recall, TPR) and specificity (FPR), and is the probability that the model will rank a randomly chosen positive case (e.g. death) higher than a randomly chosen negative case (e.g. non-death) [15]. AUROC values range from 0 to 1, with 1 indicating perfect model discrimination. When an AUROC is 0.5, it means the model has no class separation capacity and is no better than random classification.

Area under the Precision-Recall Curve (AUPRC)

Recent literature suggests other ways to examine model performance in skewed data. Davis and Goadrich introduced Precision-Recall curves for interpreting binary classification models in highly skewed datasets. In particular, optimizing on AUROC may not optimize the AUPRC [19]. Additionally, the AUPRC ignores the identification of true negative cases. In clinical practice, clinicians often care more about whether a patient is high risk for a poor outcome rather than low risk.

Defined mathematically, let Y and Z(t) be the true and predicted statuses at threshold t, respectively. As with AUROC, the AUPRC also considers sensitivity (i.e., recall, or the proportion high-risk classified as such)

$$\mathrm{Rec}(t) = \Pr\{Z(t)=1 \mid Y=1\}$$

but instead of specificity, it takes into account positive predictive value (i.e., precision, or the proportion classified as high-risk who actually are high-risk)

$$\mathrm{Prec}(t) = \Pr\{Y=1 \mid Z(t)=1\}$$

Then AUPRC is computed as the area under the curve traced across different thresholds t. As a simple example, suppose 5/10,000 patients die and we have two tests that correctly identify all 5 such patients. One test says 5 additional patients will die, while another says 20 additional patients will die. Clearly the first test is preferable; however, the false positive rates will both be 0.05% or less, whereas the PPVs are 50% and 20%, respectively. Thus, AUROC may not distinguish between the tests while AUPRC would.

Data Cleaning

EHR data frequently include missing data and erroneous values. We used a flexible approach to missing data by including dichotomous indicator variables for each feature, equaling one if the observation contained missing data or zero otherwise. This allowed the chance of death to differ across those who had missing values versus not, which is more flexible and less stringent than the common "missing completely at random" assumption required in multiple imputations. Additionally, to account for out-of-range values, we Winsorized outliers to the 1st or 99th percentile by feature.

Model Input Features

Each patient visit corresponded to a unique surgical record where features were calculated or extracted from the start of the admission until the end of the surgery. Features were split into three respective groups: Baseline, Preoperative, and Intraoperative. We also used ASA score as a separate feature to compare additive information from human judgement on top of the other objective data features. A sample of features included in models are shown in Table 2.

Baseline features included basic demographic information, like age, gender, race, and insurance type. Patient Elixhauser and Charlson comorbidity indices were also included, derived from the International Classification of Diseases (ICD9-CM/ICD10-CM) diagnostic codes [20-22].

The preoperative features contained clinical information related to the patient's admission, such as basic and extended lab measurements, medication use, and surgical procedure type. To categorize surgeries, we used AHRQ HCUP Clinical Classification Software to map each primary CPT code to 244 unique procedure groups [23]. Data for these variables was collected from the start of the admission up until the start of the surgery procedure.

Intraoperative features included descriptive intraoperative vital signs, such as minimum and maximum heart rate and blood pressure; fluid status, such as total fluid administration and estimated blood loss; and drug use, such as vasopressors and rescue medications. Data for this category was collected between the start and end of the surgery.

Modeling

We examined how adding intraoperative data to pre-hospitalization and preoperative data improved prediction across various statistical and machine learning classification models. We used four predictive modeling approaches: logistic regression, naïve Bayes, random forest, and gradient boosted machine (GBM). Logistic regression and naïve Bayes are well established statistical modeling techniques that are frequently used in predictive modeling. Random Forest and GBMs are robust machine learning ensemble classification methods. Large numbers of variables precluded the use of logistic models without feature reduction due to lack of convergence. All other models utilized all model inputs.

Feature Reduction for Logistic Regression

We used two approaches: (1) the Forward Selection (FORWARD) technique (SAS procedure HPGENSELECT), which sequentially adds variables based on model fit, terminating when no significant improvement is achieved by adding remaining features and (2) the Least Absolute Shrinkage and Selection Operator (LASSO) technique [4].

Random Forest and GBM Model Parameter Optimization

We executed a randomized grid search on our 60% training dataset for hyperparameter tuning, using three folds across 30 iterations and optimizing for PPV. We used the 20% validation set to evaluate, verify, and finalize our model parameters. Reported performance is based on the remaining 20% sequestered test dataset.

Software and Tools

Logistic regression with forward selection and LASSO models for this paper was generated using SAS software (Copyright © 2018 SAS Institute Inc). All other codes and predictive models were conducted in Python 3.6 with Pandas 0.23.3 and Scikit-learn 0.19.1 libraries.

Results

Patient Sample

Of the 71,147 adult single major noncardiac surgery encounters in our sample, 0.78% (n = 512) died in the hospital. The distribution of outcomes and preoperative clinical characteristics did not differ between training, validation, and holdout cohorts.

Patient characteristics differed significantly between those who did and did not die after surgery while in the hospital [Table 1]. Of note, the mean age of patients who died after surgery was significantly higher at 65 years (SD ± 16.1 years) vs 56 years (SD ± 16.8 years). Additionally, patients who died were proportionally more likely to be male, have Medicare, and a higher ASA score of 3 and 4 versus 2 and 3. There was also a significant difference in the mix of surgery types.

Table 1. Abbreviated Baseline Characteristics

Characteristic	In-hospital mortality cohort, n = 512 (%)	No in-hospital mortality cohort, n = 73,635 (%)
Age, mean (SD)	65 (16.1)	56 (16.8)
Gender		
Male	296 (57.81)	30,883 (41.94)
Race

Vascular	86 (16.8)	3,566 (4.84)
ASA Rating		
ASA 2	12 (2.34)	33,590 (45.62)
ASA 3	232 (45.31)	33,891 (46.03)
ASA 4	227 (44.34)	2,693 (3.66)
ASA 5	39 (7.62)	42 (0.06)
ASA Unknown	2 (0.39)	170 (0.23)

Features

A total of 112 features were extracted for model development. 53 features were identified as baseline features. 34 features were identified as preoperative features. 25 features were identified as intraoperative or during surgery features. Finally, the ASA score was extracted.

Table 2. Model Features Examples

Baseline (n = 53)	Preoperative (n = 34)	Intraoperative (n = 25)
• Gender • Race • Insurance • Marital status • Elixhauser comorbidities	• CCS_Category • Serum creatinine level • Troponin-T level • White blood cell count • Insulin administration	• Lowest heart rate • Lowest mean arterial pressure • Max crystalloid administration • Total epinephrine dose • Total surgery duration

Model Performance

Table 3 compares the predictive performance of the various modeling approaches over sequential feature set additions. All models experienced the largest gain in predictive performance when adding preoperative features to baseline features, increasing AUROCs by 0.120 up to 0.272. Adding intraoperative features led to smaller increases (up to 0.059 for logistic regression with forward selection), with the LASSO model actually experiencing a 0.049 decrease in AUROC. AUROC increases were only significant for GBM and the logistic regression with forward selection models ($p = 0.036$ and $p < 0.001$, respectively). Further, adding the ASA score was not significant across models and did not lead to meaningful improvements for any modeling approach.

In contrast to AUROC, the values for AUPRC were much lower (as noted earlier, reflecting PPV rather than prioritizing low false positive rate). Also, in contrast to results observed for AUROC, the model performance on AUPRC demonstrated large increases for every model when adding intraoperative data to baseline and preoperative data. These gains were as large as 0.148 for logistic regression with forward selection and 0.075 for random forest. The AUPRC increase in each model was significant ($p < 0.001$), except when adding ASA score, which did not meaningfully increase further. These results were consistent across modeling approaches except for the LASSO model, which demonstrated worse performance with intraoperative data.

Discussion

Our study has two important findings. First, this study demonstrates that adding intraoperative data to models predicting postoperative death after noncardiac surgery yields meaningful improvements in performance. Second, the metric used to evaluate model performance was very important to inference, highlighting limitations of AUROC in some settings such as those with class imbalance where the minority class is more important clinically. Interestingly, further adding human clinician judgement after adding intraoperative data did not provide incremental improvements. Taken together, these results indicate that intraoperative data has important clinical information that can be used to better risk-stratify patients.

Importantly, the class imbalance that exists in many mortality prediction problems rendered the AUROC metric less useful in assessing the additional value of intraoperative data than an alternative metric, the AUPRC. In fact, without examining AUPRC, our study may have yielded the opposite main conclusion, erroneously inferring little value of intraoperative data in mortality prediction for noncardiac surgery. This point is further highlighted by the greater alignment between the clinical utility of the prediction and AUPRC, rather than AUROC, because in this setting of class imbalance (low death rate) PPV is clinically more important than false positive rate.

Lastly, it is noteworthy that while most modelling approaches yielded similar inferences on predictive performance improvements, there were substantial variations in performance and performance improvement across them. GBM, random forest, and logistic regression with forward selection seemed to perform the best and extract additional information from the intraoperative data.

Future work could examine the conditions under which methods perform better than others and should use mortality outcomes outside the hospital setting after 30 and 60 days to examine generalizability. This information may be important in understanding if predictive ability begins to stagger or decrease when the outcome of interest is farther away from the surgical exposure.

Conclusions

AUROC may not be the preferred metric for model performance in imbalanced datasets under certain conditions, such as when PPV is more important. Using AUPRC indicated that adding intraoperative data to baseline and preoperative data improved prediction of postoperative mortality. These improvements are robust to multiple machine learning model approaches. Further, combining intraoperative with preoperative data captures most of the information/predictive value within clinician assessments of risk as measured by the ASA physical status classification.

Abstract

Meta-analysis, a systematic retrieval from literature databases is an essential and prevailing method for combining data from multiple studies. Unfortunately, few studies have examined its rigor, which affects its reproducibility of results. We identified 22 meta-analyses on cervical cancer in PubMed for examining the parameters defined by PRISMA, relating to the rigor of literature retrieval. We found that 16 literature databases were used, and EMBASE was a leading resource, accounting for the highest frequency (81.82%). About half (45.45%) of the meta-analyses presented a complete, reproducible search strategy for at least one database. The ratio of included to retrieved articles after redundancy removal was only 6.58%, indicating low precision due to unclear or unreported processes. Our work serves as an initial step to examine the planning and execution of meta-analysis. Future efforts need to enhance reliability on literature retrieval in meta-analysis and compliance to PRISMA.

Keywords:

Meta-Analysis; Information Storage and Retrieval; Reproducibility of Results

Introduction

It has been an essential yet challenging task for clinicians to stay aprised on new knowledge from primary research papers while practicing in clinical settings [1]. Meta-analysis, the highest hierarchy of evidence regarding intervention questions [2], is defined as "the statistical synthesis of individual patient data from varying primary studies, leading to a quantitative summary of the pooled results" [3]. Meta-analyses assist clinical decision making, guide evidence-based medicine (EBM) and clinical practice, and serve as "the policy foundation for evidence-based practice guidelines, economic evaluations and future research agenda" [4].

The quality of the above-mentioned evidence is important. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) was developed for the reporting of systematic reviews and meta-analyses. PRISMA is a 27-item checklist and four-phase flow diagram that can examine whether the systematic reviews and meta-analyses are able to identify, appraise, and summarize research in an objective fashion so that clinicians would know whether the information is reliable for decision-making; however, most reported meta-analyses do not include such a quality assessment tool or do not report the method of assessment [5]. AMSTAR, an 11-item checklist, has been employed to assess the quality of meta-analysis and systematic review. Prior studies on quality assessments have identified that the Cochrane library was of a higher quality than others. Investigations of study selection bias and data extractions returned unclear results [6].

Systematic reviews require an unbiased and a reproducible search of data resources to identify as many relevant studies as possible. Reliability is the quality or state of being reliable, the extent to which an experiment, test, or measuring procedure yields the same results on repeated trials. In the field of academic research, reproducibility refers to that for the same research problem, independent research by other researchers can use the scheme provided by the authors to reproduce the experimental results [1]. PRISMA described Section Method "Search" as "Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated" and provided a guideline for researchers to examine the reproducibility of systematic reviews and meta-analyses [7]; however, researchers have conducted few meticulous studies on examining the reproducibility of meta-analyses.

This paper aims to examine the reproducibility of search strategy reported in meta-analyses. We chose cervical cancer, because providers can often detect it early, and sometimes prevent it entirely, by having regular Pap tests. When found early, cervical cancer is one of the most successfully treatable cancers. In addition, cervical cancer is the second most common cancer among females worldwide, with 80% of the cases occurring in sub-Saharan Africa, Central America, and South-Central Asia [8]. We aim to examine the reproducibility of search strategies reported by cervical-cancer related meta-analyses and reveal the opportunities and direction for clinical informaticians toward an enhanced rigor of meta-analyses.

Methods

First, we performed a systematic literature search in PubMed database to identify meta-analyses focusing on cervical cancer published from January 1st, 2013 to October 3rd, 2018. The search strategy utilized search terms as follows: (cervical cancer) AND (meta-analysis[PT] OR meta-analysis[tiab])

Titles and abstracts of the retrieved articles were screened manually and independently by two authors (FL and PY) using the eligibility criteria. The inclusion criteria were: 1) studies or systematic reviews with meta-analysis, data synthesis or quantitative overview; 2) studies focusing on cervical cancer. The exclusion criteria were: 1) comments or corrections for articles of meta-analysis; 2) narrative reviews or meta-analyses focusing on other cancers, which are different than cervical cancer, such as head and neck cancer. Figure 1 illustrates the overall strategy.

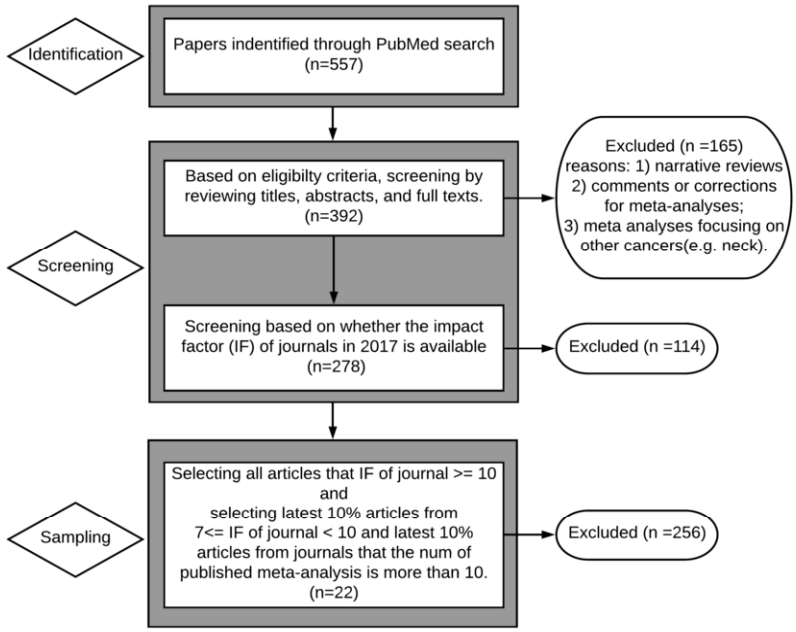

Figure 1- Flow Chart of Literature Search and Inclusion

Second, a Bibliographic Item Co-Occurrence Matrix Builder (BICOMB) analyzed the journal distribution of these articles [9]. The 2017 Journal Citation Report provided the impact factors (IF) of the journals. Next, we applied a stratified sampling strategy to the retrieved meta-analyses for further data extraction and evaluation: 1) all articles published in the journals with an IF higher than 10, 2) 10% of latest published articles in the journals with an IF from 7 to 10, and 3) 10% of latest published articles in the journals containing more than 10 articles, i.e. two gynecologic journals (*Gynecologic Oncology* and *Archives of Gynecology & Obstetrics*) and a comprehensive journal (*Plos One*).

Following the checklist of PRISMA, features of evaluation in this study were created, including journal name, publication year, electronic databases used, presence of full search strategy for all databases or at least one database, the number of retrieved articles before and after the removal of duplicates, and the number of included articles. Two authors (FL and PY) independently extracted the features from the full papers according to the checklist. Group discussions were held to resolve discrepancies involving additional authors when necessary. For each meta-analysis, we calculated the percentage of the number of included articles to the number of retrieved articles (before and after removal of duplicates).

Results

Search Results and Characteristics of Meta-Analyses

557 articles were retrieved from PubMed by applying the search strategy, among which 392 articles were included by applying the eligibility criteria. The 392 articles were published in a total of 157 journals, among which 123 (78.3%) journals, carrying 278 (70.9%) articles, possessed impact factors in the 2017 Journal Citation Report. A journal list with ranked IF in descending order and published in 2017 was created. Figure 2 illustrates the distribution of IF of journals and number of relevant meta-analyses on cervical cancer. The application of the stratified strategy resulted in 22 articles, shown in Table 1.

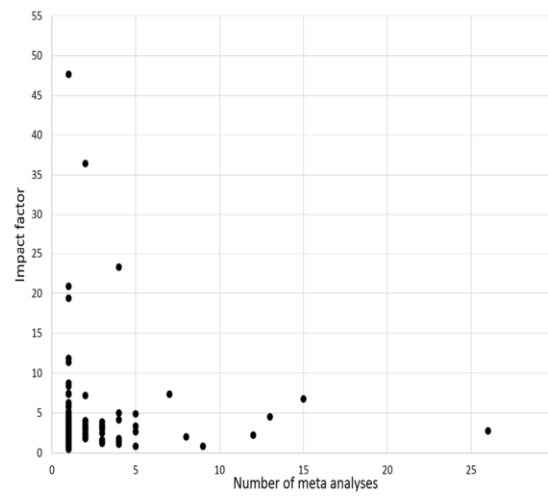

Figure 2- Distribution of Impact Factors of Journals and Number of Relevant Meta-Analyses on Cervical Cancer

Note: The journals (IF=2 to 7） contain more than 10 meta-analyses. Journals tend to publish meta-analyses on cervical cancer with IF < 10.

Notes: §: Search strategy 1 represents whether the full electronic search strategy for all databases is available. Search strategy 2 represents whether the full electronic search strategy for at least one database is available.

€: The # retrieved articles 1 is the number of retrieved articles before removal of duplicates, and 2 is that of those after removal of duplicates.

£: For % of included/retrieved articles, the first column represents the percentage of number of included articles to that of retrieved articles before removal of duplicates, and the second column represents the percentage of number of included articles to that of retrieved articles after removal of duplicates.

**: Y: available.; $: N: not available.; л: ?: not clear. ; £: The number in brackets is a rough estimate by the context.*

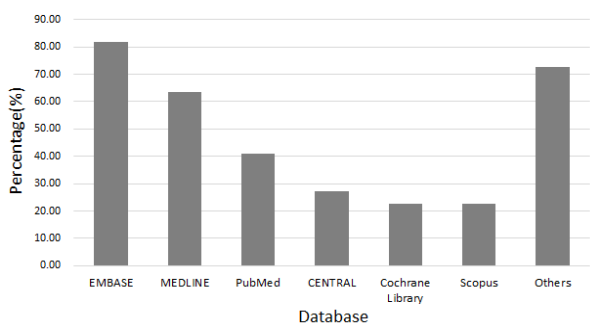

Figure 3- Literature Databases Searched in the Meta-Analyses

Notes: MEDLINE includes PubMed MEDLINE and OVID MEDLINE. Cochrane databases are part of Cochrane Library. Other resources include CINAHL, CNKI, ISI Web of Science, PsycINFO, Wanfang, CBM, Cochrane Database of Systematic Reviews, EBSCO, Google Scholar, ISI Proceedings, and PubMed/MEDLINE with a frequency ≤ 2.

Literature Databases Used in the Meta-Analyses

Seventeen literature databases (Involvement frequencies: Maximum = 9; Minimum = 2; Average = 4) were identified in the 22 meta-analyses. As illustrated in Figure 3, the top three databases involved in the meta-analyses were EMBASE (18 meta-analyses, 81.82%), MEDLINE (including PubMed MEDLINE and OVID MEDLINE, 14 meta-analyses, 63.64%), and PubMed (9 meta-analyses, 40.91%). Nine of 14 meta-analyses in which MEDLINE was searched (64.29%) did not specify the platform of MEDLINE .

Inclusion of One Full Search Strategy

Ten (45.45%) meta-analyses contained a full search strategy including any limits used for at least one database, among which eight (36.36%) meta-analyses reported the full search strategy for all databases. In the high impact journals (IF≥10), all meta-analyses presented a full search strategy for at least one database, while eight (80%) meta-analyses reported the full search strategy for all databases; however, among the low impact journals (IF<10), no meta-analyses presented a full search strategy even for at least one database.

Comparing the Number of Included and Retrieved Articles

The number of retrieved articles from each information resource was not always clearly included, shown in Table 1, resulting in the failures in determining whether or not the total amount of retrieved articles was subject to removal of duplicates. Twelve meta-analyses reported the number of retrieved articles before and after removal of duplicates and the number of included articles, among which the maximum number of retrieved articles after duplicate removal was 2,972, and its corresponding number of included articles was 62. Table 1 also presents the percentage of the number of included articles to the number of retrieved articles after duplicate removal. The percentage ranged from 1.49% to 16.03% (mean= 6.58%).

Discussion

Confusion on Literature Databases as Information Source

Based on the item regarding information sources in PRISMA 2009, it is necessary to describe all information sources (e.g., databases with dates of coverage and author contacts). Although we could provide information sources for the 22 meta-analyses we evaluated, choosing source information is frequently unclear due to the description of the names of databases and the relationship among databases. For example, PubMed and MEDLINE should not be used in the same meta-analysis, since MEDLINE is in fact a subset of PubMed. In addition, searching results may vary in different MEDLINE databases (e.g., PubMed, Ovid MEDLINE) [10]. More than one half of meta-analyses did not report the platform they used to search MEDLINE, which becomes a barrier in reproducing the results or repeating the search strategy.

The number of searched literature databases under the topic of cervical cancer varied between two and nine. The reasons of including multiple databases are extremely unclear and somewhat confusing. For example, databases like Google Scholar and ISI Proceedings are used in addition to specialized professional databases, such as PubMed and EMBASE. It is rarely reported how many additional hits were introduced by such an unclear inclusion of databases. These problems remain for future exploration, and further investigations should clarify the rules on use of databases in meta-analyses.

Poor Compliance on Inclusion of One Full Search Strategy

To establish a reasonable and detailed search strategy for each database and ensure the quality and reliability of meta-analysis, it is essential to enhance recall and precision of evidence. According to the PRISMA criteria, the search strategy should be repeatable for at least one database. Our findings indicate that only the strategies published in the high IF journals tend to be repeatable. It is necessary for meta-analysis to include at least one repeatable full search strategy for at least one database or for every database included in the search.

Lower Precision of Evidence Retrieval

Based on the data from 11 meta-analyses, we could obtain the ratio of the number of included articles to the number of retrieved articles after removal of duplicates, ranging from 1.49% to 16.03% (mean 6.58%). This percentage represents the precision of literature retrieval on meta-analyses. We found that authors usually developed a search strategy for higher recall so that the precision is much lower than general literature retrieval. The heavy workload of article screening may be subjective and prone to errors. This problem could be resolved by establishing a search strategy with clarified keyword limitations, which may reduce recall as a compromise. Therefore, systematic filters of potential eligible articles should be developed.

Lack of Reproducibility

The number of retrieved articles was not clearly presented for each information resource, which could be another barrier to repeat a meta-analysis. Table 1 shows that only three articles (13.64%) presented a full search strategy for all databases as well as the number of retrieved articles before and after removal of duplicates. The absence of full search strategy for all databases in large amounts of meta-analyses weakens the possibility of repeating them. Therefore, one full search strategy for at least one database in PRISMA is inadequate in meta-analysis. A full search strategy and number of article hits for each database should be a fundamental requirement of meta-analysis.

Recommendations

Based on the findings above, we suggest the following recommendations in order to make a meta-analysis repeatable at the literature retrieval stage. First, we propose to enhance the PRISMA criteria to present full electronic search strategies for all databases rather than for at least one. Researchers should strictly obey the item on presentation of detailed operable electronic search strategy according to PRISMA. Second, PRISMA should require that meta-analyses report the number of literature yielded from each database. Third, researchers who will participate in meta-analysis should be trained with the knowledge of information resource retrieval to control various problems that may arise from the literature search process and to ensure the repeatability of the results. In any case, reviewers and editors of journals should rigidly control the quality of literature retrieval for meta-analyses according to PRISMA.

Limitations and Future Work

Only 22 articles were included for the assessment on quality of literature search based upon a stratified sampling of 392 meta-analyses on cervical cancer. The limited sample size may have limited generalizability of the results. Nonetheless, the conclusion may be specific in cervical cancer and hold limited scalability to other gynecologic cancers. In the future, we will evaluate all the 392 meta-analyses by the AMSTAR checklist and perform a univariate and multivariate statistical analysis to investigate the factors influencing the quality of literature retrieval of meta-analyses.

Conclusions

The assessment of meta-analyses in regards to literature retrieval revealed poor performances in reporting quality of retrieval strategy and a low compliance of PRISMA. Overall, the reporting quality of literature retrieval in the meta-analysis on cervical cancer needs to be improved. Specifically, a clear justification is needed in describing the selected databases. PRISMA requires to include a complete search strategy toward reproducible results. The number of article hits retrieved from each and every database should be reported individually instead of a combined number which is a barrier for reproducibility of meta-analysis.

Abstract

This paper presents the extract-transform-and-load (ETL) process from the Electronic Patient Records (ePR) at the Heart Institute (InCor) to the OMOP Common Data Model (CDM) format. We describe the initial database characterization, relational source mappings, selection filters, data transformations and patient de-identification using the open-source OHDSI tools and SQL scripts. We evaluate the resulting InCor-CDM database by recreating the same patient cohort from a previous reference study (over the original data source) and comparing the cohorts' descriptive statistics and inclusion reports. The results exhibit that up to 91% of the reference patients were retrieved by our method from the ePR through InCor-CDM, with AUC=0.938. The results indicate that the method that we employed was able to produce a new database that was both consistent with the original data and in accordance to the OMOP CDM standard.

Keywords:

Medical Informatics; Health Information Exchange; Data Curation

Introduction

In the last decades, the field of Informatics has unveiled the, so-called, Big Data phenomenon; an intense increase of data gathering, exchanging and storage in several human activities. This phenomenon is outlined by the so called five Vs: velocity, volume, variety, veracity and value of data; posed as the big challenges for data analysis and processing [1]. Such characteristics are also common in Medical and Health Information Systems, whose databases have grown into huge amounts of patient information and health-related activities, in diverse formats, always online, and easily accessible from a mobile screen. If properly interconnected and treated, these systems offer interesting data sources for evidence-based research, such as Precision Healthcare, Population Health, Clinical Research, and more. [11]

However, this data exchange is often a significant challenge. Most of the Electronic Patient Record (ePR) systems were not explicitly designed for research; rather, they are organized by standards and structures which are local to the institutions they primarily serve, e.g. hospital facilities, clinics, pharmacies, health insurance companies, etc. Thus, interchange methods, protocols and architectures were designed to cope with this challenge, such as the HL7 standards [12] and the OpenEHR platform [13]. These approaches mediate the communication of near-line and online transaction processing (OLTP) systems, specifying standard data elements and transformations from their internal data to a common messaging format. Furthermore, data analysis follows an approach akin to online analytical processing (OLAP), using denormalized, coalesced and preprocessed data in a standard common database format.

OHDSI and the Common Data Model

In this context, the Observational Health Data Sciences and Informatics (OHDSI – www.ohdsi.org) initiative grew out of the Observational Medical Outcomes Partnership (OMOP) developing a mature data standardization model, the OMOP Common Data Model (CDM) [6]. Having a ready-to-use database in a standard common model such as the OMOP CDM simplifies the exchange and integration of standardized methods, applications, information and tools between clinical researchers; a critical feature for distributed research networks using patient-centric clinical databases. [7]

The CDM is a strong information model; its conceptual elements and their relationships are explicitly specified in a formal language, and every piece of information is connected to a standard term from SNOMED-CT. The CDM's Standard Clinical Tables include Person, Visits, Observations, Conditions, Death, Procedure occurrences, Drug exposures, Measurements and more detailed information such as Drug ingredients, and Condition modifiers. OHDSI also provides open-source CDM applications for visualization and statistical analysis of patient-exposure-outcome cohorts. [10]

The InCor data integration challenges

The Heart Institute (InCor) of São Paulo, Brazil, is one of the six institutes of the Clinics Hospital complex, University of São Paulo Medical School. In the last two decades, InCor has increased its commitment in integrating all the relevant information of its patients, successfully developing an ePR named SI³. The first version of SI was deployed in year 2000; currently, it stores the clinical history, examinations, procedures, surgeries, notes, laboratory tests, medication, bills, and more for 1.3 million patients. Since then, the system has continuously evolved, overcoming several challenges related to the exchange of information among different healthcare institutions and remote installations. Furuie et al., describe details of the system architecture [8], while a number of studies involved cohort selection based on information collected by the SI³ system [3-5].

However, the workload involved in extracting the relevant patient information from SI³ has motivated the adoption of new strategies. Recently, we started the mapping from the SI³ data model to a standard data model that can simplify the observational retrospective studies related to Clinical Research. In this paper, we present the steps related to the mapping between SI³ and the CDM data models to prepare a new standardized database, named InCor-CDM, that can be used with

the OHDSI toolset and a number of visual analytics tools. We measure the quality of the resulting InCor-CDM database using precision and recall statistics, when compared to the cohort generated by a previous study (gold standard).

Methods

Environment preparation

We prepared the InCor-CDM database environment by installing a PostgreSQL 10 DBMS, Java 10 JDK and Docker-compose in a Linux workstation. The database setup includes: (a) creating the required database users; (b) creating the OMOP CDM tables with the CommonDataModel/PostgreSQL scripts; and (c) importing the standard OMOP vocabularies from athena.ohdsi.org. All the OHDSI sources are available at github.org/OHDSI. Next, we installed the Achilles and Broadsea repositories required for the OHDSI web applications, configured the addresses and JDBC URLs and started their respective docker containers.

Database characterization

The InCor SI³ database is stored in an Oracle 12c instance, accessed with the Oracle JDBC connector and DBeaver SQL client. The first step to manage the database was sampling its tables and columns with the OHDSI's WhiteRabbit software. This application generates a spreadsheet with the most frequent values of each selected column, so we can inspect them and make decisions about which columns to ignore, especially those with irrelevant or missing values. Then, we use RabbitInAHat to parse the output of WhiteRabbit and draw relational data-flow diagrams for documentation.

Some namespaces in SI³ were ported from non-relational or older systems; such namespaces had no associated documentation, comments, constraints or foreign keys. For this reason, the database metadata had to be converted to a searchable JSON format with table and column names, types, comments, constraints and foreign keys. The column names were tokenized according to the naming scheme of the institution (e.g. abbreviations separated by underscore) and matched to similar columns in other tables; the goal was to find implicit relationships where the foreign keys were missing. Some attribute domains, such as internal record status codes, event sequence and timing diagrams, were documented from interviews with the support staff of InCor.

Patient de-identification

For de-identification purposes, personal information mapped to the CDM was limited to a minimum. Any key with a path to a patient primary key (and the PK itself) was **pseudonymized** [14], i.e., direct identification information such as citizenship document, phones numbers, addresses and names are not ported to the CDM, and the record primary key is exchanged to a *new id* (pseudonym), which is a random number drawn from an uniform distribution in the range 1×10^{10} and 9×10^{15} using Oracle's DBMS_RANDOM functions, addressing collisions with repeated sampling. This range was selected not to conflict with OMOP's standard concept ids (0 up to 2×10^{9} are reserved) and to be within the limits of JSON numbers (53-bit precision). InCor holds the mapping from the new ids to the original keys in a private table; the mapping is to be used for notifying the patient, or her/his physician, in case the result of a study can improve a patient's condition.

Numerical variables were truncated in order to satisfy a baseline level of **k-anonymity** [15], i.e., guaranteeing that any patient variable value have at least *k* patients with the same information, so no patient is uniquely identifiable. For example, event dates were truncated to yearly, monthly, daily or hourly precision where original precision were not needed. Records with spurious attributes (e.g., dates in the future, outside any visit, invalid range, null required field, missing keys) were discarded. Also, we only loaded data from patients born before 2010 (aged 18+), with at least one valid visit.

si3.pac_paciente

paci_id	tp_sexo	...
01721	M	...
01722	M	...
01723	F	...

keys

table	src_id	new_id
pac_paciente	01721	7369111123
pac_paciente	01722	1257321234
pac_paciente	01723	3038618654

gender_map

src	id
F	8532
M	8507

omop.person

person_id	gender_concept_id	...
7369111123	8507	...
1257321234	8507	...
3038618654	8532	...

Figure 1– Example: gender mapping from SI³ to the CDM.

Figure 1 shows sample data to illustrate this process. Each column from CDM person table (e.g., gender_concept_id) is extracted from the *source* table and column (e.g., pac_paciente. tp_sexo), and transformed with the appropriate domain map (e.g., value 'F' used in SI³ for female gender is mapped to CDM concept 8532). The *keys* and *gender_map* tables are populated beforehand. The standard CDM concept ids were searched in OHDSI's Athena – a web-based CDM vocabulary explorer. Then, observe the following query, which loads data from the SI³ PAC_PACIENTE table into the InCor-CDM omop.person table with remapped keys and concepts:

```
INSERT INTO omop.person
SELECT K.new_id          AS person_id,
       EXTRACT(YEAR FROM P.dt_nasc)
                         AS year_of_birth,
       COALESCE(G.id, 0) AS gender_concept_id
FROM si3.pac_paciente P
JOIN keys K ON  K.table='pac_paciente'
           AND K.src_id=P.paci_id
LEFT JOIN gender_map G ON P.tp_sexo=G.src;
```

This query operates on the table samples in Figure 1, where it is assumed that the *keys* table holds the patient's random new_id, and that the *gender_map* table is a domain map table defined as (src char(1); id integer) corresponding to values of (tp_sexo, gender_concept_id). Unmapped values receive code 0, meaning "unknown concept" in the standard CDM vocabulary. Related tables were joined to the patient PK as usual, with their PK also remapped by keys.new_id.

Coding translation

InCor SI³ uses the ICD 10 for diagnosis, a set of Brazilian vocabularies for coding clinical conditions, drugs, and procedures (TUSS is used by the Brazilian Health Care System for general terms and Brasindice for drugs – datasus.gov.br) and an internal coding system for generic billable items. Internal codes in use at InCor were inserted as new Concepts in the CDM (with ids mapped between 3×10^{9} and 9×10^{9}) under the "InCor" vocabulary, with Concept Relationships to standard concepts whenever this information was available in SI³. Initially, the records are inserted in the InCor-CDM with the original source codes, then the Concept Relationships from local to international codes are used to update the local InCor-CDM references to OMOP standardized terminologies, such as the SNOMED-CT,

RxNorm, and LOINC [6], while the preserving the original source code stored in the patient record.

Quality assessment

After loading all the CDM tables, we execute the Achilles analysis, which will report data quality issues as errors, warnings or notifications. It will also preprocess the demographic characterization of the database for the visualizations and reports; after that, we start the Atlas WebAPI and front-end servers. Atlas offers both a RESTful API and a graphical web interface to schedule the execution of OHDSI methods, automatically generating the queries on a properly built and configured CDM database.

The most relevant errors initially found were related to: (a) the referential integrity, e.g., events without associated visit or events without a valid person_id, which were discarded; (b) lack of condition_eras, drug_eras and observation_periods, which were imputed from the ePR records by collapsing all the events of a patient not apart for more than a year into a single era – in the CDM standard, an "event" era refers to a time period of interest where "events" are recorded in the ePR; (c) events with invalid date, e.g. a condition_occurrence with start date in a future date; (d) too many patients without a diagnostic or prescription; InCor-CDM keeps such records because they can be used in the condition or drug_exposure dashboards, regardless of previous diagnosis.

Statistical evaluation

After initial corrections, we evaluate the quality of InCor-CDM by using software OHDSI's Atlas to recreate a previous CVD patient cohort observed in a reference study that was executed over the InCor SI³ database by Abrahao et al. [9]. That reference study prepared a clean de-identified database named Pauá, based on a 2016 snapshot of SI³ records of patients, admissions, discharges, diagnoses, surgeries, PCI, medications, and laboratory tests. Within the Pauá database, Abrahao et al., verified the effect of statins on the survival rate of patients diagnosed with cardiovascular diseases. Our study will evaluate the InCor-CDM quality by defining a cohort with the same criteria and by verifying how many patients (with the same private InCor identifiers) were retrieved by each criteria given that reference study.

Results

In this section we evaluate InCor-CDM quality by selecting the same DCV cohort of a previous study in the Pauá database [9], by using Atlas over the InCor-CDM database. Our evaluation computes the Area Under the ROC Curve (AUC) based on the results of 12 executions of the DCV cohort at various settings. We compute predictive statistics for each cohort execution, using Pauá as a gold standard. The resulting AUC ranges from 0.5 (no different than random sampling) to 1.0 (reproduces exactly the same result as the gold standard).

Table 1– Databases cardinality (thousands of records).

Domain	SI³2016	Pauá	SI³2018	CDM
Person	1,116	323	1,346	946
Visit Occurrence	6,427	5,686	7,499	7,305
Condition Occur.	1,205	1,007	1,361	1,324
Procedure Occur.	45,024	144	53,945	51,479
Drug Exposure	83,283	2,775	100,052	38,962
Measurement	22,025	20,528	31,095	30,177
Death	17	21	18	18

In Table 1, we present the cardinality of the InCor-CDM in comparison to the SI³ and Pauá database. Note that the Procedure and Drug domains in the Pauá database have substantially less records; this is because they are restricted to surgeries and particular classes of drugs, and because Pauá only uses patients with at least one admission and diagnosis. Additionally, InCor-CDM is based on a more recent snapshot, named SI³2018 in the aforementioned table.

Cohort definition

To replicate the Pauá study, we created a cohort over the InCor-CDM database with the criteria below. Each list item directly corresponds to a HTML input field in the Atlas **cohort definition form**. These criteria are translated to SQL queries over our database in the CDM format (InCor-CDM).

- *Initial Event Cohort*: People having any of a **visit** occurrence of **Outpatient concept set** (with concept_id 9202, Outpatient Visit);
- *Additional Qualifying Inclusion Criteria*:
  - *Condition occurrence criteria*: with **at least 1** of **any condition**;
  - *Demographic criteria*: **age** greater than or equal **23** (in the censor window), matching the patients over 18 years old at the Pauá study start (1999);
  - *Demographic criteria*: with a **gender** of **MALE** (8507) or **FEMALE** (8532);
  - *Condition occurrence criteria*: of **CardioVascular Disease** (a concept set of concept ids from ICD-10 categories I20 to I25, I64 to I70 and G45, including descendants and mapped), with occurrence start between **2003-01-01** and **2013-12-31**, where event starts between **All** days before and **30** days after index end date (meaning the diagnosis was recorded around the time of the initial outpatient visit);
  - *Visit occurrence criteria*: with **at least 1** of **Outpatient concept set**, where event starts between **30** after and **All** days after index end date (a subsequent visit recording the outcome);
  - *Limit qualifying cohort to the* **earliest** *event*;
- *Era collapse gap size*: **1 day**;
- *Cohort censor window*: starting **2003-01-01** and ending **2013-12-31**.

After verifying the Concept Sets to have the correct concept ids, we generated the cohort on the InCor-CDM database and verified the cohort attrition report (the number of patients remaining in the selection after each filter) in Table 2:

Table 2– InCor-CDM CVD cohort attrition report in Atlas.

Criteria	n	%	Visualization
Initial	778,015	100.00	
a) Dx	351,205	45.14	
b) 18+	321,827	41.37	
c) M/F	303,847	39.05	
d) CVD	45,710	5.88	
e) 2nd-V	39,910	5.13	
f) People	39,498		

Table 2 summarizes the cohort definition criteria, where each abbreviation mean: (a) **Dx**: has a valid condition occurrence (diagnosis); (b) **18+**: over 18 years old; (c) **M/F**: Male or Female gender; (d) **CVD**: has any occurrence of ICD-10 I20 to I25, I64 to I70 or G45; (e) **2nd-V**: has a second outpatient visit occurrence more than 30 days after the index event (the initial visit); (f) **People**: lists how many people actually matched the events, because some patients have more than one episode. The baseline results achieved by the InCor-CDM CVD cohort indicate that 39,498 patients satisfy the criteria.

Table 3– Pauá reference CVD cohort attrition report.

Criteria	n	%	Visualization
Initial	313,894	100.00	
Dx	313,894	100.00	
18+	282,677	90.00	
M/F	263,339	83.87	
CVD	56,799	18.06	
2nd-V	27,698	8.80	
People	27,698		

In comparison, Table 3 displays an attrition report for the reference study (Pauá). The visualization was drawn with Python and GNU Gimp because Pauá's schema is not based on the CDM standard, and thus could not be used in Atlas. The reference cohort selected with the same criteria in the Pauá database has 27,698 patients (30% less than our first result), indicating the need of further refinement.

Initial Evaluation

All subject_ids in the cohort defined in Atlas were compared to the set of patient ids in the Pauá cohort. This comparison was executed by computing confusion matrices against the Pauá cohort result as a gold standard, then the derived scores: true and false positive ratios (TPR/FPR), positive and negative predictive power (PPV/NPV), accuracy (ACC) and F1-score. The confusion matrix the cohort #1 is given in Table 7, and derived scores make the first row of Table 8.

Table 7– Confusion matrix for cohort #1 (in Table 2).

InCor-CDM \ Pauá	P	N	Total
P	25,423	12,290	37,713
N	2,651	282,887	285,538
Total	28,074	295,177	323,251

Parameter refinement

Therefore, we noted cohort accuracy variations by creating additional cohorts with slightly adjusted parameters for the CVD criteria. Table 4 displays the attrition reports with increased periods for the qualifying criteria of CVD occurrence start date after index end date. Table 5 displays the attrition reports with increased periods for the qualifying criteria of Cardiopathy occurrence start date. We observe that increasing the collapse gap size to 7 and 14 days had no substantial effect on the results (Table 4).

Table 4– Varying condition start after index event (days).

Criteria \ days	7	14	21	30
Initial		778,015		
Dx, 18+, M/F		303,847		
CVD	44,967	45,255	45,484	45,710
People	39,055	39,203	39,342	39,498

Table 5– Varying condition start periods (years).

Criteria \ days	2003-2013	2000-2013	2000-2016
Initial		778,015	
Dx, 18+, M/F		303,847	
CVD	45,710	49,942	63,656
People	39,498	43,293	54,126

Table 6– Varying 2nd visit event start after index (days).

Criteria \ days	All	365	180	90
Initial		778,015		
Dx, 18+, M/F		303,847		
CVD	45,710	44,228	43,950	43,667
People	39,498	35,457	32,767	29,414

Then we evaluated all the patients selected in each cohort (from Tables 4, 5 and 6) by comparing them to the reference Pauá study, using the private Keys table to map the CDM person_ids to the SI³ patient ids (confidential to the institution), whose results are presented in Table 8. It should be noted that Pauá had an update in October 2016, after the reference study was published, and so we re-executed the query for its patient cohort, resulting in P=28,074 patients selected in the cohort (1.4% increase) and overall total P+N=323,251 patients included (3.0% increase).

Table 8– Predictive scores for each cohort.

#	TPR	FPR	PPV	NPV	ACC	F1
1	.905	.041	.674	**.990**	.953	.772
2	.901	.040	.678	**.990**	.954	.774
3	.903	.040	.677	**.990**	.954	.774
4	.904	.041	.676	**.990**	.954	.773
5	.905	.041	.674	**.990**	.953	.772
6	**.907**	.052	.623	**.990**	.944	.738
7	**.907**	.052	.622	**.990**	.944	.738
8	**.907**	.052	.620	**.990**	.943	.736
9	.889	.040	.680	**.990**	.954	.775
10	.877	.031	.727	.988	**.960**	**.795**
11	.829	.027	.743	.983	**.960**	.784
12	.754	**.023**	**.752**	.976	.957	.753

Evaluation of the ROC curve

We complete the evaluation by plotting the ROC curve from the predictive scores in Table 8. Only the patients existing in the Pauá database were used, i.e., only 37,713 patients of those retrieved in the cohort #1 also existed in the Pauá database. The highest scores of each column are highlighted in bold, e.g., cohort #10 exhibited the highest F1-score.

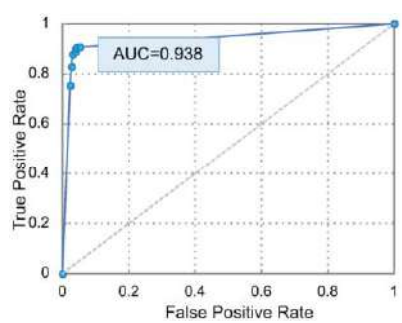

Figure 2– Empirical ROC curve for Table 8.

In this section we presented the results of the cohorts selected with Atlas from the InCor-CDM database. We also presented the effect of tweaking cohort parameters in the quality of the results (Table 8), which exhibited up to 80% F1-score, 75% Precision (PPV) and 91% Recall (TPR) at different settings. Figure 2 summarizes our results in an empirical ROC curve, exhibiting 0.938 of area under curve (AUC).

Discussion

The resulting InCor-CDM exhibits high agreement with the previous gold standard study [9]. This means that it is possible to estimate the same population-level effects (e.g. different medications) in both databases. InCor-CDM additionally benefits from the quality analyses implemented in the OHDSI Achilles tool, which warns about inconsistencies and errors found in the transformed data, and can be used for more advanced analysis in comparison with external CDM-based databases. For future work, we envision the comparison of patient cohorts between InCor-CDM and external CDM-based databases from other OHDSI work groups, further studying data quality, subpopulation characteristics between different institutes and evaluating risk scores for InCor patients.

Conclusions

We presented details of the migration process of a huge clinical database, the InCor's SI^3, to the OMOP CDM standard, an international format aimed at improving research in computer-aided medical systems. We presented the method used to extract, transform and load data between the databases commenting on the challenges regarding models, formats, terminology, and tools. We evaluated the quality of the resulting database, named InCor-CDM, by comparing cohorts obtained with the software OHDSI Atlas. We considered a previous cohort selection study used as ground truth; for a systematic comparison, we computed several information retrieval statistics and a ROC curve. The cohorts defined in Atlas exhibited from 62% to 75% precision, 75% to 91% of recall, 74% to 80% F1-score, and 0.938 of area under the ROC curve (AUC). The results indicate that the method that we employed was able to produce a new database that was both consistent with the original data and in accordance to the OMOP standard. The new database shall support a wide range of new research initiatives within the Heart Institute.

Abstract

Researchers have studied many models for predicting the risk of readmission for heart failure over the last decade. Most models have used a parametric statistical approach while a few have ventured into using machine learning methods such as statistical natural language processing. We created three predictive models by combining these two techniques for the cohort of 1,629 patients from six hosptials using structured data along with their 136,963 clinical notes till their index admission, stored in the EMR system over five years. The AUCs for structured and combined models were very close (0.6494 and 0.6447) and that for the unstructured model was 0.5219. The clinical impact of the models using decision curve analysis showed that, at a threshold predicted probability of 0.20, the combined model offered 15%, 30%, and 70% net benefit over its individual counterparts, treat-all, and treat-none strategy respectively.

Keywords:

Heart Failure; Machine Learning; Electronic Health Records

Introduction

The Affordable Care Act of 2010 in the United States mandated penalties for health organizations with high readmission rates in an effort to improve quality of care and patient outcomes. The Centers for Medicare and Medicaid Services (CMS) implemented the law via the Readmissions Reduction Program (HRRP) [10]. This program has survived three repeal efforts in the past 18 months, and, in fact, has continued to improve its risk assessment strategies for readmissions. The risk formula now looks at readmission rates for six major diseases (heart failure, elective hip/knee arthroplasty, pneumonia, chronic obstructive pulmonary disease, myocardial infraction, and coronary artery bypass graft) for stratified hospital comparisons and uses it for prospective payments to hospitals for Medicare and Medicaid patients.

This change has launched the interest and development of risk prediction models for patient readmissions to hospitals. Availability of data in Electronic Health Records (EHR) systems has pushed this development further. Many variations of models for predicting readmissions have been developed, particularly for heart failure, in the last few years [8]. Heart failure (HF) epidemiology highlights this interest: HF affects 6.6 million adults in the United States alone and 550,000 new cases are reported annually [3]. It is the most frequent and expensive disease category for 30 day readmissions [2]. The chronicity of HF disease is further marked by repeated hospitalizations and consumes 70% of total cost related to the disease [4]. Moreover, as a part of the American Heart Association's Policy Statement on forecasting the future of cardiovascular diseases in the United States, Heidenreich et al. [5] provide projections for the 2010 to 2030 timeframe for HF: an increase of 215% in direct costs, 80% in indirect costs, and 25% in prevalence respectively.

A closer examination of HF predictive models for readmission reveals their specific characteristics: mortality and readmission appear to be influenced by different predictors and hence many models have preferred to treat them as independent outcomes. Many recent studies have used a 30-day timeframe for modeling readmission risk in line with the CMS lead, whereas older studies have used a somewhat variable timeframe ranging from seven days to one year [8]. The 30-day timeframe appears to be a strong representative of readmissions for many diseases, as a similar readmission pattern arises for different diseases based on time-to-event analyses [6]. Furthermore, most models have considered all-cause readmission to encourage hospitals to implement intervention programs to improve overall care—such as better discharge coordination, medication reconciliation, and post-discharge follow-up—instead of using a narrow set of condition-specific solutions. In terms of data sources used for predictor selection, recent models prefer to use EHR systems over registry or claims-based datasets [8].

Some predictive models [7] have used parametric algorithms derived mostly from generalized linear methods bolstered with modern strategies, such as variable class weighting, cross-validation, and regularization. These models emphasize the importance of interpretability; however, they require significant construction time especially with larger predictor sets and their interactions. Furthermore, they asymptotically become numerically unstable and even fail to build due to combinatorial explosion during variable selection process. Meanwhile, other predictive models [9] have deployed non-parametric methods mostly using machine learning techniques with large datasets comprising many predictors. This class of models focuses more on predictive accuracy at the cost of sensitivity to the configuration parameters of the underlying algorithms as well as to the features of datasets. Howerver, combining and comparing both the approaches with the same underlying patient population remains unexplored.

In this study, we built three predictive models: one based on the parametric approach using structured predictors readily available in the EHR system; the second based on a non-parametric approach using Natural Language Processing (NLP) on unstructurred data representing patient notes in the EHR system; and a third that combined predictors from both the approaches. We further compared discriminative power,

calibration, and usefulness of each model in clinical decision making.

Methods

Patient Population and Data Extraction

We used EHR data at six hospitals from the Veterans Health Administration system to derive and validate the predictive models for this observational retrospective cross-sectional study. We selected all the hospitals from one network of hospitals from the western region of the United States for this study. The datasets from all hospitals under the health system are extracted and loaded into a central repository on a regular basis and we leveraged this infrastructure for the data collection for our study.

Based on our review of past literature [8] describing the predictive models built for estimating risk of readmission for heart failure, we used variables from clinical, administrative, and psychosocial categories that are routinely collected during episodes of care. Application of the same data policy framework imposed by the EHR system helped us to develop common logic and programs for data extraction. Datasets for five consecutive calendar years from 2011 to 2015 were extracted using International Classification of Diseases version 9 – Clinical Modification (ICD-9-CM) codes for heart failure as a principal discharge diagnosis. We used 2011 – 2014 data for derivation cohort and 2015 data for validation cohort formations. This setup provided an external temporal validation for the models. Since the validation cohort consisted of patients from different regions, the setup also provided an external geographic validation for the models.

Primary Outcome

We adhered to the commonly adopted definition of any-cause 30-day readmission in the literature [6], which excludes hospitalizations with a length of stay less than one day and any elective hospitalizations. If the patient encountered multiple readmissions within the 30-day timeframe from the discharge date of the index admission, only the last readmission episode was considered so that the latest health status for the patient is used for predicting the risk of future readmission. This setup provided us with the sample of patients that was blinded for outcome by programming for the above rules. The sample was also statistically independent and mutually exclusive across the two classes of admission groups of non-readmitted and readmitted patients.

Predictors

Structured data predictors were broadly classified into clinical, administrative, and psychosocial categories based on prior literature survey and expert clinical consultation [8] and are shown in Table 1. All the variables were collected either on or before the discharge date but closest to it depending on the data availability.

Unstructured data for the patients in the cohort were obtained from clinical notes—such as history and physician note at admission, progress notes, social worker notes, and discharge summary—till the date of discharge for the index admission. Since the bulk extraction of the structured and unstructured data from the EHR system was carried for the study cohort, predictor assessment was blinded to the other predictor and outcome variables.

Table 1 – Structured Dataset

Clinical Set	Predictor Name
Labs & Vitals	Sodium
	Potassium
	Blood Urea Nitrogen

Statistical Analysis

The extraction of data from the EHR system yielded a sample size of 1629 admissions with 114 variables with dummy variable formats for categorical variables. We did not have any missing values for the dependent variable; a few independent variables such as BNP and blood glucose had up to 5% missing values. We used multiple imputation by chained equations resampled over five imputed datasets for the missing values assuming missingness at random. We created separate dummy variables for missing values with higher rate of missingness for the categorical variables. This strategy allowed us to use all the available records in the analysis. Continuous variables were also examined for nonlinear effects and transformations were carried wherever necessary.

We extracted 54 different types of clinical notes totaling 136,963 (102,055 for derivation cohort and 34,908 for validaton cohort) for our study and could not find any notes for 10 patients for the timeframe of interest. We eliminated these patients from the structured dataset for fair comparison of models using structured and unstructured datasets. Our final structured dataset thus contained 1,619 total patients (1,279 for derivation cohort and 340 for validation cohort). The corpus datasets for derivation and validation cohorts were created separately and processed for tokenization and stop words. They were then treated with term frequency-inverse document frequency statistic for vectorization with bigram range and term frequency thresholds of 0.01 and 0.80 for minimum and maximum cutoff respectively. We linked the structured and unstructured datasets on patients and their admission episodes for creating a combined dataset.

We fitted all three models using logistic regression with their respective feature sets to predict the outcome of 30-day readmission and reported their results for the validation datasets. We did not apply any special variable selection methods in this study. All confidence intervals were calculated at 95% level using 2,000 stratified bootstrap replicates. We further calculated and plotted the discriminative power using c-statistic, precision, recall, and model calibration for each model along with the top 10 words most predictive of readmission in the unstructured data. We also carried out decision curve analysis using the three models to understand their relative utilities with respect to treat-none and treat-all strategies. We used Microsoft SQL Server Version 12 Release 2, R version 3.0.2 (The R Foundation for Statistical Computing Platform), and Python version 3.6.4 for data extraction and statistical analyses. This Pilot Project under Quality Improvement initiatives was exempted from the review of full committee Institutional Review Board.

Results

Our validation cohort's empirical readmission rate was 32.7% excluding repeated patient readmissions. We created and fitted three separate models with structured, unstructured, and the combined datasets. Figure 1(A) shows precision and recall plotted on the left and right Y-axis respectively against percentage of population on the X-axis for the models. The Area-Under-Curve (AUC) or c-statistic was calculated for the models and plotted as Receiver Operating Characteristic (ROC) curves as shown in Figure 2(A). The AUC values with 95% confidence interval were: structured model: 0.6494 [0.5885-0.7103]; unstructured model: 0.5219 [0.5157-0.5281]; combined model: 0.6447 [0.6386-0.6508].

Calibrations with ideal, apparent, and bias-corrected fits with 300 bootstrap repetitions for the models were carried out and plotted as actual probabilities on Y-axis against model-predicted probabilities on X-axis as shown in Figure 1(B). The word sets with the top 10 words that were most predictive of readmission versus non-readmission using notes are shown in Figure 2(B). The Feature Importance Plot for the combined dataset is shown in Figure 2(C).

Finally, we carried out decision curve analysis (DCA) [11] for the models to understand net benefit for each model at various thresholds of predicted probabilities. It is shown in Figure 2(D).

Discussion

As shown in Figure 1(A), precision and recall seem to have benefited from combining the structured and unstructured datasets especially when examining the 20% of the population with the highest precision: the combined dataset precision climbed to 70% from 45-50% precision of the individual datasets. Similarly, the combined dataset recall climbed to 40% from 20-30% recall of the individual datasets. Precision measures the accuracy of the model when it predicts an index admission as likely to have a readmission. Recall measures the ability of the model to find index admissions that have readmissions. As there is a tradeoff between these two measures, they can be varied and plotted for various thresholds of population as well.

As shown in Figure 2(A), the ROC curves represent the discriminative ability of the models by plotting the ratio of true positives to predicted positives on Y-axis against the ratio of true negatives to predicted negatives on X-axis. The curve that represents the maximum pull in the northwest direction of the graph signifies the best discrimination, while the diagonal axis represents random prediction. The unstructured data model had poor discrimination in our study, whereas the structured data model and combined model had similar discrimination with the combined model showing slightly better performance for non-readmitted patients. Our empirical datasets represented high class-imbalance (~30% readmitted versus 70% non-readmitted patients) and hence precision-recall curves might be better measures of model performance in the absence of tuning performed on the class-weight parameter.

Calibration plot scheme using bootstrapping method works as an efficient bias estimator since the difference between fits of the whole sample and a new sample is estimated by the difference between fits of the whole sample and a sample with replacement. The plots in Figure 1(B) show presence of over-fitting for predicted probabilities over 0.35 for all the models. The ideal fits with no over-fitting and no over-estimation are shown as the dotted diagonal axis at 45^{o} in the plots. All the models also show under-fitting below 0.35 of predicted probabilities. Moreover, all the models are under-estimated with positive Y-axis intercepts indicating need for better functional form for the models.

When we identified the top 10 words for both readmitted and non-readmitted patients as shown in Figure 2(B), there was only one dyad (*pulmonary discomfort*) common to both the classes. However, closer examination of the word sets reveals that some other words, even though written differently, are semantically equivalent: for example, word pairs such as *gcs commands* (Glasgow Command Scale) and *respond meaningfully*; *regarding mrsa* (Methicillin-Resistant Staphylococcus Aureus) and *mrsa status*. Such semantically

Figure 2 – Decision Analysis for Models

similar words need to be clustered together to further guide supervised learning. Given a large set of clinical documents for each patient episode, it would also be useful to further analyze specific documents with targeted word selections that have greater impact on readmission prediction.

The combined dataset has over 4900 predictors and hence we showed a plot of relative importance of the top 10 predictors in the model in Figure 2(C). Laboratory tests such as creatinine and hematocrit from the clinical set of structured predictors along with some administrative predictors such as patient hospital boarding characteristics and office visits status have strong influence on the readmission risk in our model. These predictors seem to be in line with the ones reported by the previous studies. Particularly, no predictor from the unstructured dataset made up to the top 10 list of the influencers of the patient readmission in the combined set.

Note that logistic regression is used as a baseline for the model development in all three. This is merely for convenience during methods development in this pilot study. The demonstrated methods could be used with any other parametric or machine learning models or the combination of both for structured and NLP datasets.

DCA is a method of evaluating usefulness of predictive models in clinical settings. It combines strengths of traditional biostatistical methods and decision-analytic methods while eliminating their limitations. For example, AUC for the model does not convey how high of an AUC is needed in order to deploy it in clinical practice. On the other hand, traditional decision analysis involves complex mathematics not suitable for continuous outcomes that is typical of predictive models. DCA is based on the relative harms caused by false positives and false negatives and is expressed as a threshold for

probabilities predicted by the models. As seen in Figure 2(D), the use of any predictive model provides positive standardized net benefit over both *treat none* (X-axis) and *treat all* (lowest curve cutting X-axis at risk threshold of 0.30) strategies. Either structured or unstructured data model appears to provide about the same net benefit of 55% over *treat none* and 15% over *treat all* strategies at risk threshold of 0.20. Moreover, the combined model (topmost curve in Figure 2(D)) shows consistently higher standardized net benefit over the other two models (15%) as well as *treat all* (30%) and *treat none* (70%) strategies.

Clinical Impact and Implications for Practice

We have combined and compared two seemingly different techniques for predicting 30-day readmissions for heart failure using most commonly available data in the EHR systems. Methods presented here pave the foundation for combining automated harvesting of predictors from unstructured data with carefully selected predictors from structured dataset. We have further demonstrated the ability to select the most useful model that has the greatest clinical impact. Decision analysis in this study has shown that the use of *some* predictive model is better than both using *no* model at all and treating *all* the admitted patients with the same readmission reduction program interventions. This appears to be valid despite having average descriminative capabilities (AUC = 0.6447) of the predictive model. Discharging physicians and case managers could make decisions for post-discharge care with their patients by identifying risks and benefits using such models. Even though the model development and associated activities of data processing pipeline might seem difficult to implement in practice, application of the selected risk threshold and outcome prediction could be captured in a simple mobile application for the clinicians in future implementations.

Limitations

This study represents a pilot project that brings together techniques for combining structured and unstructured data into a model for predicting readmissions for heart failure. It has used data from all the clinical notes for the patients till the index admission. Targeted use of notes with specific topic and word importance might help in better performing NLP system and remains unexplored in this study. Readmissions outside the index hosptials, even though deemed low, are not considered in this study. Finally, the study has applied external temporal validation but external geographical validation will further evaluate generalizability of this approach.

Conclusions

We built separate predictive models with the same EHR system's structured and unstructured data with two different modeling techniques. We compared the performance metrics for the two models and their combination. Our analysis showed that there was some benefit in combining these data although AUC for structured data model (0.6494) was not very different from the combined data model (0.6447). The combined model showed better results in terms of calibration plot and precision-recall curves. The decision curve analysis for assessing the clinical impact of practical usefulness of the models showed that the combined model offered 15% net benefit over its individual counterparts at a threshold predicted probability of 0.20. We have described the model development and validation efforts for this study using the Transparent Reporting of a multivariate prediction model for Individual Prognosis or Diagnosis (TRIPOD) guidelines [1].

Abstract

Recently, researchers have been applying many new machine learning techniques for predicting the risk of readmission for heart failure. Combining such techniques through ensemble schemes holds a promise to further harness predictive performance of the resulting models. To that end, we examined two ensemble schemes and applied them to a real world dataset obtained from the EMR systems for 36,245 patients from 117 hospitals across the United States over five years. Both the ensemble schemes provided similar discriminative ability (AUC: 0.70, F1-score: 0.58) that was at least equal to or better than the base models that used a single machine learning method. The clinical impact of the models using decision curve analysis showed that at a threshold predicted probability of 0.40, the ensemble models offered 20% net benefit over the treat-all and treat-none strategies.

Patient Readmission; Heart Failure; Machine Learning

Introduction

Heart Failure (HF) is a chronic disease that affects 6.6 million adults in the United States alone and 550,000 new cases are reported annually [5]. The incidence of disease occurs mainly in older adults over 65 years who frequently have many other comorbidities. The main expense for the HF management is attributed to the hospitalizations (70% of total cost) [6] and the future financial burden forecasted until 2030 by the American Heart Association, estimates an increase of 215% in direct costs, 80% in indirect costs, and 25% in prevalence respectively [8]. It has thus become the most frequent and expensive disease for 30 day readmissions [4]. As a major insurance payer for older adults in the United States, the Centers for Medicare and Medicaid Services (CMS) has enacted penalties through its Readmissions Reduction Program (HRRP) for the healthcare organizations with high readmission rates [15]. The penalties are applied to the prospective payments to hospitals for medicare and medicaid patients. These developments have launched the interest and development of risk prediction models for patient readmissions to hospitals. Availability of data in Electronic Health Records (EHR) systems used in the hospitals has helped this development further.

Many variations of models for predicting readmissions have been developed, particularly for heart failure, over the last decade [12]. There are several interesting observations about the earlier models: many reserachers have modeled mortality and readmission as composite outcomes but that trend has declined recently since these outcomes appear to be influenced by different predictors. Along simliar lines, many older studies have used different timeframes for readmission ranging from seven to 365 days [12]. The more recent trend of using a 30-day timeframe appears to be a strong representative of readmissions for many diseases, as similar readmission patterns occur for different diseases based on time-to-event analyses [9]. Furthermore, most models have considered all-cause readmission to encourage hospitals to implement intervention programs to improve overall care; such as better discharge coordination, medication reconciliation, and post-discharge follow-up instead of using a narrow set of condition-specific solutions. In terms of data sources used for building predictive models, recent studies appear to use EHR systems more than registry or claims-based datasets due to the close data availability at the hospital level [12].

Focusing more on the methods used for building the models, and a recent systematic review of predictive models for HF [12], two main categories are noted: (a) interpretation oriented parametric and semi-parametric approaches such as logistic regression, elastic net, and LASSO; (b) predictive accuracy focused machine learning methods such as decision trees, random forests, neural nets, and gradient boosting. Recently, some studies [2; 11; 13] have also compared different methods for their effectiveness and discriminative abilities. The parametric methods suffer from long model building time and numerical instability with a large set of variables whereas machine learning methods are computation intensive with hyper-parameter tuning and show signs of over-fitting to training datasets. To this end, Laan van der et al. [10] have created a theoretical foundation to mitigate the shortcomings of individual methods and to harness the predictive power of different classes of models by combining them. In practice, humans have used such heuristic decision making in forms such as election voting and expert consultations. Perhaps the most well known example of such an approach over the last decade is from the winning team of Netflix's movie recommendation system contest. The team combined many models from the prior years' competitions to deliver the best possible performance for predicting and recommending movies for system users. In the healthcare domain, Shameer et al. [16] have recently experimented to predict readmission risk for HF patients by combining multiple models using correlation-based feature selection criteria for a large set of features extracted from the EHR system. Similarly, Turgeman et al. [17] have used two machine learning methods to overcome some of the limitations of individual methods while predicting risk of readmission for HF patients. However, use of newer and more advanced methods, called ensemble, for building risk prediction models for health outcomes remains largely unexlpored. In this study, we examined basic

properties and types of ensembles and applied them to a set of patient population to predict the risk of readmission for heart failure. We further explored their discriminative power, calibration, and usefulness in clinical decision making.

Methods

Patient Population and Data Extraction

We used EHR data at 117 hospitals from a large nationwide health care system in the United States to derive and validate the predictive models for this observational retrospective cross-sectional study. The datasets from all hospitals under the health system are extracted and loaded into a central repository on a regular basis and we leveraged this infrastructure for the data collection for our study.

Based on our review of the past literature [12] describing the predictive models built for estimating the risk of readmission for heart failure, we used variables from clinical, administrative, and psychosocial categories that are routinely collected during episodes of care. Application of the same data policy framework imposed by the EHR system helped us to develop common logic and programs for data extraction. Datasets for five consecutive calendar years from 2011 to 2015 were extracted using International Classification of Diseases version 9 – Clinical Modification (ICD-9-CM) codes for heart failure as a principal discharge diagnosis. We used 2011 – 2014 data for derivation cohort and 2015 data for validation cohort formations. This setup provided an external temporal validation for the models. As the validation cohort consisted of patients from all the hospitals, it also provided external geographic validation for the models within the United States.

Primary Outcome

We adhered to the commonly adopted definition of any-cause 30-day readmission in the literature [9], which excludes hospitalizations with a length of stay less than one day and any elective hospitalizations. If the patient encountered multiple readmissions within the 30-day timeframe from the discharge date of the index admission, only the last readmission episode was considered so that the latest health status for the patient is used for predicting the risk of future readmission. This setup provided us with the sample of patients that was blinded for outcome by programming for the above rules. The sample was also statistically independent and mutually exclusive across the two classes of admission groups of non-readmitted and readmitted patients, even though machine learning based methods do not impose this constraint.

Predictors

Structured data predictors were broadly classified into clinical, administrative, and psychosocial categories based on prior literature survey and expert clinical consultation [12] and are shown in Table 1. All the variables were collected either on or before the discharge date but closest to it depending on the data availability. Since the bulk extraction from the EHR system was carried for the study cohort, predictor assessment was blinded to the other predictor and outcome variables.

Statistical Analysis

The extraction of data from the EHR system yielded a sample size of 36,245 admissions with 72 variables including dummy variable formats for categorical variables. We counted 27,714 admissions for the derivation cohort and 8,531 admissions for the validation cohort with the overall observed readmission rate of 35.7%. We did not have any missing values for the dependent variable; a few independent variables such as BNP

Table 1 – Structured Dataset

Clinical Set	Predictor Name

and blood glucose had up to 5% missing values. Some methods such as decision trees and its variants accept predictors with mising values, whereas some other methods such as logistic regression need all predictor values to be present. Hence, for consistency we used multiple imputation by chained equations resampled over five imputed datasets for the missing values assuming missingness at random. We created separate dummy variables for missing values with higher rate of missingness for the categorical variables [1; 7]. This strategy allowed us to use all the available records in the analysis. Continuous variables were also examined for nonlinear effects and transformations were carried wherever necessary.

We investigated 10 different base learning models in this study. The base learners were chosen to represent various method families such as linear models, tree based and bagging models, boosting-based models, and neural networks. The base learners were run individually for the optimal AUC (Area Under Curve) performances by tuning their respective hyper-parameters. Figure 1 shows general setup of an ensemble system. The given dataset is applied to each *base learner* that implements a predictive model to predict the outcome of interest. A set of these predicted outcomes is then applied to a final model called a *meta learner* that uses some method to produce the final predictive outcome that is used to score the risk on the data that is not seen previously. We used Super learner and Subsemble schemes to combine base learner outputs using varying number of folds, partitions, and meta learner models to understand the effect of variations in these parameters on the ensemble performance. More details about the ensemble structure are provided in the Discussion section below.

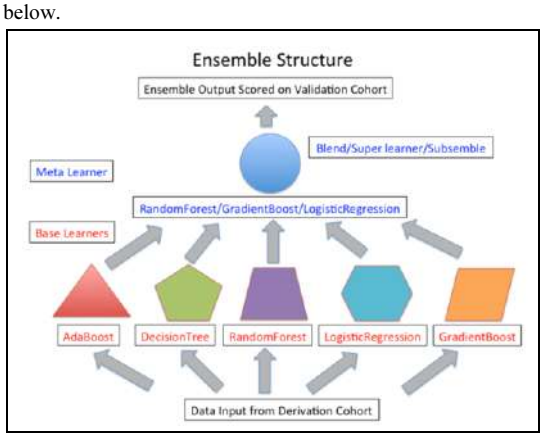

Figure 1 – Ensemble Structure

All confidence intervals were calculated at 95% level using 2000 stratified bootstrap replicates. We further calculated an AUC and a F1-score for each base learner and ensemble and also plotted a calibration plot and ROC (Receiver Operating Characteristics) curves for showing discriminative power. We also carried out decision curve analysis for the base learner and two ensemble schemes to understand their relative utilities with respect to treat-none and treat-all strategies.

We used Microsoft SQL Server Version 12 Release 2, R version 3.0.2 (The R Foundation for Statistical Computing Platform), and python version 3.6.4 for data extraction and statistical analyses. This Pilot Project under Quality Improvement initiatives was exempted from the review of full committee Institutional Review Board.

Results

We fitted 10 different base models with the derivation cohort by tuning with their respective hyper-parameters to optimize for the AUC using the validation cohort. The models and their individual performances are shown in Table 2.

The ensemble methods were tried with LogisticRegression, RandomForest, GradientBoost, and NeuralNetwork as meta learners. There was no performance difference in terms of root mean square errors and the AUCs between the Super learner and Subsemble schemes for the same meta learner. Furthermore, ensembles performed at the same level when the number of folds and partitions of the cross-validation scheme were changed. The final ensemble schemes used 16-fold, 16-partition combination on the validation cohort with GradientBoost and RandomForest meta learners for the Super learner and Subsemble respectively. The F1-score in Table 2 represented harmonic mean between precision and recall for the models.

Table 2 – Base Learners and Ensembles

Base Learner	AUC [95% CI]	F1-Score
RandomForest	0.6922 [0.6791-0.7058]	0.5780
AdaBoost	0.6612 [0.6496-0.6747]	0.5726
LogisticRegression	0.6914 [0.6801-0.7030]	0.5797
GradientBoost	0.6725 [0.6611-0.6840]	0.5676
DecisionTrees	0.6192 [0.6081-0.6326]	0.5437
ExtraTrees	**0.6993 [0.6885-0.7107]**	**0.5841**
KNearestNeighbor	0.6498 [0.6385-0.6611]	0.5592
NeuralNetwork	0.6962 [0.6854-0.7076]	0.5869
NaiveBayes	0.0095 [0.0041-0.0679]	0.5388
SupportVectorMachine	0.6869 [0.6748-0.6980]	0.5797
Ensemble		
Super Learner (using GradientBoost)	**0.6987 [0.6872-0.7101]**	**0.5843**
Subsemble (using RandomForest)	0.6914 [0.6798-0.7030]	0.5747

The KNearestNeighbor as a base learner was chosen merely to highlight the differentiation in the curves in Figure 2(A) and Figure 2(C). The AUC or C-statistic was calculated for the base learner and both the ensembles and was plotted as ROC curves for comparison as shown in Figure 2(A).

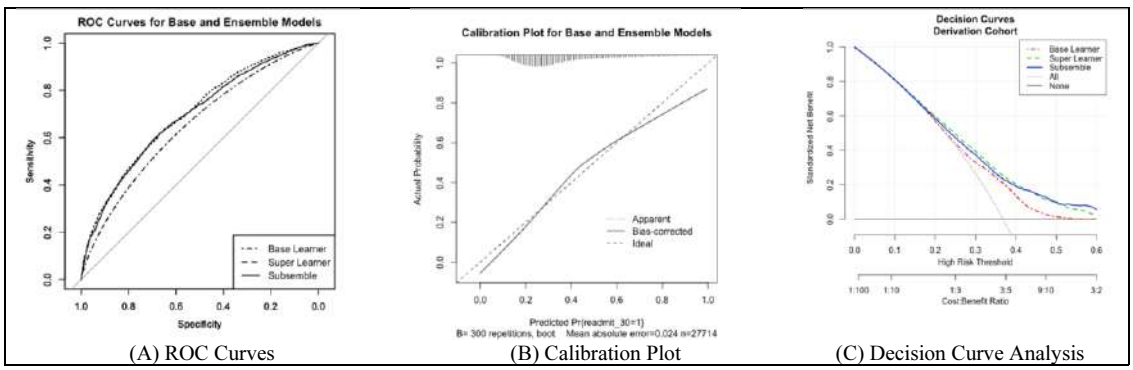
Calibration with ideal, apparent, and bias-corrected fits with 300 bootstrap repetitions for the derivation cohort was carried out and plotted as actual probabilities on Y-axis against model-predicted probabilities on X-axis as shown in Figure 2(B).

Finally, we carried out Decision Curve Analysis (DCA) [18] for the base learner and both the ensembles to understand net benefit for each model at various thresholds of predicted probabilities and is shown in Figure 2(C).

Discussion

Characteristics of Ensemble System

The seemingly simple ensemble structure shown in Figure 1 is based on a few important principles: (a) A meta learner in the ensemble has to learn optimal combination of the base learners' predictions. In its simplest form, this could mean to implement simple or weighted majority-voting algorithm if the



(A) ROC Curves (B) Calibration Plot (C) Decision Curve Analysis

Figure 2 – Performance Plots for Base and Ensemble Models

outcomes of the base learners are discrete numbers or a class such as that resulting from the support vector machine algorithm. For continuous outcome predictions from models such as logistic regression and boosting, simple arithmetic combinations (mean, sum, or product) could be applied.

In practice, most ensembles apply complex combination of algorithms to arrive at the final predictive outcome from the meta learner. (b) The ensembles improve their performance by correcting the base learners' prediction errors. Moreover, the prediction errors need to be relatively uncorrelated to improve the overall ensemble performance. This principle partly relies on the choice of the base learners and their hyper-parameter tuning. A use of a set of base learners is embraced from the *no free lunch theorem*, which suggests that no single algorithm is optimal to solve every problem. Another important point highlighted by this principle is that combining the base learner outputs in the ensemble does not necessarily lead to the performance that is guaranteed to be better than the best base learner; rather, it reduces the likelihood of choosing a suboptimal model with poor performance. (c) A part of the improvement in the ensemble performance comes from the ability of the base learners to see diverse data during their training phase. This objective is achieved by implementing various strategies discussed below that give rise to different types of ensembles.

Blend ensemble divides the input dataset into two parts, each of which is used by the base learner layer and the meta learner layer. Each layer in turn divides its data into a proportion of a train set and a test set. As in any supervised learning scheme, the learners use the train set to fit their models and the test set to assess the predictive performance. This ensemble is useful for training large datasets in a short time but has a shortcoming that the input dataset is used only once by the system.

Super learner ensemble uses cross-validation methods by formulating the minimization of the cross-validated risk over the base learners as a new least squares regression problem which itself is carried out by the meta learner using cross-validation itself, thereby preventing over-fitting of the cross-validated risk. The training time for this ensemble could be long, especially with large datasets using a large number of cross-validation folds, but the performance is much better than blend ensemble, especially with a high variance noisy data [10].

Subsemble ensemble partitions the full dataset into subsets of observations, fits a specified base learner's underlying algorithm on each subset, and uses a novel form of K-fold cross-validation to output a prediction function that combines the subset-specific fits. At the meta learner layer, this ensemble evaluates the performance relative to the underlying algorithm fit just once on the full dataset and hence is useful for small, medium, and large datasets [14]. Since our dataset comprised of one data record for one patient admission/readmission, it did not empirically fall into high volume, high velocity dataset. Moreover, each layer of the Blend ensemble uses only half the dataset. Hence, in order to effectively use our data, we did not use Blend ensemble structure. We applied our dataset to Super learner and Subsemble by systematically varying the parameters such as folds, partitions, and underlying meta learner. We did not notice significant difference in the performance of these two ensembles for the same set of parameters except that the Subsemble was able to complete the computations in 1/3rd amount of time taken by the Super learner. This might be attributable to its strategy to further partition data in each fold and work on all the partitions in parallel. We observed some but not significant performance differential between the two schemes if the underlying meta learners are different. This could be confirmed by looking at mostly overlapping ROC curves for the ensembles in Figure 2(A); the ensembles, however, show significantly better discriminative ability than the base learner.

Calibration plot in Figure 2(B) shows presence of over-fitting for predicted probabilities in the lower and upper tertiles, whereas under-fitting in the middle tertile. The ideal fits with no over-fitting and no over-estimation are shown as dotted line diagonal axis at 45^{o} in the plot. The dataset further demonstrates some over-estimation with negative Y-axis intercept indicating need for better functional form for the model.

DCA is based on the relative harms caused by false positives and false negatives and is expressed as a threshold for probabilities predicted by the models. As seen in Figure 2(C), the use of *any* predictive model provides positive standardized net benefit over both *treat none* (X-axis) and *treat all* (lowest curve cutting X-axis at risk threshold of 0.37) strategies. The model based on either ensemble scheme appears to provide about the same net benefit that is consistently better than the base learner model as well as the *treat all* and *treat none* strategies across all the predicted probabilities above 0.20. For example, at threshold probability of 0.40, the ensemble based models show 20% net benefit over the *treat all* and *treat none* strategies.

Clinical Impact and Implications for Practice

Researchers are developing many new methods for effective predictive modeling for outcomes important for patients and healthcare organizations alike. We have examined, applied, and compared various individual as well as ensembled

machine learning techniques for predicting 30-day readmissions for heart failure using most commonly available data in the EHR systems. Decision analysis in this study has shown that the use of *some* predictive model is better than both using *no* model at all and treating *all* the admitted patients with the same readmission reduction program interventions. Discharge physicians and coordinators as well as case managers could make post-discharge decisions with their patients by taking into account risks and benefits by applying such models in practice. Even though the model development and associated activities of data processing pipeline might seem daunting to implement in practice, the predicted risk threshold and outcome could be easily displayed in a simple mobile application for the clinicians.

Limitations

This study represents a pilot project that explored techniques for combining different machine learning models for predicting readmissions for heart failure using a limited dataset. It also used data from different hospitals but within the same health system. Many machine learning algorithms are known to work better with a large dataset and this study could be further explored in that setup.

Conclusions

In this study, we built predictive models with the EHR system data using various machine learning techniques independently, and in combination by deploying two different ensemble schemes. We compared the perfmance metrics for the base models and their ensembles. Our analysis showed that the ensemble techniques deliver the performance that is at least as good as the best performing base model. The decision curve analysis for assessing the clinical impact of practical usefulness of the models showed that the ensemble based models offered 20% net benefit over not using any model at a threshold predicted probability of 0.40. We have described the model development and validation efforts for this study using the Transparent Reporting of a multivariate prediction model for Individual Prognosis or Diagnosis (TRIPOD) guidelines [3].

Abstract

Sugar Sweetened Beverages (SSB) are the primary source of artificially added sugar and have a casual association with chronic diseases. Taxation of SSB has been proposed, but limited evidence exists to guide this public health policy. Grocery transaction data, with price, discounting and other information for beverage products, present an opportunity to evaluate the likely effects of taxation policy. Sales are often non-linearly associated with price and are affected by the prices of multiple competing brands. We evaluated the predictive performance of Boosted Decision Tree Regression (B-DTR) and Deep Neural Networks (DNN) that account for the non-linearity and competition across brands, and compared their performance to a benchmark regression, the Least Absolute Shrinkage and Selection Operator (LASSO). B-DTR and DNN showed a lower Mean Squared Error (MSE) of prediction in the sales of most major SSB brands in comparison to LASSO, indicating a superior accuracy in predicting the effectiveness of SSB taxation. We demonstrated the application of machine learning methods and large transactional data from grocery stores to forecast the effectiveness food taxation.

Beverages; Machine learning; Public policy

Introduction

Unhealthy diet is the leading preventable cause of global death and disability, claiming 11 million lives and 241 million disability adjusted lost life years in 2012 [1]. Diet-related chronic diseases, such as obesity, cardiovascular diseases, cancers, and type-2 diabetes mellitus impose a considerable burden on society and individuals. Taxation has been proposed as a public health policy to discourage the purchasing of unhealthy foods [2], most notably Sugar Sweetened Beverages (SSB). The primary source of artificially added sugar with a recognized association with obesity and major chronic diseases [3,4], SSB consists of beverages such as soda (carbonated soft drinks), fruits drinks, sports and energy drinks each containing many product brands (e.g. Coca-Cola™ and Pepsi™ in the category of soda). The expected effectiveness of taxation is determined by the magnitude of reduction in SSB purchasing that is likely to occur with an increase in the price of SSB. Formally, this value is called the *price elasticity of demand* and is quantified as the percent reduction in product purchased in response to a one percent increase in price.

Grocery transaction data are generated by scanning products at the time of purchasing from a large number of retail food outlets and can be used to estimate changes in SSB purchasing from price fluctuations. The data include the quantity of food products sold and ourchase details, such as the price and promotions (e.g. discounting, in-store display, and flyer). Although rarely used for public health research, grocery transaction data can be used to predict SSB sales conditional on pricing, promotions, consumer demographic and economic attributes of the store neighborhood (e.g. income and family size). Because sales of a product are influenced by its features (*focal features*), but also by the features of competing products in the same store (*competing features*), the prediction of beverage purchasing must take into account the influence of numerous competing brands.

Due to correlations in price and promotion across many food products, feature selection is critical. Researchers previously performed ad-hoc dimensionality reduction, such as aggregating product sales and features into broader SSB categories or modeling only a small number of brands [5]. These approaches masks the complex patterns of competition among individual food products, potentially resulting in biased estimate of price elasticity due to aggregation bias or omitted confounders. Therefore, prediction at the level of individual food items or brands is critical.

More importantly, associations between product features and sales are non-linear (i.e. deal-effect curve), and multiple product features can jointly affect sales through statistical interactions, or non-additive effects due to competitive interference and synergistic effect of promotions. The shape of the relationship between sales and product features is determined by a mix of factors including: 1) a threshold effect, where the quantity of sales remains constant until the price or promotion reaches a threshold value; 2) a saturation effect, where the growth of sales plateaus as consumers are de-sensitized by price reduction or promotions above certain levels; 3) a cross-item deal effect, where the sales of brands are affected by the price of a large competing brands; 4) an interaction between features of multiple brands e.g., price reduction of a brand fails to increase sales due to promotional activities of a larger competing brand; and 5) an interaction between features of the same brand e.g. the effect of discounting can be enhanced by promotions of the same brand [6].

While parametric estimators (e.g. linear regression) are traditionally used to model product demand, manual specification of non-linear functions and interactions is not feasible with dozens or hundreds of competing product features. In contrast, non-parametric algorithms, such as decision trees and artificial neural networks, naturally incorporate non-linear associations and interactions. Although typically used for classification, these algorithms can be used in a regression context where the output variable is numeric (i.e. sales).

Table 1 - Description of Brand-level, Temporal, and Store Neighborhood Predictive Features of Sugar Sweetened Beverage (SSB) sales. Each transaction record consists of sales (target variable) of specific SSB brands and these features at a given week and store. The third column describes either the number of categories (if categorical), or the range of values (if numerical).

Feature description	Type	Category count or numeric range
Brand-level features		
Chain code where product was sold	Categorical	3
Percent price discount (%)	Numeric	0 - 98.225
Prices in Canadian cents	Numeric	0.001 - 1399
Display advertisement frequency	Numeric	0 – 1
Flyer advertisement frequency	Numeric	0 – 1
Brand name	Categorical	154
Store code where product was sold	Categorical	74
Temporal features		
Month of Sale	Categorical	12
Week of Sale	Categorical	53
Store neighborhood features		
Proportion of post-secondary certification	Numerical	0.435 - 0.891
Average family size	Numerical	2 – 3
Proportion of family with child	Numerical	0.207 - 0.530
Proportion of single parent family	Numerical	0.103 - 0.274
Median family income ($/family)	Numerical	38046 - 108735
Proportion of immigrants	Numerical	0.005 - 0.606
Number of dwellings (families)	Numerical	2885 - 58710
Total population (inhabitants)	Numerical	7460 - 133570
Dwelling density (families/km2)	Numerical	1.145 - 6289.960
Total		
Log of Weekly Sales of brand	Numerical	-1.403 - 11.761

To date, SSB taxation is rarely implemented in developed nations, and the price elasciticy of demand is for the most part estimated by observational data using parametric demand estimation models that tend to suffer the limitations mentioned above [7]. Traditional econometric approaches (e.g. linear regression) to estimate the effect of price on SSB (price elasticity of SSB demand) is infeasible when modling the interaction of a large number of beverage products. We thus aim to evaluate the accuracy of non-parametric learning algorithms for predicting the sales of SSB from scanner grocery transaction data.

Data

We obtained weekly transaction records of food products purchased from 44 stores sampled to be geographically representative of three large retail grocery chains in the province of Quebec, Canada between 2008 and 2013. The data were indexed by time (week), store identification code, product name, price, and three promotional activities: discounting, in-store display (placement of a product in a prominent location) and flyer advertising. Price indicates the dollar amount paid by the consumer at the time of purchase (i.e. net price), while discounting is the percent reduction of the purchase price from the regular price calculated as the maximum purchase price in a three month trailing window [8].

Among many types of beverages, we were interested in predicting the sales of SSB, or artificially sweetened beverages which included soda, energy and sports drink, carbonated fruit beverage, frozen fruit juice, fruit drink, and carbonated soda water. There were 2,608 distinct SSB products defined by brand, flavor, and package type. Because products in the same brand tended to exhibit similar pricing and promotional patterns, we aggregated the value of sales, pricing and promotion into a smaller set of 154 distinct SSB brands, such as Coca-Cola™ and Pepsi™. Brand-level predictive features (i.e. price, discounting, display, and flyer advertisement) were calculated as the mean (price and discounting) and proportion promotion (display and flyer) across the products belonging to the brand.

Let $t := week, i := brand, j := store$. There were 1,509,280 weekly transaction records for the 154 SSB brands across all stores, with each record representing the brand-specific sales denoted as Y_{ijt}, which was the target variable and defined as the natural-log of the sales of brand i in store j at week t. The sales quantity was standardized to the U.S Food and Drug Administration serving size of 240 milliliters. Although the log transformation was relevant to parametric regression modeling only [9], we applied this transformation in accordance with existing practice in demand modeling.

The vector of brand-level focal features was denoted as X_{ijt} (Table 1, Brand-level features). We let S_j be the features of the store where the products were sold (categorical indicator of chain and store identification code) and store neighborhood socio-economic and demographic features that may influence food purchasing were obtained from the 2011 Canadian census (Table 1, Store neighborhood features). We let M_t and W_t represent categorical features indicating the month and week for each record to account for temporal fluctuations in purchasing (e.g. increases on holidays). As noted above, sales of a brand depend on the pricing and promotion of that brand (*focal brand features*) and on the features of popular competing brands (*competing brand features*). Because a few brands accounted for most of the market share in each SSB category (e.g. Coca Cola™ and Pepsi™ have nearly 70% of share in the soda category), their brand features have a strong influence on the sales of other brands. Thus, we extracted price and promotions of twenty brands with the highest market

Table 2 - Mean Squared Error of most popular brands of Sugar Sweetened Beverages

	Pepsi	Coca Cola	Seven Up	Crush	Sprite	Canada Dry	Nestle
LASSO	0.51	0.44	0.46	0.35	0.45	0.38	0.41
B-DTR	**0.17**	**0.16**	0.22	0.28	**0.22**	**0.24**	0.41
DNN	0.19	0.23	**0.21**	**0.23**	0.23	0.27	**0.31**

share among SSB that are denoted as C_{kjt}. The dimension of each feature vector was: (X_{ijt}, 245), (C_{kjt}, 80), (S_j, 9), (M_t, 12), and (W_t, 53).

Methods

We used two non-parametric methods: an ensemble of Decision Trees with Adaptive Boosting (B-DTR) and a fully-connected Deep Neural Network (DNN). The baseline model was a regularized linear parametric model (LASSO, or Least Absolute Shrinkage Selection Operator). The DNN was implemented in Keras [10], and the other models were implemented in Scikit-Learn [11]. Unless otherwise noted, normalization was done using standard mean shifting and variance scaling.

LASSO regression identifies a sparse set of features through shrinkage via L_1 regularization [12] and has been previously used for demand forecasting in high-dimensional feature space [13], even though explicit specification of non-linear features (e.g. spline) becomes unrealistic when modeling the sales of a large number of brands. We selected the regularization parameter λ by iterating over a range of values and selecting the one with lowest average mean squared error (MSE) through three-fold Cross Validation.

Decision Tree Regression is a rule-based learning algorithm that identifies a binary segmentation of predictive features, where the cut-point for each feature represents a decision boundary that minimizes the prediction loss (e.g sum of squared errors) for a target vector Y_{ijt}. The partitioning ends when pre-specified criteria, such as a maximum number of branches or a minimum number of observations at each terminal node, are met. The decision trees implement the Classification and Regression Trees algorithm due to its ability to predict numerical values [14].We used Drucker's improved Adaptive Boosting [15] meta-estimator to form an ensemble of 100 weak learners. The weight of each learner was determined by a linear loss. Each learner was a Decision Tree with varying depths, set to a maximum depth of 30 nodes. The value of each node was determined by the partition that best minimized the MSE.

The DNN model with the best results had four fully connected layers. Adam optimization was used to enable convergence with large data and noisy gradients [16]. The optimum values of exponential decay rates and fuzzy factors were selected based on training stability and the ability to converge. The network weight parameters were initialized using Normalized Initialization [17] to accelerate convergence. We trained the model using mini-batches of 128 samples to leverage the richness of the data and to provide inherent regularization [18], while maintaining a stable training process. We chose the activation function to be a Rectified Linear Unit due to its biological properties and strong experimental results on high-dimension datasets [19], due in part to its non-linearity, which allows the DNN to learn complex relationships between features.

The DNN had an input layer dimension of 389, and fed a 400-dimension vector to the first hidden layer. The first hidden layer output a 100-dimension vector to the next layer with a L_1 regularization and ReLU activation. The last hidden layer output was a 25-dimension vector to the output layer. The final layer outputs a single numerical value corresponding to the predicted log of sales, using a linear activation function to take into account negative target values (brands with extremely low sales has negative log values).

We extracted the first five years (2008-2012) of the transaction data for training and validation. We randomly sampled 90% of these data as the training set for learning algorithm parameters, leaving the remaining 10% as the validation set for evaluating the prediction accuracy of the algorithms. The final year (2013) of data was reserved to estimate prediction accuracy, measured as Mean Squared Error (MSE). Data were managed using Numpy, Pandas and PostgreSQL.

Results

The MSE for the prediction of all SSB brands in the 2013 transaction data was 0.67, 0.72, and 0.91 for DNN, B-DTR, and LASSO, respectively.

At the individual brand level, DNN, B-DTR, and LASSO showed best predictive performance for 80, 31, and 21 brands, respectively. Prediction error of seven most popular SSB brands driving overall sales of SSB is presented in Table 2. The DNN and B-DTR had comparable prediction accuracy for these brands, while LASSO showed the lowest accuracy except for the Nestle brand. Category-level prediction is of public health interest, since each beverage category can have different health effects. We thus calculated a category-level MSE (Table 3). The DNN had the highest prediction accuracy for the soda category, the most important source of added sugar consumption. LASSO showed the lowest prediction accuracy for all the categories.

Table 3 – Mean Squared Error for each Beverage Category, Across all Stores

	Soda	Soda Water	Energy Drinks	Frozen Juice	Frozen Drinks
B-DTR	0.650	0.743	0.956	**0.600**	**0.631**
DNN	**0.609**	**0.647**	**0.691**	0.660	0.640
LASSO	0.756	0.852	0.819	1.228	0.887

Using the most accurate predictive algorithm (DNN), we generated price elasticity, which is the predicted percent reduction in SSB sales conditional on increased beverage prices in reference to the predicted SSB sales due to observed SSB price. The elasticity across all stores was -1.74 (95% Confidence Interval [CI]: -0.89, -2.69), implying that the increase of SSB price by 1% results in the expected reduction of SSB purchasing by 1.74%.

Discussion

The superior prediction accuracy demonstrated by B-DTR and DNN over LASSO is likely due to their ability to model non-linear relationships and interactions across predictive features of the 154 brands. Conventional approach to model low-dimentional data, such as Ordinary Least Square and its extension adapted for a high-dimentional varaible space (LASSO) may be a suboptimal approach in predicting the sale of SSB in a competitive retail environment due to its linear constraint Although it is theoretically possible to manually specify appropriate non-linear functional forms guided by model-fit criteria (e.g. Akaike's Information Criterion) in LASSO, this approach is not feasible when the number of competing brands grows large.

The estimated own-price elasticity was slightly higher than the mean estimate from a systematic review of previously reported observatioinal studies in the United States (-1.21, range: -0.71 to -3.87) [7] but was lower than the elasticity (-3.1) estimated by the exsiting natural experiment in Berkley, California [20].

Non-parametric learning algorithms, in particular DNN as demonstrated by the superior prediction accuracy in our study, are free from the linearity assumptions. They are a promising alternative to predict the sales of a large number of brands, thus providing a better quality of public health evidence to guide policy on SSB taxation.

Future work includes in-depth investigation of store-level difference in the estimated effectiveness of taxation, or price elasticity. Identification of store-level features (e.g. promotion and the number of competing items) and neighborhood features driving differential store-level elasticity is a critical public health interest, since the analysis allows the characterization of communities that are less likely to benefit from taxation and consequently in need of community-specific interventions addressing local obstacles of healthy eating. As well, variation of prediction error (MSE) across stores and beverage categories warrants thorough investigation to improve the performance of the models.

A limitation of our study, as in the majority of research estimating price elasticity using observational transaction data, is the lack of the sales data generated by the simultaneous increase of SSB price across all beverages due to taxation, which may induce purchasing patterns different from the observed price fluctuation without the taxation. Thus, our ability to formerly validate the predictive performance of these algorithms under SSB taxation is limited. Future research therefore includes the evaluation of these algorithms in a (rare) setting where the taxation is applied. Nevertheless, our study adds an important contribution to the existing methodological research in estimating the price elasticity of demand using the transaction of a large number of food products.

From a public health perspective, unique aspects of our study include the evaluation of the effectiveness of health policy using a large amount of transactional data, which have become recently available to public health researchers. More importantly, analytical strategies for learning food demand from high-dimensional data were also lacking. Our novel approach to predicting SSB sales using machine learning methods should improve the accuracy of estimating the effectiveness of SSB taxation, while demonstrating the effective use of scanner transaction data for public health research. In addition, our analytical framework offers a scalability in terms of geographic coverage (e.g. expansion to national-level analysis) and food categories that are not modelled in this study but are often proposed as part of SSB including 100% fruit juice and sweetened milk, albeit having much lower market share than soda.

Conclusions

Overall, our study demonstrated the utility of non-parametric machine learning algorithms in predicting unhealthy beverage sales in the presence of complex interactions across a large number of SSB brands and non-linear effect of sales and product attributes. The higher accuracy of the non-parametric learning algorithms, in particular DNN, over parametric algorithm highlights its utility in predicting the potential effect of SSB taxation.

Abstract

During the acquisition on a low-dose radiation computed tomography (CT) scan, images are usually marked by heavy noise and undesired artifacts, which dramatically reduce its applicability in the image processing workflow. A noise reduction and detail preservation filter based on mathematical morphology is presented in this paper. The filter is geared to allow control of an opening operator followed by a systematic contrast limited adaptive histogram equalization (CLAHE) in conjunction with a reconstruction by dilation in last stage. A quantitative metric built on peak signal-to-noise ratio (PSNR), structural similarity (SSIM), and mean-squared error (MSE) were applied to check noise reduction, detail preservation, and performance. The results obtained by the proposed filter were compared with those obtained in the literature, showing very good results: compared with the best-tested filter, the filter had a gain of 7.91% on PSNR, 7.57% on SSIM and 37.8% on MSE.

Introduction

Computed tomography, commonly known as CT, is a painless, non-invasive diagnostic tool that uses a specialized form of X-ray coupled with computer technology to produce cross-sectional images (scans) of soft tissue, organs, bone and blood vessels. Although scans have been applied to improve diagnostic imaging capabilities, the exposure to sufficiently high levels of radiation increases cancer risk. Radiation doses during CT procedures are higher than conventional radiography and are linked to an increased risk of cancer [1].

Research [1] suggests that low-dose CT scans provide effective radiation risk reduction when compared to traditional levels. However, the radiation dose will generate an image corrupted by noisy and undesired artifacts, interfering the diagnosis to a certain extent. Many algorithms have been proposed in the literature to reduce the noise, usually classified in both spatial and frequency domain. Well-known spatial domain filters include Gaussians, Median, Wiener filters. Fourier transforms, wavelet transforms, and anisotropic diffusion are some filters related to frequency domain techniques. Even though these filters produce a significant noise reduction and enhances image quality, they are not designed for edge preservation and noise reduction of images [2].

Median and Gaussian low-pass filters [3-4] are applied over the entire image by following the same procedure. A sliding neighborhood operation (sliding window) is an operation performed one pixel at a time, determining the value of any given pixel in the output image by applying an algorithm to the values of the neighborhood of the corresponding input pixel. For the median filter, the centered pixel receives the median value of its neighborhood pixels while the Gaussian filter allows only low-pass frequencies through, which is the center of the frequency transformed image. The drawbacks of such filters are that they tend to break up image edges, produce false noise edges in the presence of small signal-to-noise ratios, and cannot suppress noise distributions.

The Wiener filter [5] performs an optimal interaction between reverse filtering and noise smoothing. It generates an estimate of the original image and minimizes the square error overall mean. Tomasi and Manduchi [6] have proposed a non-interactive edge-preserving smoothing method called bilateral filtering. Average similar and nearby pixel values replace the value of the processing pixel. The bilateral filter averages the small and weakly correlated differences between noise-caused intensities.

He and Tang [7] introduced Guided Filtering, using a guidance image, an input image, and an output image. The pixels from the guidance image are processed by a sliding window *MxN* and applied to the input image. The value of the pixels is calculated according to the color and similarity of the space. The output image will be processed once this calculation is done.

Greece [8] suggested a bitonic filter where the signal is deemed bitonic. A bitonic sequence is one that monotonically increases to a peak and monotonically decreases. That is, if it has only one local maximum or minimum value, or no maximum or no minimum, a signal is considered bitonic.

Dabov et al [9] proposed the block matching 3D (BM3D) filter based on sparse representation in the transform domain. The filter gathers fragments of similar 2D images into 3D arrays of data, called groups. The BM3D filter is split into two steps. A block-wise estimate is performed in the first step, called basic estimate, where similar fragments are grouped in a 3D group. After that, a hard-thresholding collaborative is done, bringing the fragments back to their original position for aggregation. The final estimate is called the second step. This step uses the baseline estimate output to perform an improved grouping followed by Wiener collaborative filtering. The fragments are then aggregated to result in the final image of the output.

Operators of mathematical morphology are also used to reduce noise. In addition, morphological operators are able to detect boundaries, edges, and important details. These operators use a certain shape and size structuring element [2]. The two basic operators are dilation and erosion. These operators describe the interactions of an image *f* with a structuring element *B*.

The dilation operator δ of an image *f* by a structuring element *B* in a certain pixel *x* is the maximum value of *f* in the window defined by *B* centered in *x.* This operator is described by (1) below.

1. $\left(\delta^B(f)\right)(x)=\max_{b\in B} f(x+b)$

Contrarily, the erosion ε is the minimum value of *f* in the window defined by *B* centered in *x* and is described below by (2).

2. $\left(\varepsilon^B(f)\right)(x)=\min_{b\in B} f(x+b)$

While the dilation operator increases sets and eventually connects them if the size of the structuring element is greater than the space between them, the erosion operator decreases sets and disconnects them. If combined, these two operators can represent two other useful morphological operators: opening and closing operators.

The opening operator γ consists in dilating an image *f* by a structuring element *B* after eroding *f* with the same structuring element. The γ operator can be defined as:

3. $\gamma^B=\delta^B\left(\varepsilon^B(f)\right)$

On the other hand, the closing operator φ consists in eroding an image *f* by a structuring element *B* after dilating *f* with the same structuring element and can be expressed as:

4. $\varphi^B=\varepsilon^B\left(\delta^B(f)\right)$

The opening operator removes clear areas in the image where the structuring element does not fit [10], breaks narrow joints and eliminates narrow reliefs. Similarly, the closing operator removes dark areas in which the structuring element does not fit [10], widens narrow gaps and eliminates small holes.

This paper presents an image filter to reduce noise and preserve details in low-dose dental CT images. The proposed filter is based on the morphological opening operator, followed by the contrast limited adaptive histogram equalization (CLAHE) algorithm and morphological image reconstruction by dilation. Experimental results demonstrated that the proposed filter reduced the noise and preserved edges, borders and details better than the compared filters. In order to validate our approach, PSNR, SSIM and MSE were used as quantitative metrics.

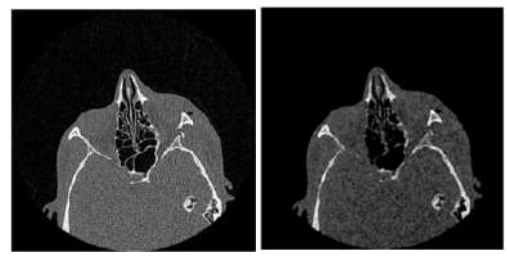
This paper is organized as follows: The Proposed Method section presents in details the proposed filter. The method validation is displayed in the Results section, comparing it to different filters. A discussion on the previous section is presented in the Discussion section. The work is summarized in the last section with the findings and future work.

Proposed Method

The first step is to preprocess the input noisy image, denoted as *F* to get its gray scale level, denominated as *G.* A low-dose dental CT input noisy image is illustrated by Figure 1 (a).

After that, in order to reduce noisy artifacts, the opening operator is applied to *G* with a diamond shaped structuring element with size 2 called *B*. The output image of this step, denominated *K* is illustrated by Figure 1 (b) and described as:

5. $K=\delta^B\left(\varepsilon^B(G)\right)$



(a) *(b)*

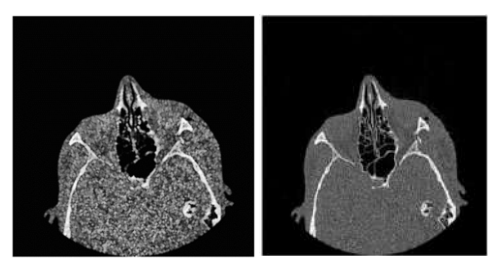
Figure 1 – (a) Low-dose dental CT noisy image. (b) Resulting image K after the opening operator.

Once the opening operator analyzes the visual results in *K*, it is possible to see that some edges, borders and small structures have been degraded. We used the CLAHE enhancement algorithm before restoring these fragments to enhance all the preserved details. CLAHE is an improved version of the adaptive histogram equalization (AHE) [11]. The algorithm basically divides an image into regions of nearly the same sizes. The number of regions is usually 64 for a 512x512 image. Then, with these regions, three different groups are formed. The first group, called corner regions, is made up of four corner regions of the image. The second group, called the Border Region (BR), includes the 24 border regions. Lastly, the third group is called the internal regions (IR) and it has all the other regions. The histogram of each region is calculated and enhanced after this grouping separation. These processed groups are combined back to use bilateral interpolation to perform the output image. The output image *C* is shown by Figure 2 (a).

The filter's last step is to restore the degraded edges, boundaries and small structures. To do this, we used dilation to reconstruct a morphological image. In the marker image C, dilations are done until the contour fits under the mask image G. The final output image, called Q, is the reconstruction of the morphological image between these images by dilation and is described by (6):

6. $Q=R_G^{\delta}(C)=\delta_G^i(C)$

where *i* is such that $\delta_G^i(C)=\delta_G^{(i+1)}(C)$.The result image of the proposed method following these steps is shown by Figure 2 (b).



(a) *(b)*

Figure 2 – (a) Image C. (b) Final output image Q.

Experimental Results and Validation

A dataset of 991 low-dose dental CT images corrupted by natural noise was taken to test the performance of the proposed method. Median filter, Wiener filter, Gaussian filter, guided filter, bilateral filter, BM3D filter, and bitonic filter performance were compared. The parameters were set to their optimal values for each filter tested.

The proposed algorithm was evaluated using quantitative quality metrics of peak signal-to-noise natio (PSNR), mean-square error (MSE) and structural similarity (SSIM). The mean-square error (MSE) between the original image f and the processed image g is computed as

7. $$\text{MSE}=\frac{1}{\text{MxN}}\sum_{i=1}^{\text{MxN}}\left(g(x,y)-f(x,y)\right)^2$$

where M x N specifies the size of the image, $g(x,y)$ is the processed image and $f(x,y)$ is the original image. The PSNR describes the quality of the reconstructed image after applying any technique on it and is described as:

8. $$\text{PSNR}=10\log_{10}\left(\frac{255^2}{\text{MSE(f, g)}}\right)$$

A high PSNR value means a good quality of the processed image. The structural similarity (SSIM) measures the similarity between the enhanced picture and the original picture [12]. A near-1 SSIM value means that the images are identical in structure. The structural similarity of the reconstructed image g between the original image f and g can be formulated as:

9. $$\text{SSIM(f, g)}=\text{l(f, g)}*c(\text{f,g})*s(\text{f,g})$$

where

$$l(\text{f,g})=\frac{2\mu_f\mu_g+\text{C}_1}{\mu_f^2+\mu_g^2+\text{C}_1},c(\text{f,g})=\frac{2\sigma_f\sigma_g+\text{C}_2}{\sigma_f^2+\sigma_g^2+\text{C}_2},s(\text{f,g})=\frac{\sigma_{fg}+\text{C}_3}{\sigma_f\sigma_g+\text{C}_3}$$

with $C_1=(k_1L)^2$, $C_2=(k_2L)^2$, $C_3=\text{C}_2/2$, $k_1=0.01$and $k_2=0.02$ by default and L is a dynamic range of the pixel values. The terms $l(f,g)$ refers to the luminance comparison where μ is the average of f and g; $c(f,g)$ is the contrast function where σ is the variance of f and g and $s(f,g)$ is the structure comparison function. When the SSIM value is close to 1, it means that the processed image had the structures preserved and is similar with the original one. The performance evaluation in terms of PSNR for each tested filter is shown by the graphic on Figure 3.

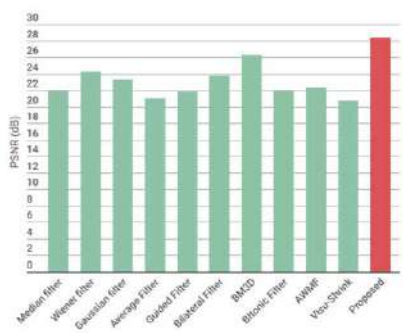


Figure 3 - Average PSNR values for each tested filter.

According to the results, it can be seen that our proposed method outperformed all the tested filters with an average PSNR of 28.35dB, 7.91% more efficient than the BM3D technique.

A low MSE value means better results, that is, the resulting image did not have much loss of information. That being said, it is possible to confirm, according to the graphic shown by Figure 4, that the proposed method had a better average MSE value for all processed images between the tested filters. The average value was 116.41, 37.8% better than the BM3D technique with 187.38.

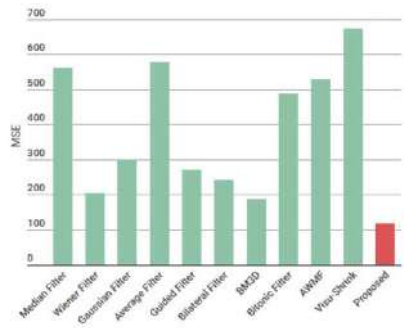

Figure 4 - Average MSE values for each tested filter.

In terms of structural similarity (SSIM), the proposed method also performed better than the tested filters. The average value obtained by the proposed filter on this quality metric was 0.71, 7.57% better than BM3D, with 0.66. The results for the SSIM metric are shown by Figure 5.

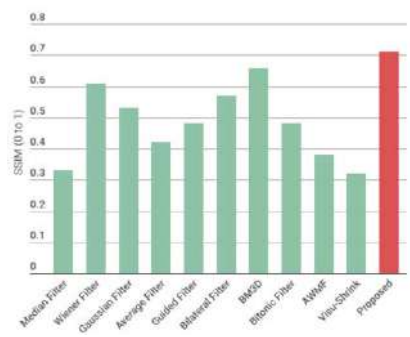

Figure 5 - Average SSIM values for each tested filter.

Table 1 – PSNR, SSIM and MSE average values for all the evaluated filters.

Filters	PSNR	SSIM	MSE
Median Filter	21.92	0.33	561.95

Discussions

The performance results of each filter evaluated above are discussed in this section. In addition to quantitative comparisons, subjective visual comparisons are also made between images processed by all filters evaluated. Figure 6 shows the visual results and interpretation of low-dose dental CT images obtained from each tested filter.

Figure 6 (a) is a noisy low-dose dental computed tomography taken as input for each evaluated filter. Figure 6 (b) is the denoised image processed by the median filter, which it can be noticed that the noise was well removed but it blurred some small structures and edges, which can also be proved by its low SSIM value, 0.33, and its high MSE average value of 561.95.

On Figure 6 (c), the image was processed by the Wiener filter. Visually speaking, it is still possible to see some noise and that the image was moderately blurred with a slightly almost transparent line across the image rounded border. On the other hand, the average values for the Wiener filter proves that it has a reasonable filtering performance and it does not degrade small structures and edges.

The image processed by the Gaussian filter, illustrated in Figure 6 (d), was blurred just like the Wiener and the median filter.

The average filter left the image in Figure 6 (e) with the same visual results as in Figure 6 (d), although the average filter had a lower PSNR value compared to the Gaussian filter. The high average MSE value shows a significant information loss for the average filter and the low average SSIM value shows that the filter degrades structures.

For the PSNR and SSIM metrics, the guided filter had nearly the same average values as the average filter, which can be seen in Figure 6 (f) because the noise was still present, and the image was blurred. Figure 6 (g) is the image processed by the bilateral filter. The filter reduced the noise quite well and had a slightly better result in visual terms than the Wiener filter.

The image processed by the BM3D, Figure 6 (h), showed no damage to its structures and details, proving to be the best among the filters evaluated by its average SSIM value of 0.66. The filter had a good performance in terms of noise reduction under the image's circular structure, which encompasses all important details. The filter also had the best average value for PSNR and MSE between the filters tested. Some minor noisy pixels can still be noticed in the dark area of the image, but they do not affect the image's main structures.

The bitonic filter preserved edge and details in Figure 6 (i) better than the median filter, demonstrated by its higher average SSIM value, and had nearly the same visual results and noise reduction performance as the Gaussian filter. The average weighted median filter (AWMF) had nearly the same visual results as the median filter as shown in Table 1 by the mean values. The difference is that smaller structures were slightly less blurred by the AWMF than the median filter. Visu-Shrink was the worst filter among the comparison. We can see the poor noise reduction and detail preservation performance according to Figure 6 (k). Also, in Table 1, it describes its low performance in quantitative values.

The resulting image of the proposed method can be analyzed through Figure 6 (l). Our method exceeded all the above-mentioned filters in both quantitative and visual ways. The average PSNR of 28.35, 7.91 percent higher than the BM3D, shows that our method reduced the noise that affected the quality of the image better. Our method also retained important details and smaller structures 7.57 percent higher than the

BM3D and had almost no information loss, proven by its low average MSE of 116.41.

Conclusion

In this paper we presented an effective noise reduction and detail preservation filter based on mathematical morphology or low-dose dental computed tomography images. The filter works with the opening morphological operator, CLAHE enhancement algorithm and a morphological image reconstruction by dilation. Extensive experiments have been conducted on almost 1000 low-dose dental CT images to demonstrate the superior noise reduction and detail preservation performance of the proposed method. Experimental results indicated that the proposed filter outperformed the evaluated filters by providing higher quantitative values on PSNR, SSIM and MSE metrics with 28.35dB, 0.71 and 116.41, respectively. Compared to the best evalutated filter, the BM3D, our filter had a gain of 7.91% on PSNR, 7.57% on SSIM and 37.8% on MSE. For future work, we intend to develop an additional technique to this proposed filter in order to obtain better noise reduction performance, and, consequently, better visual results.

Knowledge Learning Symbiosis for Developing Risk Prediction Models from Regional EHR Repositories

Jing Mei[a], Eryu Xia[a]

[a] *IBM Research, Beijing, China*

Abstract

Secondary use of regional EHR data suffers several problems, including data selection bias and limited data size caused by data incompleteness. Here, we propose knowledge learning symbiosis (KLS) as a framework to incorporate domain knowledge to address the problems and make better secondary use of EHR data. Under the framework, we introduce three main categories of methods: knowledge injection to input features, objective functions, and output labels, where knowledge-enhanced neural network (KENN) was first introduced to inject knowledge into objective functions. A case study was conducted to build a cardiovascular disease risk prediction model on the type 2 diabetes patient cohort using regional EHR repositories. By incorporating a well-established knowledge risk model as domain knowledge under our KLS framework, we increased risk prediction performance both on small and biased data, where KENN showed the best performance among all methods.

Keywords:

Electronic Health Records, Machine Learning, Risk Assessment

Introduction

Adoption of electronic health record (EHR) systems has increased dramatically in recent years. In 2008, 9.4% of US hospitals adopted a basic EHR system, while the number climbed to 83.8% in 2015 [1]. Along with the increasing use comes the accumulation of EHR data. Efforts of secondary use of EHR data have been made for clinical research purposes such as risk prediction [2,3], patient similarity [4] and treatment recommendation [5].

Compared to traditional risk prediction research, studies based on EHR have several different features [6]. Traditionally, risk prediction models are developed from large cohort studies [7,8], which have predefined inclusion criterion, long-term and regular follow-up, specified metrics to collect, and protocols for adjudicating outcomes. EHR-based risk prediction studies, however, are based on data collected irregularly (only when the patient uses medical services at a certain place), and collect only metrics that are necessary for each specific encounter. These lead to data bias, data inaccuracy and data incompleteness. One resulting feature of EHR-based risk prediction studies is that missing values are frequent in such studies and they are always missing not at random. Traditionally, missing values can be dealt with by either data imputation or removal of incomplete cases. Data imputation hardly work on EHR-based studies due to the extremely high missing rate, and for instance, the missing rate of regular HbA1c tests (every 3 months for diabtic patients) can be higher than 90% from our experience. Another way to deal with missing value is the removal of incomplete cases, which not only decreases the cohort size significantly, but also creates bias on the selected cohort compared to the original cohort and affects the results and conclusions [9]. Another feature of EHR-based risk prediction studies is that since there are no predefined inclusion criterion and data is generated de-facto, there may be severe bias between the population the prediction model is built upon, and the population the model is to be used upon. As an example, patients who visit community hospitals usually have less severe conditions than those who visit emergency rooms though they may have the same diagnosis code. This thus renders a model built on one population hard to be generalized to other populations. Generalization has always been an important concern of risk prediction models. In a review of cardiovascular disease risk prediction models [10], authors pointed out that though risk prediction models may have good discrimination performance in the original cohort, the performance was lower in external validation cohorts, and results in different cohorts were largely different. This shows the problem of overfitting and lack of generalizability, which gets exacerbated when using EHR data. As a summary, EHR-based risk prediction studies suffer from small data size and data bias, and require carefully designed techniques to increase both model performance and model generalization based on the available dataset.

We thus propose knowledge learning symbiosis (KLS) as a framework to incorporate domain knowledge to increase model performance and generalization, and to improve secondary use of EHR data. Here we use domain knowledge to refer to the clinical insights accumulated with time, validated extensively, and accepted widely by the medical community, primarily written into clinical guidelines as logical rules, entity relationships, or mathematical formulas, etc. While domain knowledge is easy to interpret and well-accepted by the community, they suffer from the drawbacks of prone to outdating, too general for precision medicine, and limited availability. By data mining of EHR data, we gather real-world evidence [11,12] using data documented from medical practices among heterogeneous sets of patients in actual clinical settings. Real-world evidence, on the contrary to domain knowledge, can easily and automatedly be updated and are specialized for individual cases, but suffer from the problems of dependency on large amount of high-quality data, are prone to overfitting, and difficult to interpret. KLS thus represents an attempt which uses domain knowledge to complement real-world evidence to leverage the advantage of both.

Previous studies for KLS have shown its benefits in increasing treatment recommendation accuracy [13]. In this study, we explore the capacity of KLS in overcoming the two major

flaws of EHR data for secondary use. We have two experiment scenarios: (1) learning from small data; and (2) learning form biased data, with the main aim of building accurate and generalizable risk prediction models.

Methods

The study was driven by the need to build a localized risk prediction model for 4-year atherosclerotic cardiovascular disease (ASCVD) on a type 2 diabetes patient cohort using 5-year de-identified EHR data of a city in China. ASCVD is the leading cause of morbidity and mortality for individuals with diabetes and is the largest contributor to the direct and indirect costs of diabetes [14].

Cohort Construction

The study cohort was constructed as follows. We included patients with at least one diabetes-related diagnosis and one diabetes-related prescription. Date of the first diabetes-related diagnosis or diabetes-related prescription, whichever is earlier, was defined as the index date. The observation window was defined as one year before the index date, while prediction window was defined as four years after the index date. Patients were excluded if they: (1) had at least one diagnosis of gestational diabetes or type 1 diabetes (to focus on a cohort of type 2 diabetes mellitus [T2DM] patients); (2) were under 18 years old; (3) did not have gender recorded; (4) had observation of ASCVD before index date; (5) had no medical records within the observation window; or (6) had no medical records after the prediction window (right-censored). The EHR repository has medical records of over 3.6 million patients in total. This constructed cohort includes 54,482 patients. Outcome was defined as having at least one ASCVD event observed in the prediction window.

Feature Construction

Features were constructed based on: (1) previously reported risk factors; (2) medical events in the EHR data. Nine risk factors previously reported in literature were identified: gender, age, race, total cholesterol (TC), high-density lipoproteins cholesterol (HDL-C), systolic blood pressure (SBP), antihypertensive treatment, diabetes, and smoking. As our study was focused on a Chinese T2DM cohort, race and diabetes were not included. For TC, HDL-C, SBP, antihypertensive treatment, and smoking, the latest report in the observation window was used if more than one record was available. We also constructed features to reflect medical events in the observation window. By grouping all diagnosis into 22 categories based on the 22 chapters of ICD-10 codes, we constructed another 22 bool features. For such a feature denoting a disease category, patients with at least one diagnosis falling into this category received a value of 'true'.

Extensive missing values were observed, especially in laboratory tests. Only 4,722 (8.7%) of the patients had at least one HDL-C value, and 6,986 (12.8%) patients had at least one TC value, which would render imputation strategies difficult. We thus included 4,143 (7.6%) cases without missing values in seven previously reported risk factors. Of the 4,143 cases, 1,535 (37%) had a positive outcome.

Domain Knowledge

Here we used the Pooled Cohort Equations (PCE) as our knowledge model. The PCE model is a widely validated risk prediction model to estimate the 10-year ASCVD risk and has been recommended in ACC/AHA guidelines [14]. Its difference from our study is that: (1) Cohort. While PCE is built on a multi-race general cohort, we attempt to build our model on a Chinese type 2 diabetes cohort; and (2) Period. While PCE is a 10-year risk prediction model, we attempt to build a 4-year prediction model. Its similarity to our study is that: (1) Outcome. Both are predicting ASCVD risk; and (2) though it is a 10-year prediction model, it is a Cox model, where the predictive value for 10-year risk is positively correlated with its predictive value for 4-year risk. PCE has the 9 risk factors as listed in our feature construction, and a previous study [22] elaborated different experiments on extending PCE risk factors with ICD-10 codes. For each patient in the studied cohort, we calculated its risk score using the PCE model as the knowledge risk score. Actually, we did not use any cutoff of the PCE score, considering the cutoff itself might increase the imprecision in different cohorts.

KLS Methodologies

Methods for KLS can be divided into three main categories based on where knowledge is injected: (1) into input features; (2) into objective functions; and (3) into output labels. When taking KLS as a fusion of knowledge and data, these three categories correspond to early fusion at the feature level, intermediate fusion in the learning process, and late fusion (or output ensemble). Schematic representations of KLS methodologies are shown in Figure 1.

Formally, we denote $P = \{P_1 \ldots, P_n\}$ as the set of patients. Given a patient $P_i (1 \le i \le n)$, we define:

- $\boldsymbol{x}_i = (f_i^1, \ldots, f_i^m)$ as the feature vector;
- y_i as the patient's ASCVD outcome (1 for positive cases and 0 for negative cases);
- z_i as the knowledge risk score calculated using the PCE model (continuous value between 0 and 1).

We implemented methods in each of the three categories as elaborated below, where l denotes the loss function (cross entropy as used here), θ represents the learning parameters.

[KLS#1] Knowledge Injection to Input features

The knowledge risk score z_i is added as an additional input feature, thus making the learning objective function to be: $argmin_\theta \frac{1}{n}\sum_{i=1}^{n} l\big(y_i, \sigma_\theta(\boldsymbol{x}_i, z_i)\big)$. Here we employ two base learning methods: logistic regression (LR, denoted as LR-K) and multi-layer perceptron (denoted as NN-K).

[KLS#2] Knowledge Injection to Objective Functions

We regard the knowledge risk score as another learning target to be leveraged in the learning process. We implemented two methods, described below and illustrated in Figure 1 (bottom).

1. Teacher-student network (TSNN) adapted from [15].

TSNN is composed of two independent networks: the teacher network ρ and the student network σ, which learn from each other and are optimized iteratively. The objective function of teacher network is: $argmin_\theta \frac{1}{n}\sum_{i=1}^{n} l(\sigma_\theta(\boldsymbol{x_i}), \rho_\theta(\boldsymbol{x_i})) + \pi_T l(z_i, \rho_\theta(\boldsymbol{x_i}))$ and the objective function of student network is: $argmin_\theta \frac{1}{n}\sum_{i=1}^{n} l(\rho_\theta(\boldsymbol{x_i}), \sigma_\theta(\boldsymbol{x_i})) + \pi_S l(y_i, \sigma_\theta(\boldsymbol{x_i}))$, where π_T and π_S are weighting parameters. After convergence, both networks can be used for prediction.

2. Knowledge-enhanced neural network (KENN).

KENN is a modular neural network composed of three modules: knowledge representation network, data representation network, and decision network. The objective

function is defined as: $argmin_\theta \frac{1}{n}\sum_{i=1}^{n}(1-\pi)l(y_i,\sigma_\theta(\boldsymbol{x_i})) + \pi l(z_i,\sigma_\theta(\boldsymbol{x_i}))$, where π is the weighting parameter to adjust the relative knowledge importance.

[KLS#3] Knowledge Injection to Output Labels

Let $s_i = \sigma_\theta(\overline{x_i})$ and denote the predictive score of a pure data-driven model (LR used in this study). We propose knowledge injection into output labels with a meta-learning function φ, where the objective function is $argmin_\theta \frac{1}{n}\sum_{i=1}^{n} l(y_i,\varphi(z_i,s_i))$. In Figure 1 (top right), we illustrate decision fusion using LR as the meta model, which is trained on data learning predictive score and the knowledge risk score.

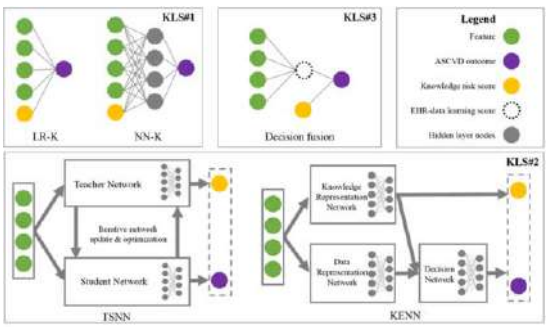

Figure 1. Schematic Representations of KLS Methodologies

Experimental Design

We designed two experiments to explore KLS's capability in dealing with small data and biased data to build accurate and generalizable risk prediction models (Figure 2, EX-1 for small data, EX-2 for biased data). For all studies, we evaluated eight methods: one knowledge-based method (PCE as applying PCE model without modification), two pure data-driven models (LR, and NN implemented as multi-layer perceptron), and five KLS models (LR-K, NN-K, TSNN, KENN, and Decision fusion).

LR, LR-K and Decision fusion were implemented using the Python library 'sklearn'. NN, NN-K, TSNN, and KENN were implemented using the Python library 'keras' with 'theano' backend. We trained each neural network for 50 epochs, with the activation function of softmax and a dropout (of 0.5) layer to avoid overfitting before the last Dense layer. All hidden layers are set up with 64 cells, and the batch size is 32. Finally, we evaluated the prediction performance in terms of AUC (area under curve) based on ROC (receiver operating characteristic), as ROC tries all of the cut-points and plots the sensitivity and specificity.

[EX-1] Learning from Small Data

In the extreme case where we have extremely large amount of data that fully captures information in the knowledge model, KLS would have no advantage over data-driven methods. To the other extreme, where we have extremely small amount of data, knowledge-based methods would be the best as data provides little information. In this experiment, we explored KLS methods with data size between the two extremes. Briefly, for each round, we first randomly selected 30% of instances as the testing data. We then randomly selected a certain proportion of the remaining instances as the training data. All eight models were trained on the training data and evaluated on the testing data by AUC (Area Under the ROC Curve) for risk prediction. We included eight proportion settings: 1%, 2%, 5%, 10%, 20%, 30%, 50% and 70%. For each proportion, 50 rounds of experiments were repeated.

[EX-2] Learning from Biased Data

Bias is unavoidable when using EHR data for building risk prediction models, such as in age, race, and disease severity distribution. Such bias can render the model hard to generalize and apply to clinical practice. In this experiment, we explored the performance of each method in learning from biased data. Since bias is hard to quantify, we intentionally generated data bias to make it easy to evaluate. Briefly, models were trained on a selected sub-cohort (patients with hypertension) and tested on the general cohort. In practice, in each run, we first randomly selected 30% of instances as the testing data. From the remaining 70% of instances, all patients with hypertension were included in the training data. Each of the eight models was trained with the training data and evaluated using the testing data in terms of prediction AUC. Fifty rounds were run.

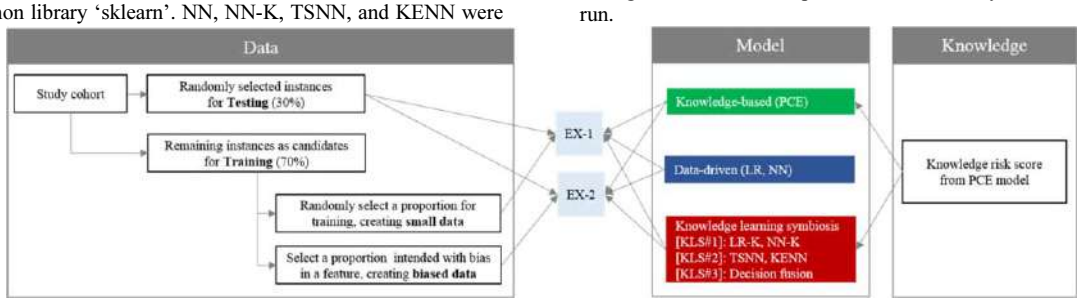

Figure 2. Schematic Representation of Experimental Design

Results

[EX-1]

A knowledge-based model and two purely data-driven models were used for comparison. Five KLS models were included and compared to assess the performance of different knowledge injection strategies. Risk prediction performance was evaluated by calculating average AUC on the testing data from 50 rounds. For TSNN, which was composed of two networks, results from both networks were reported (TSNN-S for results from the student network, and TSNN-T for results from the teacher network). Experiment results for EX-1 are summarized in Figure 3. In all plots, PCE had a stable AUC of around 0.65. Data-driven models (LR and NN) had increasing AUC with the increase of sample size. When the sample size was small (proportion less than 10%), NN had better performance compared to LR, but as the sample size increased, the performance of LR was better than NN. In KLS#1, the line of LR-K overlapped with LR, while the line of NN-K overlapped with NN, suggesting that in our study, knowledge injection to input features cannot improve model performance. Similarly, in KLS#3, the line of Decision fusion

overlapped when the proportion was larger than 1%. These could possibly be explained by the fact that the knowledge risk score was not a strong signal, since it had only an AUC of around 0.65 on the study cohort. Using such a weak signal as feature or label may not be able to increase the performance to a discernible scale.

In KLS#2, however, the performance was different. While TSNN, regardless of TSNN-T or TSNN-N, had unsatisfactory performance, KENN was shown to increase the performance. When the proportion was between 2% and 20%, KENN had the best performance compared to all other methods. When the proportion increased beyond 20%, different methods tended to have similar performance. From these experiments, we concluded that when using small data, KLS had the effect of increasing risk prediction performance. However, this increase was not prevalent for all KLS methods. Among all methods evaluated, only KENN can bring increase to the performance, and this increase was consistent for a number of sample sizes.

[EX-2]

In EX-2 of learning from biased data, we created biased data for training and evaluated the performance on the general data. Here we trained models using patients with hypertension and tested models on the general study cohort. In all runs, the training data (hypertension patients in the cohort after setting aside 30% samples for testing) constituted around 19% of the study cohort, and thus included for comparison the risk prediction performance in EX-1 when the training proportion was 20% as the prediction performance without bias. The results are summarized in Figure 4. All other methods outperformed PCE, suggesting the power of data in training risk prediction models. When trained with unbiased data, LR, NN, KENN, LR-K, decision fusion, and NN-K showed similar performance, suggesting that 20% of unbiased data is sufficient to capture features from knowledge models and that all methods, if properly trained, can have comparable performance. This, however, changed when the models were trained with biased data (bars with dense patterns). Two KLS methods: KENN and LR-K, showed better prediction AUC compared to both data-driven methods, suggesting that KLS can benefit learning from biased data, and increase model generalization. Again, KENN had the best performance among all models, proving its success as a KLS model for learning from biased data.

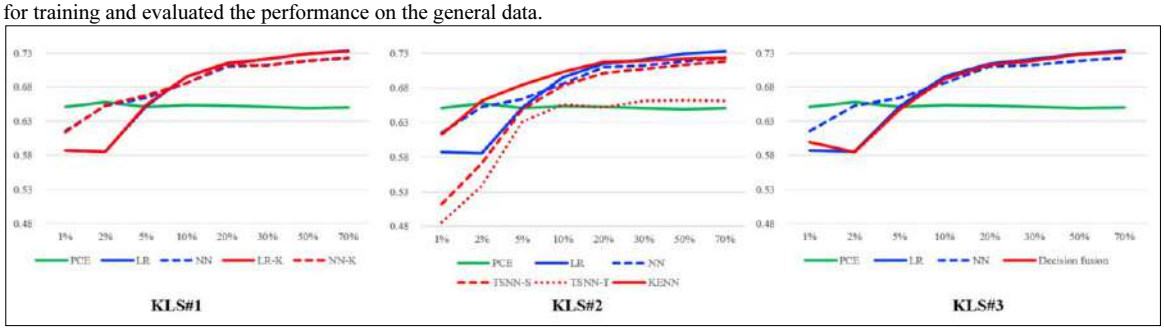

Figure 3. Performance comparison of learning from small data in EX-1 using mean AUC. The y-axis shows the mean AUC. Three plots were generated to show the performance of different KLS categories. In all plots, the knowledge-based model was colored green, data-driven models were colored blue, and KLS models were colored red.

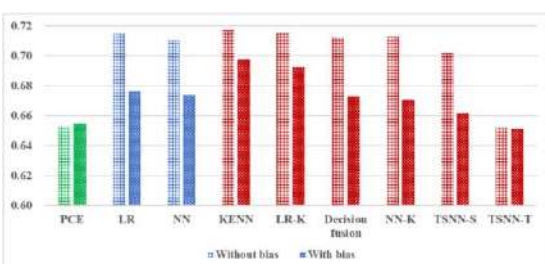

Figure 4. Performance comparison of learning from biased data in EX-2 using mean AUC. The y-axis shows the mean AUC. Knowledge-based model, data-driven models, and KLS models were plotted in green, blue, and red, respectively. Performances while trained with biased data was shown as bars with dense pattern, while performances trained with unbiased data was shown as bars with sparse pattern.

Discussion

Deep Learning in EHR Analytics

Recently, healthcare analytics have been moving its focus from well-designed prospective registry studies or randomized clinical trials toward gathering real-world evidence from EHR data. EHR data is accumulating at an amazing speed, and has some properties compared to traditional healthcare data: (1) it is collected unintentionally and includes information from all aspects of clinical practices; and (2) it is highly heterogeneous. These properties, data complexity and heterogeneity, attract researchers' attention to deep learning techniques [16]. Despite the promising results obtained from deep EHR analysis, there remain several unsolved challenges, and as pointed out in [17], data volume and data quality are the two key issues. After looking into the data issues of our local EHR repositories, we summarized the major problems to overcome in EHR analytics as: (1) learning from small data; and (2) learning from biased data. Therefore, we proposed the KLS framework to address the two problems. Experimental results demonstrated that KLS can address the problems by increasing model generalization and robustness.

Transfer Learning for KLS

Our proposal of knowledge-learning symbiosis is from an application perspective, as a way to leverage knowledge-based and data-driven analytics to improve clinical decision support. Technically, similar topics include transfer learning [18] and domain adaptation [19]. Transfer learning is a technical domain that focuses on using knowledge gained while solving one problem for a different, but related problem. It calls for less sample and less learning time to solve the new, yet related problem and is thus related to our target of learning from small and biased data. Domain adaptation is a research field associated with transfer learning. It is useful when we have a

well-performing model, trained from a source data distribution, and aim to build a model on a different, but related target data distribution. This is similar to our target of learning from biased data. Both transfer learning and domain adaptation are broad research domains with a few common used methodologies. An example practice of transfer learning is in medical imaging [20], which utilizes transfer learning by using medical images to fine-tune the convolutional neural network, trained with general-purposed ImageNet images. Another example is that logic rules are transferred into neural networks, followed by refining the neural networks using a few examples [21]. Many domain adaptation methods include space projection, and not necessarily re-training the model. In our study, we followed the idea of transfer learning and proved its usefulness in healthcare analytics. However, since our knowledge model was relatively simple (a Cox regression model) with a limited number of features, we did not use complex methodologies as designs. In the future, when we have more expressive knowledge like logic rules, we would consider more complex ways of encoding knowledge, and leverage commonly-used, transfer learning methods for KLS purposes.

Small, High-Quality Data or Large Noisy Data?

There are a few questions we can ask in the big data era. Is big data always better than small data? Can the problem of noise be solved when we have sufficient data? Which would be better: small high-quality data or large noisy data? Our results provide us a glimpse of the comparison between small data and big data. In Figure 3, all models have better performance when the training set size increases, but the increase gradually becomes smaller. The results illustrate that for these machine learning methods, the importance of training set size decreases when the size is already large. Another insight from our result comes from a comparison between EX-1 and EX-2. In EX-2, we intentionally created biased data, which can be regarded as a kind of data noise. We can refer to the models' performance trained on 19% of biased data and locate the proportion of unbiased data used in EX-1 that has achieved comparable performance. For KENN, 7% of unbiased data can achieve equivalent performance. For LR, NN, LR-K, NN-K, and Decision fusion, the numbers are 7%, 7%, 10%, 7%, and 7%, respectively. This suggests that compared with using noisy data, using high-quality data can build a model of comparable performance using less data. From different understanding of the questions, two approaches can be taken for future study: learning from small data and learning from big, but noisy data.

Conclusions

In this study, we proposed knowledge learning symbiosis as a framework to address the challenge of learning from small data and biased data. For experiments, we built localized prediction models using regional EHR repositories with the help of a well-established, knowledge risk model. The performance results were promising, which demonstrated that knowledge-learning symbiosis methods can increase risk prediction performance, both on small and biased data, compared to purely data-driven methods, especially for KENN which was first introduced in this study and showed the best performance among all methods.

Abstract

Several definitions of chronic diseases exist. The objective is to reuse a nationwide medical-administrative database (PMSI) to estimate the lifespan of diagnostic codes, hence the chronicity of the corresponding diseases. We analyzed 162 million inpatient stays from 2008 to 2014, and estimate the lifespan of every ICD-10 code for every patient, identified by a unique imprint. We calculated 200 indicators for different time and survival values, and selected the ones that maximized the area under the ROC curve (AUC) drawn by comparison against 4 chronic disease classifications: CCI, ALD, result from the analysis of ICD-10 labels, and a handmade list. The best indicator was the time to reach a survival of 4.5%. It enables to get the following AUC: 78.9% compared with CCI, 90.3% compared with ALD, 75.1% compared with labels analysis, and 91.5% compared with the handmade list. This indicator enables to classify 23,349 ICD-10 codes from "most chronic" to "most acute". The 100 most chronic codes are listed.

Keywords:
Chronic disease, Patient discharge, Big data.

Introduction

Chronic conditions are the world epidemic of the 21st century, accounting for about two-third of all deaths [1–4]. For the WHO, a chronic condition is of long duration and generally slow progression [5]. Other definitions propose a chronic/non-chronic classification according to time thresholds which vary from 3 to 12 months [2,6]. In France, the compulsory health insurance provides with a list of 30 categories of chronic conditions, called "ALD List" [7]. In the USA, the American Agency for Healthcare Research and Quality publishes the Chronic Condition Indicator (CCI) which provides a chronic/acute status for all ICD-10-CM codes [8].

The French nationwide hospital discharge database (PMSI) comprehends all the impatient stays from both profit and non-profit hospitals. This exhaustive nationwide database comprehends about 25 to 30 million inpatients stays per year [9]. For each inpatient stay, the data notably comprehend the ICD-10 principal and secondary diagnostic codes, the anonymized date of the stay, and a unique cryptographic patient identifier. This identifier enables to follow the readmissions of any patient without disclosing his identity, even in different hospitals. The PMSI data are initially collected for billing purposes.

Our objective is to reuse the big data [10,11] from the PMSI to estimate the temporal persistence of the ICD-10 codes of French patients, in order to propose a ranking of the ICD-10 codes according to their chronicity.

Methods

Population of interest

We processed the anonymous data from the French PMSI from 2008 to 2014, which comprehends 162 million stays after exclusion of sequential treatments (e.g. hemodialysis, radiotherapy, etc.). An authorization was issued from the French agency for data protection (CNIL) [9].

Computation step

The stays were sorted by inpatients identifiers thanks to their unique imprints. Patients who wished to remain anonymous (e.g. for an abortion) accounted for 0.4% of all stays and were excluded. The sample then comprehended 46 million patients, 161 million inpatient stays, and 503 million ICD-10 codes.

For each inpatient, we listed all the codes found during the observation period (2008-2014), then we looked when they appeared and disappeared, to calculate their lifespans. We assumed the date of every diagnostic code was the first day of the inpatient stay. Then, if a code was first found in a stay at date *t1* and last found in a stay at date *t2*, its lifespan was *(t2 – t1 + 1)*. In order to simplify computations, we did not implement right-censoring. A code "disappeared" when it was not followed by itself (or any code having the same 3 first digits) within 720 days (this method was determined after several tests, using a 10% training sample). For instance, "J18.1" and "J18.9" both relate to "J18". For a given patient, the presence of "J18.9" will extend the lifespan of "J18.1". From our experience, those codes variations are more often due to inaccurate coding than patient's disease evolution.

This way, for every ICD-10 code and every patient, we could compute a duration. Those durations were plotted through survival curves which, in the absence of censoring, correspond to empirical distribution functions of the durations [12]. From those curves, we could compute the survival at a given time

(we tested 100 times, from 1 to 100 days), or the time to get a certain survival (we tested 100 survival rates, from 50% to 0,5%). For each ICD-10 code, we could then store 200 values.

We used the R programming language with the additional packages data.table, survival, and proc [13].

Validation step

Overview

The external validation was performed against 4 lists of diseases, presented hereafter:

- "**CCI**": list of chronic ICD-10-CM codes provided by the American Agency for Healthcare Research and Quality published in 2017 [4,8], and mapped to French ICD10 codes.
- "**ALD**": list of 30 "long duration diseases" provided by the French compulsory insurance in 2015, and mapped to 122 3-digit ICD-10 codes [7]
- "**ICDlabel**": the result from text analysis of the wordings of all French ICD-10 codes [14,15]
- "**Handmade100**": a list of 100 chronic diseases identified from the ICD-10 from our knowledge.

Preparation of the "CCI" list

The 2017 American CCI provides the chronicity of 64,955 ICD-10-CM codes [4,8] while the 2017 French ICD-10-FR has 40,519 codes. A mapping between both classifications was realized as follows. For 6,003 codes, a direct matching was possible. Then, when a French code did not have any match, the ICD-10-CM codes starting with the same characters were considered. For a given ICD-10-FR code, if all the corresponding codes were chronic or non-chronic in the CCI classification, the French code could be classified as chronic or non-chronic. If the corresponding codes were of mixed type, the French code couldn't be classified. We retrieved 11,034 codes, 10,487 of which were found in our population. We kept the 4,323 chronic codes and selected the 4,323 most frequent non-chronic codes to obtain a total list of 8,626 codes.

Preparation of the "ALD" list

Among the 23,349 codes of our database, 1,733 were matching the 122 3-digits codes from the official 2015 ALD list [7]. We made the simple assertion that all the conditions which were not in the ALD list were non-chronic.

Preparation of the "ICDlabel" list

We searched for the keywords "acute" and "chronic" in the free-text labels of the 2017 French version of ICD-10 [14,15]. We removed all the results which contained terms like "sub-acute", "not specified as acute or chronic" or "antecedent of acute/chronic", etc. We then obtained 283 "acute" codes and 236 "chronic" codes. Among acute codes, we only kept the 236 most frequent ones.

Preparation of the "Handmade100" list

For each ICD-10 code of the database, we calculated how many patients had this code at least once, in order to get the cumulated prevalence of those codes during the period. We sorted the codes by decreasing prevalence, reviewed them, and selected the codes for which we fully agreed with the CCI classification, until we got 100 chronic and 100 acute codes.

Indicators selection

For this step, the statistical individual was the patient. The aim was to discriminate "chronic" codes from "acute" codes (other codes were ignored). For each of the 200 available indicators, we draw a ROC curve [16] against each of the 4 validation lists and calculated the AUC. For each of the 4 validation lists, we then selected the indicator that obtained the highest AUC. With the best indicator, we then selected the threshold giving the closest values of sensibility and specificity (respectively *Se* and *Sp*, which are only provided for descriptive purposes). In some cases, a sensibility analysis was also performed, as described hereafter.

Results

Example of survival curve

For a typical chronic condition, such as end-stage renal disease (Figure 1), the survival curve begins with a moderate drop, then decreases slowly. The drop corresponds to the patients in which either the code is present once, or our algorithm failed to detect any recurrence of the code. The survival at the end of our study is always zero as we did not implement right-censoring.

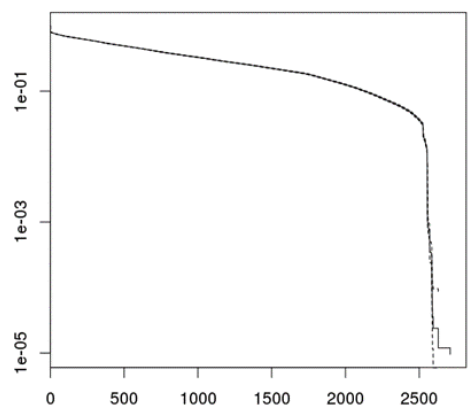

Figure 1. Survival curve of a chronic code, N180 (end-stage renal disease; time in days; Y axis in logarithmic scale)

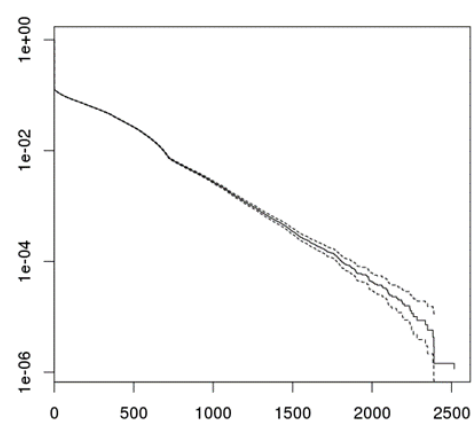

Figure 2. Survival curve of an acute code, E559 (vitamin D deficiency; time in days; Y axis in logarithmic scale)

For a typical non-chronic condition, such as vitamin D deficiency (Figure 2), the initial drop is important, and the survival rate rapidly approaches zero.

It is worth noting that these curves do not show the actual duration of the diseases, but only enable to estimate their chronicity.

Indicator selection

Overview

In this step, for each validation list, and for each of the 200 indicators, we draw a ROC curve and selected the indicator associated with the highest AUC value.

Indicator selection for "CCI"

Compared with the "CCI" list (4,323 chronic codes, and 4,323 acute codes), the best indicator is the time required to reach a survival of 4.5%. It obtains an AUC of 0.789 [0.780; 0.799] (Figure 3). The best point, with a threshold of 182 days, gets a specificity of 72.4% and a sensitivity of 72.7%.

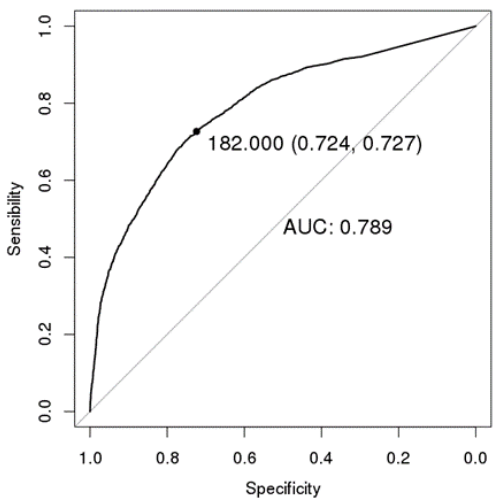

Figure 3. ROC curve of the indicator "time until survival=4.5%" against the "CCI" validation list

A first sensibility analysis, restricting the evaluation to the 6,003 codes (over 8,646) having an exact match between ICD-10-FR and ICD-10-CM, enables to select the same indicator too, with AUC=0.8, Sp=73.2% and Se=73.3% for a threshold of 218 days.

In a second sensibility analysis, we only included the codes that were used in only *n* patients, and reran the analysis. With the threshold n≥10, the AUC rises up to 0.817 (with the same indicator). For a threshold n≥1000, the AUC rises up to 0.83 (with another indicator, the survival rate at 85 days).

The third sensibility analysis consisted of including all the 10,487 codes from the CCI data. We then obtain an AUC of 0.796 with the same indicator, and Sp=73.2% and Se=73.4% for a threshold of 174 days.

Indicator selection for "ALD"

Compared with the "ALD" list (1,733 chronic codes, and 21,616 non-chronic codes), the best indicator is the time required to reach a survival of 7%. It enables to get an AUC of 0.903 [0.897; 0.909] (Figure 4). The best point, with a threshold of 168 days, gives Sp=Se=82.7%.

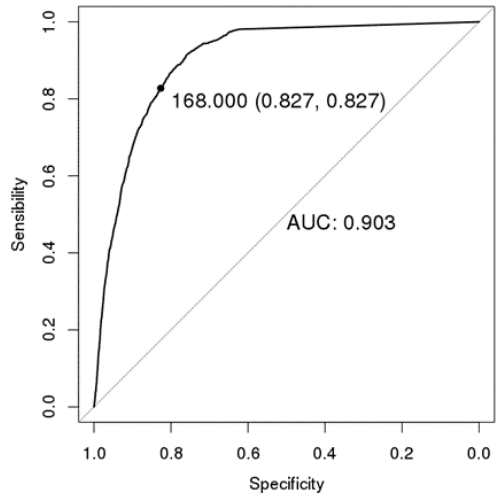

Figure 4. ROC curve of the indicator "time until survival=7%" against the "ALD" validation list

The sensibility analysis consisted of choosing manually the same indicator as previously, namely the time required to reach a survival of 4.5% (instead of 7%). This indicator obtains an AUC of 0.899, and the best threshold (322 days) enables to reach Sp=Se=82.2%.

Indicator selection for "ICDlabel"

Compared with the "ICDlabel" list, the best indicator is the time required to each a survival of 4.5%. It obtains an AUC of 0.751 [0.707; 0.794]. The best point, with a threshold of 210 days, gives Sp=Se=61.9%.

The sensibility analysis consists of comparing this list of codes to the "CCI" list. The comparison between both lists leads to a specificity of 81.1% and a sensibility of 85.5%. By removing the codes from the "ICDlabel" list which are not in the "CCI" list, we obtain an AUC of 0.774 for the same indicator, and the best threshold is 200 days, with Se=70.6% and Sp=70.1%.

Indicator selection for "Handmade100"

Compared with the "Handmade100" list (100 chronic codes, and 100 acute codes), the best indicator is the time required to reach a survival of 4.5%. It obtains an AUC of 0.915 [0.876; 0.954]. The best point, with a threshold of 258 days, enables to reach Sp=Se=84%.

The first sensibility analysis consisted of refactoring this list by exact matching with the CCI list, and not by expert-operated construction, for both the chronic codes list, and the acute codes list. We then obtain an AUC of 0.81 with the same indicator, and the threshold of 317 days enables to reach Sp=Se=74%.

The second sensibility analysis did the same but with the 100 less frequent chronic and acute codes. We then obtain AUC=0.911 for the same indicator, and the threshold of 102 days leads to Sp=85% and Se=86%.

List of "chronic" ICD-10 codes

The four validation steps enabled to identify that, among the 200 indicators, the indicator "time until survival=4.5%" was the most accurate, as it was nearly always selected regarding the AUC criteria. The ICD-10 codes were sorted by decreasing value of this indicator, which enabled to select the 100 "most chronic" conditions, which are presented in Table 1.

Table 1. List of top-100 chronic ICD-10 codes

#	Code	Wording
1	Q861	Fetal hydantoin syndrome
2	E761	Mucopolysaccharidosis, type II
3	D595	Paroxysmal nocturnal hemoglobinuria
4	M834	Aluminum bone disease
5	E763	Mucopolysaccharidosis, unspecified
6	D800	Hereditary hypogammaglobulinemia
7	E760	Mucopolysaccharidosis, type I
8	M0511	Rheumatoid lung disease with rheumatoid arthritis of shoulder
9	E849	Cystic fibrosis, unspecified
10	Z941	Heart transplant status
11	Z942	Lung transplant status
12	E840	Cystic fibrosis with pulmonary manifestations
13	E848	Cystic fibrosis with other manifestations
14	N180	End stage renal disease
15	G243	Spasmodic torticollis
16	Z943	Heart and lungs transplant status
17	G245	Blepharospasm
18	G513	Clonic hemifacial spasm
19	G241	Genetic torsion dystonia
20	G242	Idiopathic nonfamilial dystonia
21	E841	Cystic fibrosis with intestinal manifestations
22	Z948	Other transplanted organ and tissue status
23	D570	Sickle-cell anemia with crisis
24	Z9481	Bone marrow transplant status
25	E710	Maple-syrup-urine disease
26	E711	Other disorders of branched-chain amino-acid metabolism
27	G244	Idiopathic orofacial dystonia
28	Q812	Epidermolysis bullosa dystrophica
29	C83	Non-follicular lymphoma
30	M8336	Adult osteomalacia due to malnutrition, leg
31	N16	Renal tubulo-interstitial disorder in diseases classified elsewhere
32	D86	Sarcoidosis
33	Z944	Liver transplant status
34	E762	Other mucopolysaccharidosis
35	B676	Echinococcus multilocularis infection, other and multiple sites
36	Z940	Kidney transplant status
37	E752	Other sphingolipidosis
38	D562	Delta-beta thalassemia
39	D571	Sickle-cell disease without crisis
40	M0508	Felty's syndrome, other joints
41	G120	Infantile spinal muscular atrophy, type I [Werdnig-Hoffman]
42	M0720	Psoriasic spondylopathy, multiple sites
43	E740	Glycogen storage disease
44	M05	Rheumatoid arthritis with rheumatoid factor
45	E21	Hyperparathyroidism and other disorders of parathyroid gland
46	M349	Systemic sclerosis, unspecified
47	M340	Progressive systemic sclerosis
48	Z491	Renal dialysis
49	N18	Chronic kidney disease (CKD)
50	M0758	Enteropathic arthropathies, other joint
51	W443	Foreign body, eye
52	E661	Drug-induced obesity
53	M0503	Felty's syndrome, wrist
54	D839	Common variable immunodeficiency, unspec.
55	M058	Other rheumatoid arthritis with rheumatoid factor
56	M341	CR(E)ST syndrome
57	E662	Morbid (severe) obesity with alveolar hypoventilation
58	M0801	Unspecified juvenile rheumatoid arthritis, shoulder
59	B24+0	Pre-AIDS
60	D812	Severe combined immunodeficiency with low or normal B-cell numbers
61	M9411	Relapsing polychondritis, scapular region
62	B675	Echinococcus multilocularis infection of liver
63	M0833	Juvenile rheumatoid arthritis (seroneg.), wrist
64	Q819	Epidermolysis bullosa, unspecified

Discussion

In this paper, we proposed an automated method to identify chronic conditions from ICD-10 codes. We validated the results against four different classifications, and obtained good and stable results. We finally proposed a list of 100 "most chronic" ICD-10 codes.

French rules specify that a diagnostic code should be used when the disease has had a significant impact on the medical management of the patient, which means not only the disease was still active, but also the disease had to be actively treated during the inpatient stay. According to that definition, our work should not enable to identify chronic conditions, but conditions which induce a chronic need for care.

We provide a ranking of the ICD-10 codes according to their chronicity instead of a binary classification. It is possible to calculate and compare the indicator for different periods or different inpatient populations. Results can be used for many applications without the need for a threshold.

Our work is based on years of nationwide data validated by physicians. This database does not comprehend ICD-9 codes. It does not rely on patient self-report, is not limited in time like a cross-sectional study, is not limited to local morbidity registries and does not depend on the judgment of a group of experts.

As our data relate to inpatient stays, codes for non-severe diagnostics are scarce. There is poor tracking, and stays can be several years apart. The evolution of a disease can be different between outpatients and inpatients, e.g. the reason for the admission can be a surgery that cures the chronic condition. The data may be biased due to per-service pricing, as coders pay more attention to codes that bring money to their hospital.

The CCI classification did not perfectly fit our task. It has additional conditions to define whether a code is a disease or not, thus a code can be chronic without being a chronic condition. Our population consisted of inpatients, while the CCI is determined for all patients. As the CCI is made for the American population, some discrepancies might result from differences between French and American morbidities.

The list of the French ALD was not a very good control list either, as it only relates to few chronic conditions, which are far better coded in the PMSI than other conditions. It gives an estimate of how our indicator would perform if the coding was perfect.

Conclusion

We designed a quantitative indicator of the chronicity of the ICD-10 diagnostic codes by reusing 161 million stays of the French hospital nationwide discharge database from 2008 to 2014. This indicator has positive and negative likelihood ratios of 2.63 and 0.38 respectively when compared to the CCI from the AHRQ, and of 4.78 and 0.21 respectively when compared to the ALD from the French public health insurance. This indicator enabled to rank 23,349 ICD-10 diagnostic codes according to their chronicity.

Abstract

The identification of brain morphological alterations in newly diagnosed PD patients (i.e. 'de novo') could potentially serve as a biomarker and accelerate diagnosis. However, presently no consensus exists in the literature possibly due to several factors: small size cohorts, differences in segmentation techniques or bad control of false positive rates. In this study, we use the CAT12 pipeline, to seek for morphological brain differences in gray and white matter of 66 controls and 144 de novo PD patients from the PPMI database. Moreover, we search for subcortical structure differences using the VolBrain pipeline. We found no structural brain differences in this de novo Parkinsonian population, neither in tissues using a whole brain analysis nor in any of nine subcortical structures analyzed separately. We conclude that some results published in the literature may appear as false positives and we contest their reproductibility.

Keywords:

Biomarkers, Magnetic Resonance Imaging, Brain

Introduction

Parkinson's Disease (PD) is a complex neurodegenerative disorder that affects more than 10 million people worldwide [1]. It is mainly characterized by the depletion of dopaminergic neurons situated in the substantia nigra that consequentially disturbs the functions of subcortical nuclei and triggers cortical neuropathological changes causing a plethora of heavily disabling motor and non-motor symptoms [2].

In general, the diagnosis of PD takes place after the manifestation of motor symptoms, which have been found to occur once 50 % of nigrostriatal neurons are lost and dopamine levels are dropped by 80 % [2], [3], creating an urgent need to detect PD biomarkers at the earliest pre-clinical stages of illness possible [4].

The study of morphological brain differences between pathological and healthy groups could potentially identify key regions affected during the PD prodromal phase to better understand PD pathophysiology and its treatment. Magnetic Resonance Imaging (MRI) has positioned itself as a valuable tool for the non-invasive study of the brain's structure. Many automated non operator-dependent techniques have been developed for the analysis of structural MRI data. Voxel-based morphometry (VBM) is the most popular, it allows the detection of subtle morphometric group differences at voxel level [5].

In order to elucidate the nature of morphological differences in de novo PD patients, we investigated 210 subjects from the PPMI (Parkinson Progressive Markers Initiative) through both 1) the well-established Computational Anatomy Toolbox (CAT12) (University of Jena) via the current version of the Statistical Parametric Mapping (SPM12) software and 2) via a new online platform: volBrain [6]. Both pipelines have complementary strengths that are exploited in this study: volBrain performs state of the art quality segmentation of subcortical nuclei [7] and CAT12 facilitates group analysis. Furthermore, we looked for quantitative differences between the tissue classification performed by the two approaches, both including partial volume estimation.

Methods

It is well-known that gathering large cohorts of subjects is a time and resource-consuming task. This is why several efforts have been made by the community to generate databases that benefit for more than one research group. The PPMI (Parkinson Progression Markers Initiative) project is a longitudinal study that gathers data from 35 centers that follows PD patients for five years. The database is openly available for researchers and contains, among other clinical test results, structural MRI images at baseline for 412 patients and 182 healthy subjects.

The scans being heterogeneous, we chose to pool data acquired with the same acquisition parameters, notably magnetic field and scanner manufacturer, to eliminate any additional sources of bias. As a result, our study included 144 de novo PD patients (age: 61.30 ± 9.06; sex: 53 F, 91 M) and 66 healthy controls (age: 60.12 ± 11.39; sex: 23 F, 43 M) from the PPMI database. The structural T1-weighted MRI images extracted were acquired with a 3T Siemens Trio Tim scanner with repetition time (TR) = 2300 ms; echo time (TE) = 2.98 ms; flip angle = 9 degrees; field of view (FOV) = 240 x 256 mm; matrix size : 240 x 256; thickness = 1mm. We note that although T2-weighted images are generally prefered to the delineation of brain structures in neurodegenerative diseases, the available scans on PPMI are provided with low-resolution and thus barely suitable for VBM studies.

Using the CAT12 pipeline

Imaging data were first analyzed using the CAT12 toolbox included in SPM12. All 3D T1-w MRI scans follow a pre-processing protocol including intensity normalization, bias and noise-correction with the Spatially Adaptive Non-Local Means (SANLM) filter introduced in [8] that removes spatially varying noise while maintaining edges. Then the images were spatially normalized using an affine and non-linear (DARTEL and Geodesic Shooting) registration to a reference template brain. Tissue segmentation served to classify the MRI scans into gray matter (GM), white matter (WM) and cerebrospinal fluid (CSF) components. CAT12 integrates a classical Markov Random Field and the Adaptive Maximum Posterior (AMAP) technique that reduces the dependency on Tissue Probability Maps (TPM). In addition, the segmentation approach uses a Partial Volume Estimation (PVE), taking the three pure tissue classes

as input and estimating two additional mixed classes: GM-WM and GM-CSF. This allows for more precise segmentation as single voxels are likely to contain more than one tissue type. Next, the total intracranial volumes (TIV) were estimated for each subject and the segmented images were modulated by scaling with the amount of volume changes due to non-linear spatial registration, so that the total amount of grey matter in the modulated image remains the same as it would be in the original image.

The resulting images, appearing in Figure 1, were smoothed with an isotropic Gaussian kernel (8mm), and ready for statistical analysis.

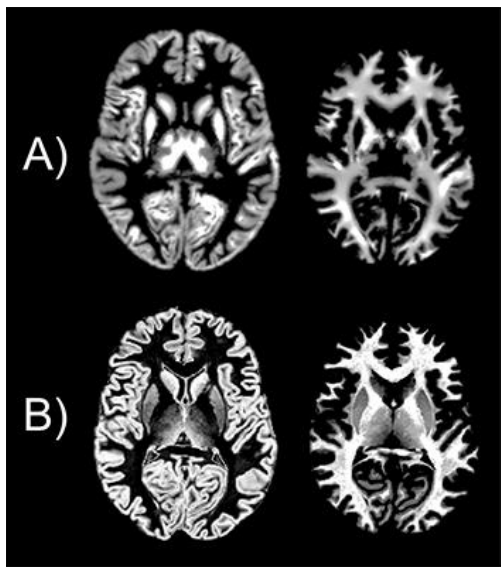

Figure 1– A) CAT12 GM and WM segmentations (modulated) B) volBrain GM and WM segmentations (raw).

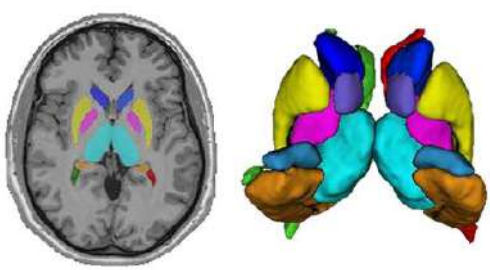

Figure 2– Segmented structures using volBrain.

Using the volBrain pipeline

In parallel, imaging data were analyzed via the volBrain online platform. This system not only provides a state-of-the-art segmentation of the brain tissues (WM, GM, CSF and TIV) (Figure 1), but also segments brain regions like the cerebrum, cerebellum and brainstem; the ventricules; and GM structures such as the putamen, the caudate, the globus pallidus, the thalamus, the hipocampus, the amygdala, and the accumbens [9], as shown in Figure 2.

The multi-template method employed to segment the above mentioned structures considers non-local label fusion schemes using a library built from the manual segmentation of 50 subjects.

The segmentation performed by volBrain provides results in the native and MNI space along with a report containing normality bounds corresponding to the age and sex of the considered subject. These bounds were estimated from the IXI dataset containing 600 normal subjects covering most of adult lifespan.

The pipeline starts by some pre-processing steps. The image is denoised using a SANLM filter, goes through a rough inhomogeneity correction using the N4 method, is registered to the MNI space with a linear affine transformation, goes though a fine SPM based inhomogeneity correction and intensity normalization. Then, segmentation takes place. Tissue classification is obtained by the TMS method that robustly estimates the mean values of the different tissues by excluding partial volume voxels from the estimation jointly with the use of an unbiased robust mean estimator. Partial Volume Coefficients (PVC) are computed from the mean values and completely leave aside tissue probability maps. Next, GM and WM are divided into cerebrum, cerebellum and brainsteam, discriminating between the two hemispheres; and last, subcortical structure segmentation is performed.

VolBrain results analysis by CAT12

Since some subcortical structures of the brain are impacted by PD, we decided to do VBM analysis for the regions provided by volBrain. To do this, we brought volBrain output images to the template space of CAT12 by applying the forward deformation DARTEL field. Once in the same space, the segmented images were used as input for the subsequent statistical analysis. For tissue segmentation analysis (GM & WM), corresponding volBrain's PVC maps were, similarly to CAT12's PVE maps, spatially smoothed with a 8mm kernel.

Statistical analysis

We chose to employ a two-sample T-test to compare the CAT12 modulated tissue maps (GM and WM) of patients versus controls with a general linear model (GLM) where age, sex, and TIV were entered as covariates. The same test was effectuated on volBrain's PVC maps.

A recent study investigating the high rate of false positive present in VBM studies recommends the use of the same group size to detect morphological differences between two groups [10]. Following this recommendation, we repeated our analysis five times to compare the tissue maps of 66 controls versus 66 randomly selected patients using sampling with replacement technique. Their age and sex characteristics are summarized on Table 1.

Table 1– Characteristics of the original study population and the 5 sub-samples of patients equal in size to the control group

	Age	Sex
Controls	60.1 ± 11.4	43 M, 23F
Patients	61.3 ± 9.1	91 M, 53F
PD sample 1	61.0 ± 8.7	40 M, 26F
PD sample 2	60.6 ± 9.7	41 M, 25F
PD sample 3	61.7 ± 9.5	44 M, 22F
PD sample 4	61.9 ± 8.7	38 M, 28F
PD sample 5	59.6 ± 8.6	38 M, 28F

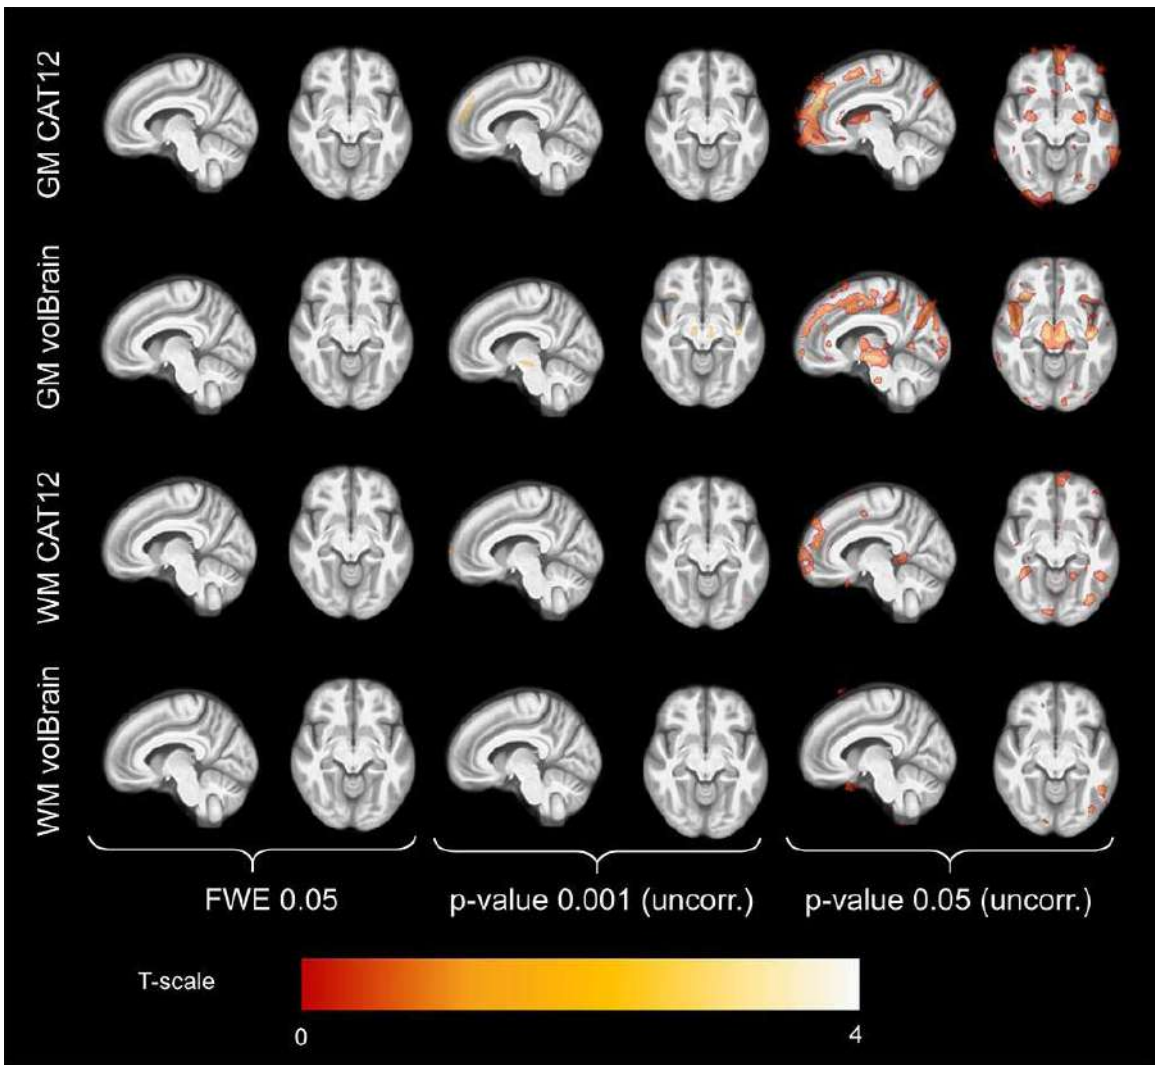

Figure 3– Comparison of PD patients vs controls. Clusters detected for GM an WM diminution in patients using CAT12 and volBrain for different statistical thresholds. The selected slices in the template's MNI space are x=99 and z=64.

Results

When choosing a p-value of 0.05 with Family Wise Error (FWE) correction for multiple comparisons, no voxels survive the difference analysis between PD patient and control groups with tissue map computed with CAT12 or volBrain. In order to replicate some literature results (exploratory study), we decreased the statistical threshold to $p<0.001$ and $p<0.05$ and refrained from any type of correction. Several clusters were then found in PD patients showing volume decrease both in GM and WM as seen in Figure 3.

Also, two-sample T-test comparisons of each independent subcortical structure (computed by volBrain) failed to detect any differences in GM and WM contents $p<0.05$ while FWE corrected. Differences were found in the caudate nucleus, the hipocampus and the putamen for an uncorrected p-value of 0.001.

"Small volume" analysis in SPM12 was used as well to study possible morphometric changes in the substantia nigra, key structure in PD research, using volBrain maps. We observed that differences were only present in gray matter for an uncorrected p-value of 0.001 and did not survived multiple comparison correction.

For all of the 5 new equal size sub-populations (see Table 1), no differences were found in GM or WM for $p< 0.05$ FWE corrected, whilst several significant clusters appeared for an uncorrected p-value of 0.001, esspecially in the frontal cortex for gray matter.

Discussion

Using two recent approaches for accurate segmentation of tissues (CAT12 and volBrain) and subcortical structures (volBrain) we failed to detect robust structural differences in de novo PD patients and healthy controls. We took special care to consider a relatively large cohort of subjects, consider the

effects of an unbalanced number of patients and controls and correct for multiple comparisons. We controlled for multiple comparison using FWE approach, which is known nevertheless to produce some false positives [11]. Following these precautions, no morphological differences were found in PD patients, neither on whole brain GM and WM group analysis or on the analysis of several subcortical structures separately.

In the literature, several studies have reported structural brain differences in PD patients compared to controls. However, these findings tend to be contradictory. In studying a different PD population than in our study, Summerfield and colleagues detected gray matter loss on the right hipocampus, the left anterior cingulate region and the left superior temporal gyrus (p=0.001 uncorrected) in PD patients (n= 13) compared to controls (n=13) [12]. Nyberg and colleagues found an augmentation in the volume of the hipocampus (p=0.03 uncorrected) of PD patients (n=21) and shape deformations of the right accumbens nucleus (p=0.005 uncorrected) compared to controls (n=20) [13]. Radziunas and colleagues observed that PD patients (n=28) with sleep disturbances had bigger ventricules and smaller hipocampus (p-FDR<0.05) than healthy controls (n=28) [14].

Similarly to our study, some VBM studies used the PPMI database and reported structural differences in PD patients. Jia and colleagues noted gray matter losses (p-FWE<0.001) in the fronto-parietal areas and the caudate nucleus, as well as an increase in the size of the limbic and paralimbic areas, the globus pallidus and the putamen of PD patients (n=89) [15] versus controls (n=55) using SPM8.

This lack of consensus on the morphological differences present in de novo PD patients may be due to a variety of factors.

Some studies were carried out on small cohorts, no more than 60 subjects in total, so one may argue that the inconsistencies could be resolved with a larger cohort more representative of the population.

Although, in [10], it was brought to light that sample size does not appear to influence false positive rate, a small sample may incorrectly represent a pathological population, hindering the reproductibility of results.

We note that there is a wide variety of softwares for pre-processing MRI images (i.e. SPM, Freesurfer, FSL), all using different techniques that will inevitably influence the final statistical results as proven by [16] on the study of Multiple Sclerosis. By combining the latest improvements on VBM analysis present in CAT12 (notably denoising and partial volume estimation) with the state of the art segmentations of volBrain [7] we sought to reduce estimation bias considerably.

Finally, correction for multiple comparison is vital to reduce the false positive rate, even if it is not perfect to hope providing robust and reproducible results [11]. Exploratory studies, which use lenient statistical thresholds, could be interesting to indicate some trends in the observed population, that should be confirmed by more robust studies. Then, in our exploratory action (p<0.001 uncorrected) we were able to reproduce some GM results reported in [17]. In the case of [15], the tests were FWE corrected, but the the study was effectuated on VBM8 while, according to [18], the CAT12 toolbox can contribute to more robust detection compared to VBM8.

Regarding the differences we observed between the tissue classification with CAT12 versus volBrain, raw volBrain's PVC maps seem to better distinguish the presence of gray and white matter in the subcortical nuclei. However, as in this study, no morphological robust differences were found between PD patients and controls, a more in depth investigation would be necessary to pertinently test the performances of both methods of partial volume estimation.

In order to further this research, other morphometric methods should be explored, notably Surface Based Morphometry (SBM) and Deformation Based Morphometry (DBM) [17].

Conclusions

In sight of the lack of morphological differences, we suspect that early PD biomarkers may lie on the physiological properties of the Parkinsonian brain and could be investigated through quantitative MRI techniques.

Finally, we reinforce the message that VBM is a delicate technique involving many parameters that should be handled with care to avoid false positive influencing the final results.

Abstract

Predicting the risk of mortality for patients with acute myocardial infarction (AMI) using electronic health records (EHRs) data can help identify risky patients who might need more tailored care. In our previous work, we built computational models to predict one-year mortality of patients admitted to an intensive care unit (ICU) with AMI or post myocardial infarction syndrome. Our prior work only used the structured clinical data from MIMIC-III, a publicly available ICU clinical database. In this study, we enhanced our work by adding the word embedding features from free-text discharge summaries. Using a richer set of features resulted in significant improvement in the performance of our deep learning models. The average accuracy of our deep learning models was 92.89% and the average F-measure was 0.928. We further reported the impact of different combinations of features extracted from structured and/or unstructured data on the performance of the deep learning models.

Electronic Health Records, Machine Learning, Deep Learning

Introduction

In 2016, the top two death causes were heart disease and cancer, accounting for 44.9% of all deaths in that year [1]. Based on a recent report from the American Heart Association, cardiovascular disease and stroke are accounted for tremendous economic and health-related burdens in the United States and worldwide [2]. Acute myocardial infarction (AMI) is an event of myocardial necrosis caused by the unstable ischemic syndrome. It is the leading cause of mortality worldwide [3]. Appropriate management of AMI and timely interventions play a key role in reducing mortality from cardiovascular diseases. Nevertheless, this requires us to understand the past trends and patterns of AMI-related mortality and subsequently to inform the design of future tailored interventions based on the available data and models [4][5].

Prediction models have been increasingly used in hospital settings to assist with risk prediction, prognosis, diagnosis, and treatment planning, ultimately leading to better health outcomes for patients. For example, predictive modeling can inform personalized care based upon health conditions of each individual patient [6]. Specifically, mortality prediction models estimate the probability of death for a group of patients based on their characteristics including the severity of their illness and many other associated risk factors for death [7]. They are important complementary tools to assist in clinical decision-making [8][9]. In current clinical practice, score-based mortality prediction systems, such as the series of the acute physiology and chronic health evaluation (APACHE) scoring system, are widely used to help determine the treatment or medicine should be given to patients admitted into intensive care units (ICUs) [10]. Nevertheless, these scoring systems have significant limitations, e.g., 1) they are often restricted to only few predictors; 2) they have poor generalizability and may be less precise when applied to specific subpopulations other than the original population used for the initial development; and 3) they need to be periodically recalibrated to reflect changes in clinical practice and patient demographics [6]. The wide adoption of electronic health record (EHR) systems in healthcare organizations allows the collection of rich clinical data from a huge number of patients [11]. Large EHR data enables one to 1) build more precise prediction models considering a wider range of patient characteristics; 2) be able to refresh these prediction models more frequently with less engineering efforts; and 3) improve the quality of these prediction models with fewer issues such as the common generalization problem [12].

One contemporary approach to build these prediction models is to use Machine Learning (ML) methods. ML is a field of computer science closely related to artificial intelligence that has drawn significant attention in the last few years. ML methods can be used to extract patterns and to predict different outcome variables (e.g., mortality) based on a training dataset. They have been shown to improve the predictive power in many real-world prediction tasks; and especially on biomedical problems, ML methods can lead to a better prognosis with richer predictors compared to traditional statistical approaches [6][13]. Most ML methods require significant feature engineering efforts, which rely on a deep understanding of the data and their underlying relationships with the outcome variable. Traditional artificial neural networks, even though relaxed the requirements of feature engineering, have a limited number of layers, connections and learning capacity because of the constraints of their computational power. In recent years, with the fast growing evolutions in both computer hardware (e.g., graphics processing unit, GPU) and training algorithm developments (e.g., the backpropagation algorithm that fine-tunes the whole network toward optimized representations [14]), deep learning systems now have the ability to use multi-layer architecture to learn patterns based on raw input data in every layer, in which features are not engineered by human but are learned from data automatically.

In recent years, a number of studies have deployed different deep learning architectures to predict mortality using EHR data. For example, Du et al. used a deep belief network (DBN) to

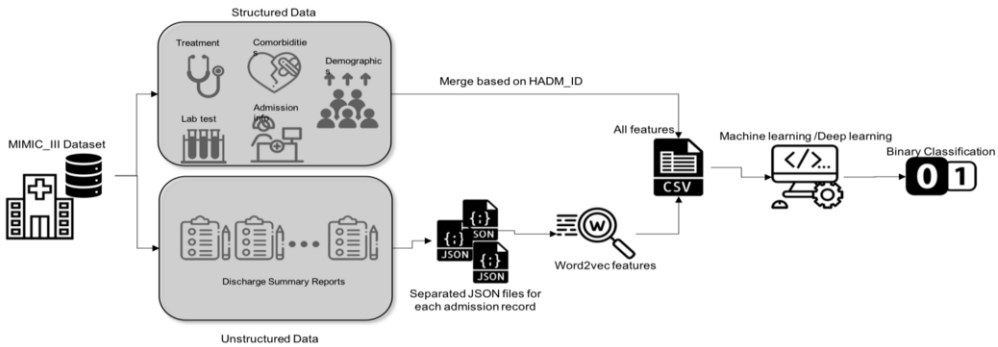

Figure 1– The workflow of the study (Icons made by https://www.flaticon.com)

predict critical care patient's 28-days mortality [15]. Zahid et al. used self-normalizing neural networks to predict 30-day mortality and hospital mortality in ICU patients [16]. Rajkomar et al. proposed a new representation of raw medical data and used deep learning to predict multiple medical events including in-hospital mortality 24 hours after admission [17]. However, these studies either did not consider free-text data in their feature sets or were only concentrated on short-term mortality prediction such as 24-hour mortality, for which any interventions might be too late.

In a previous study [18], we built a number of machine learning models using structured EHR data including admission information, demographics, diagnoses, treatments, laboratory tests, and chart values. The aim of the study was to predict one-year mortality in patients diagnosed with AMI or PMI. We compared the prediction results of these different machine learning models (i.e., shallow learners such as random forest and adaboost); and then compared the prediction performance of the best performing shallow learners to a deep learning model—a fully connected neural network. The results showed that the deep learning model enhanced recall and F-measure metrics (i.e., from a recall of 0.744 to 0.820; and a F-measure of 0.715 to 0.813) while preserving a good prediction accuracy of 82.02%.

In this study, we advance our previous work by adding unstructured data to the previous models. Word embedding features are extracted from free-text discharge summaries and added to the structured features. This study aims to improve the deep learning model performance using the mixture of both structured and unstructured data, which will be called mixed data throughout this paper. Also, the best performing shallow learners from the previous study are compared once again with the deep learning model using the same mixed data. Further, we examine the performance of the deep learning model using the unstructured set of data only, as well as five different combinations of the structured and unstructured data. We aim to determine which set of features contributes the most in enhancing the performance of deep learning models.

Methods

In this section, we first briefly introduce our preparation of the structured data as well as the free-text data. Our goal was to build and compare deep learning and traditional machine learning (i.e., shallow learner) models to predict one-year mortality in ICU patients with AMI and PMI. Many tasks in natural language processing (NLP) have benefited from neural word representations. These representations do not treat words as symbols; but rather can capture the semantics of the words and reflect their semantic similarities. These methods that represent words as dense vectors are referred to as "neural embeddings" or "word embeddings". Word embeddings have been proven to benefit a variety of NLP tasks [19]. Then, we briefly introduce the best performing shallow learners from the previous study, which was used to build new models based on the new mixed dataset. Then, we explain the architecture of the deep learning model. A workflow of this study is depicted in Figure 1.

Dataset Processing

Data Source and Patient Cohort

We used the data from the Medical Information Mart for Intensive Care III (MIMIC-III). MIMIC-III is a freely accessible, de-identified critical care patient database developed by the MIT Lab for Computational Physiology [20]. The latest version of the MIMIC-III dataset includes information about 58,000 admissions to the Beth Israel Deaconess Medical Center in Boston, Massachusetts from 2001 to 2012. Using the International Classification of Diseases, Ninth Revision (ICD-9) codes of 410.0-411.0 (Acute myocardial infarction, Postmyocardial infarction syndrome), we identified 5,436 admissions into our experiment dataset.

Structured Data Processing

The structured data in MIMIC-III include admission information (e.g., total days of admission, initial emergency room diagnoses, etc.), demographics (e.g., age at admission, gender, etc.), treatment information (e.g., cardiac catheterization, cardiac defibrillator, and heart assist anomaly, etc.), comorbidity information (e.g., cancer, endocrinology, etc.) and lab and chart values (e.g., cholesterol ratio, alanine transaminase, etc.). We selected these features based on the features used in similar studies. For details, see [18]. They were further refined and limited by their availabilities in MIMIC-III. To ensure that there was only one admission per instance, duplicates were removed. If duplicates existed because of multiple treatments or comorbidities for the same admission, all of them were counted. Regarding the demographics, since age and death age for people over 89 years old were masked in MIMIC-III by adding 211 to the actual age, we changed them back by subtracting 211 from their value. Some lab values were entered with a '0' and associated with a note of 'see comment'. Thus, 0 values were removed from the lab. Also, the lab or chart values that were biologically invalid were removed. We replaced removed values with the mean value of each feature column. The data was imbalanced with 30% positive and 70%

negative cases. The outliers were removed based on the interquartile range rule [18]. Data values were normalized between 0 and 1.

Unstructured Data Processing

The unstructured data were retrieved based on the corresponding admission IDs in the structured dataset using NOTEEVENTS table of MIMIC-III, from discharge summaries associated with each admission. Discharge summaries are the main method to communicate a patient's plan of care to the next provider [21]. Thus they include rich information about a patient's condition and treatments. Skip-gram model is a neural embedding method to learn an efficient vector representations of words from unstructured text data. These representations of words encode many linguistic regularities and patterns. The Skip-gram model finds the word representations that can predict the surrounding words [22]. The resulting dense vectors are called word embeddings. In this work, we opted to use document embeddings which is the average of word embeddings vectors for the words in the discharge summary of an admission, because the order of the words is not associated with the outcome (i.e., mortality). We used the Word2Vec algorithm in the Gensim library, a free Python library for processing plain text [23]. We used the embeddings pre-trained with Gensim using scientific articles (i.e., PubMed abstracts and PubMed Central full texts [24]).

Case Labeling

The goal of this study was to predict one-year mortality, i.e., whether a patient will die within a year after admission or not. Thus, the admission records of the patients who died within a year were labelled as positive instances, and of those who did not die within a year were labelled as negative instances.

Predictive Modeling

Machine Learning Models

Waikato Environment for Knowledge Analysis (WEKA) is a freely available Java-based software developed at the University of Waikato, New Zealand. Based on the results from our previous study [18], simple logistic and logistic model trees (LMT) classifiers in WEKA produced the best results using the dataset of structured features including admission information, demographics, treatment information, comorbidity information, lab values, and chart values. The simple logistic classifier in WEKA, builds linear logistic regression models. LMT in WEKA builds classification trees with logistic regression functions at the leaves [25].

Deep Learning Model

The deep learning model we used in this work consists of four layers (i.e., the input layer, two hidden layers, the classification layer). Figure 2 shows the deep neural network architecture used in this study. We used the Keras library [26] running on top of the Tensorflow framework [24], as well as a number of other Python packages including SciPy [27], Scikit-learn [28], NumPy [29], and Pandas [30].

The deep neural network we used for this study had 2 hidden layers fully connected with 400 neurons in each layer. The input dimension was 279. We used hyperbolic tangent activation function in hidden layers, and softmax activation function in the classification layer. We used the stochastic gradient descent method for optimization and categorical cross entropy as the loss function. To avoid over-fitting, we used L2 regularization in each hidden layer as well as dropout with a rate of 0.3. Batch size was 100 and epoch size was 60. In each hidden layer we applied batch normalization. All the deep learning architecture settings were chosen based on an extensive examination of different values and their impact on the overal performance. Since the data size was limited, we considered 10-fold cross-validation technique for model validation. We shuffled the data before each run.

Model Evaluation

We ran each algorithm 10 times. In each run, the data was shuffled randomly and 10-fold-cross-validation was employed to evaluate the performance (90% for training and 10% for testing). The performance metrics (i.e., accuracy, precision, recall and F-measure) were averaged after 10 folds.

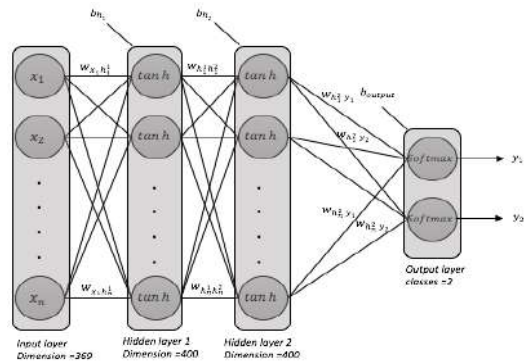

Figure 2 – a fully connected deep neural network architecture: two hidden layers, each with 400 neurons, initial weights=random uniform, initial bias=zeros, learning rate =0.001

The accuracy metric reports the model overall performance on the test set; however, recall and precision metrics of these models are more important in our task. If the actual outcome for a patient is mortality within a year, recall metric evaluates how many times the model was able to predict this correctly that a patient died within a year (true positive) out of all the patients who actually died within a year (true positive + false negative). Precision, on the other hand, evaluates how many times a correct prediction (true positive) happened out of all positive predictions made by the model regardless of their correctness (true positive + false positive). False negative in this study means that a patient who is predicted to live within a year actually died. False positive in this study means a patient who is predicted to have died within a year did not die. F-measure evaluates the balance between these two metrics. Although the receiver operator characteristics (ROC) curve is another popular evaluation metric, its interpretation requires caution when used with imbalanced datasets [31]. Since our dataset is imbalanced, we used precision-recall plot for the visual evaluation of the binary classifier.

Results

In our previous study [18], we first compared the performance of various machine learning models on each set of structured features separately and then compared them to the performance of machine learning models on the combined dataset (admission + treatment + lab and chart values + demographics + comorbidities). We observed that LMT and simple logistic models achieved the best accuracy of 85.12% on the combined dataset. The recall values were low (from 0.499 to 0.660). Only the J48 classifier yielded a precision of 0.993 using the admission dataset alone, while other performance metrics decreased notably comparing to using the combined dataset.

Then we showed that a deep learning model can enhance the performance. Our deep learning model achieved 82.02% accuracy, while boosted recall and F-measure metrics to 0.820 and 0.813, respectively. All features used in the previous study were derived from structured data.

Table 1– Comparing machine learning models to deep learning model based on the mixed dataset

Model	Accuracy	Precision	Recall	F-measure
LMT	85.78%	0.856	0.621	0.724
Simple Logistic	85.71%	0.863	0.623	0.723
Deep Learning	**92.89%**	**0.931**	**0.929**	**0.928**

In this work, we first compared the performance of machine learning and deep learning models on the mixed dataset (i.e., features from both structured and unstructured data). Then, we created different combinations of structured data with unstructured data to examine which set of features has more predictive power for our classification task. Table 1 shows the performance of the two top performing traditional machine learning models (as obtained from our previous study) and a deep learning model on the mixed dataset. The deep learning model outperformed the best shallow learners considerably.

In Table 1, we can see that the precision values of shallow learners are higher than their recall values, which means they are exact but not complete. A low recall value indicates a large number of false negatives (i.e., incorrectly classified as not dying within a year), which is suboptimal in this classification task. The dimension of data in our previous study was 79 considering only features from structured data. Adding features derived from unstructured data increased the total number of features and increased the input data dimension up to 279. Table 2 illustrates the comparison between the previous work and current study. We can see from the results that shallow learners did not benefit from more features (and higher data dimensionality). Accuracy slightly improved, while precision slightly dropped. Recall improved less than 0.03. Unlike the shallow learners, our deep learning model showed considerable improvements with more than 10% increase in accuracy and ~10% improvement in both precision and recall. Further, we were interested in comparing the performance of deep learning models using only free-text features vs. using different combinations of structured and free-text features. Results are summarized in Table 3.

Table 2– Comparing machine learning and deep learning models based on structured dataset vs. mixed dataset (structured + unstructured),-p means previous study, -c means current study

Model	Accuracy	Precision	Recall	F-measure
LMT-p	85.12%	0.867	0.594	0.705
LMT-c	85.78%	0.865	0.621	0.724
Simple Logistic-p	85.12%	0.867	0.549	0.705
Simple Logistic-c	85.71%	0.863	0.623	0.723
Deep Learning-p	82.02%	0.831	0.820	0.813
Deep Leanirng-c	92.89%	0.931	0.929	0.928

From the results we observed, demographic and admission information are two key groups of structured features in enhancing the deep learning model. Demographic information in this dataset includes age at admission, gender, religion, ethnicity and marital status. Admission information includes total days of admission, discharge location and initial ER diagnosis as AMI or rule out AMI.

Table 3– Comparing using unstructured data only vs. different combinations with structured data in the deep learning model

Data	Accuracy	Precision	Recall	F-measure
Free text	81.83%	0.836	0.818	0.816
Free text + lab results	83.61%	0.853	0.836	0.833
Free text + treatment	84.15%	0.850	0.841	0.840
Free text + comorbidity	84.69%	0.856	0.846	0.842
Free text + demographics	87.37%	0.881	0.874	0.872
Free text + admissions	88.25%	0.885	0.882	0.881

The combination of admission information with free-text features produced an accuracy of 88.25% in the deep learning model; while, the accuracy of the deep learning model based on the combination of demographics data with free-text features was 87.37%. We compared these two models to the accuracy of another deep learning model based on the complete mixed dataset, which produced an accuracy of 92.89%. Figure 3 illustrates the precision-recall curve resulted after 10 rounds of deep learning algorithm run. Table 4 shows a comparison of other recent works in mortality prediction using deep learning methods on EHR data.

Table 4– Comparing recent work in mortality prediction using deep learning methods on EHR data

Paper	Mortality Prediction Task	AUC	ACC
Payrovnaziri et al. *(this paper)*	1-year	0.916	92.89%
Du et al.[15]	28-days	Not reported	86%
Zahid et al.[16]	30-days/hospital	0.8445/0.86	Not reported
Rajkomar et al.[17]	24 h after admission	0.92-0.94	Not reported

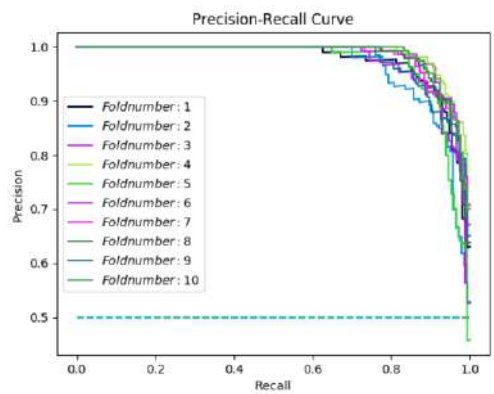

Figure 3– Precision-Recall Curve, after 10 runs average precision = 0.931, average recall = 0.929

Discussion and Conclusions

In this work, we enhanced our previous deep learning model by combining unstructured and structured data to predict one-year

mortality in ICU patients with AMI and PMI. For unstructured data, we extracted word embedding features from discharge summaries of each patient admission. While these word embedding features had no impact on the shallow learners, the performance of our deep learning model increased and achieved an accuracy of 92.89%, precision of 0.931, recall of 0.929 and F-measure of 0.928.

Our findings suggest that a richer data dimension through adding features from unstructured data will enhance deep learning model performance. We also confirmed our previous findings that initial emergency room diagnosis, gender, age, and ethnicity are important factors for the prediction of one-year mortality. One limitation worth noting is that using ICD-9 CM codes for cohort identification may introduce some noise. But this noise should not impact the findings of this study. In future work, we are interested in: 1) designing deep neural network ensembles that have the potential to further improve the model performance; 2) exploring the unstructured sequential data through other state-of-the-art models such as recurrent neural networks and long short-term memory (LSTM) techniques; and 3) the potential to enrich the textual features by extracting Unified Medical Language System (UMLS) concepts from the free-text data.

Abstract

Chemicals derived from plants (phytochemicals) are major concepts of interest in the study of medicinal plants. To date, efforts to catalogue and organize phytochemical knowledge have resorted to manual approaches. This study explored the potential to leverage publicly accessible semantic knowledge sources for identifying possible phytochemicals. Within the context of this feasibility study, putative phytochemicals were identified for more than 4,000 plants from the Medical Subject Headings Supplementary Concept Records and the Semantic MEDLINE Database. An examination of phytochemicals identified for five selected plant species using the method developed here reveals that there is a disparity in electronically catalogued phytochemical knowledge compared to information from Dr. Duke's Phytochemical and Ethnobotanical Databases maintained by the United States Department of Agriculture. The results therefore suggest that semantic knowledge sources for biomedicine can be utilized as a source for identifying potential phytochemicals and thus contribute to the overall curation of plant phytochemical knowledge.

Keywords:
Plants, Medicinal; Knowledge Bases; Phytochemicals

Introduction

A major facet of ethnobotany, the study of human uses of plant species, is the identification of chemicals that may have an active role in potential medicinal effects [1]. Such chemicals, referred to as "phytochemicals," are identified through a range of extraction and analysis techniques [2]. Reports of phytochemicals associated with a given plant species are then catalogued in monographs or articles that provide description of their actions and constituency. A major foundational step in evaluating the potential medicinal utility of a given plant species therefore requires a listing of associated phytochemicals. The process for identifying and recording phytochemical information is mostly manual, labor intensive, and costly.

A limited number of electronic databases exist, including Natural Products Alert (NAPRALERT) [3] and Dr. Duke's Phytochemical and Ethnobotanical Databases (Dr. Duke's) [4], and are artifacts of manually curated resources (e.g., more than 200,000 articles for NAPRALERT and a limited number of monographs for Dr. Duke's). Maintenance and updating information within such databases can be difficult due to challenges in available resources that are not able to keep up with the growing volume of knowledge.

Within biomedicine, there have been significant advances in developing computational approaches for identifying relevant entities from electronically accessible literature resources. Such approaches commonly utilize publicly accessible biomedical knowledge sources, which are enriched with semantic information that facilitates the inference of putative relationships. Those resources of note include the Medical Subject Headings (MeSH) Supplemental Concept Records (SCR) [5], the Unified Medical Language System [6] Metathesaurus (UMLS Meta), the UMLS Semantic Network (UMLS SN), and the Semantic MEDLINE Database (SemMedDB) [7].

MeSH SCR provides an index of chemicals, drugs, and other concepts of interest to MeSH descriptors (which are, in turn, used for cataloguing biomedical artifacts such as publications in MEDLINE). UMLS Meta is a collection of more than two million biomedical concepts collected from more than 200 classifications, codings, thesauri, and controlled vocabularies organized based on synonymy and discernable relationships between concepts. UMLS SN is a set of broad subject categories that organize concepts from UMLS Meta and relationships among them [8]. Finally, SemMedDB is a database of more than 80 million semantic predications (subject-predicate-object triples), which have been extracted by the SemRep [9] natural language processing tool and underpin the Semantic MEDLINE system [10].

Biomedical knowledge resources are thus designed with at least two purposes, to:

1. Facilitate information retrieval tasks; and
2. Support identification of putative relationships between biomedical concepts.

With regards to the latter, a number of studies have demonstrated how the aforementioned resources can be leveraged for the identification of disease risk factors [11], clinical adverse events [12], disease relationships based on genetic knowledge [13], gene-disease relationships [14], as well as many others. To date, there have been no studies exploring the potential to leverage biomedical knowledge sources for the identification of phytochemicals.

The purpose of this feasibility study was to develop an approach to identify phytochemicals from MeSH SCR and SemMedDB using biomedical concepts indexed in UMLS Meta. In addition to identifying putative phytochemicals, a detailed manual comparison of predicted phytochemicals was done for five selected plant species.

Methods

Recent versions of MeSH, UMLS Meta, UMLS SN, and SemMedDB were accessed from a local MySQL database. The list of plant species that were analyzed for this study originated from NCBI Taxonomy. Processing and analysis of data were done through programs written in Julia [15]. A graphical overview of the process for identifying chemicals associated with plants is shown in Figure 1.

Identification of Chemicals from MeSH SCR

MeSH was queried for each plant species name using an exact match of all plant names from NCBI Taxonomy, resulting in a set of entry terms. For each entry term, the associated MeSH descriptor was identified. When available, additional relevant MeSH descriptors and associated entry terms were identified through entries in the "See Also" (FX) field. Only FX field entries of UMLS semantic type "Organic Chemical" (T109; 'orch') or "Pharmacological Substance" (T121; 'phsu') were included. For the final set of MeSH descriptors, chemical names and corresponding UMLS Meta concept unique identifiers (CUIs) were retrieved by querying the MeSH SCR. The overall process used to identify chemicals from MeSH SCR is graphically depicted in Figure 1 as A1-A7 (green arrows; top half of figure).

Identification of Chemicals from SemMedDB

For each plant species name from NCBI Taxonomy, three queries were made of strings indexed in UMLS Meta to identify a query set of UMLS Meta CUIs:

1. The plant species name itself;
2. The plant species name plus the word "extract"; and
3. The set of MeSH entry terms determined as an artifact of the previous identification of chemicals from the MeSH SCR chemical identification process.

All UMLS Meta CUIs for the resulting query set were required to be of semantic type "Plant" (T002; 'plnt'). SemMedDB was then queried with the query CUIs for the given plant for predications that included one of the following predicate types: "ISA", "LOCATION_OF", or "CONVERTS_TO."

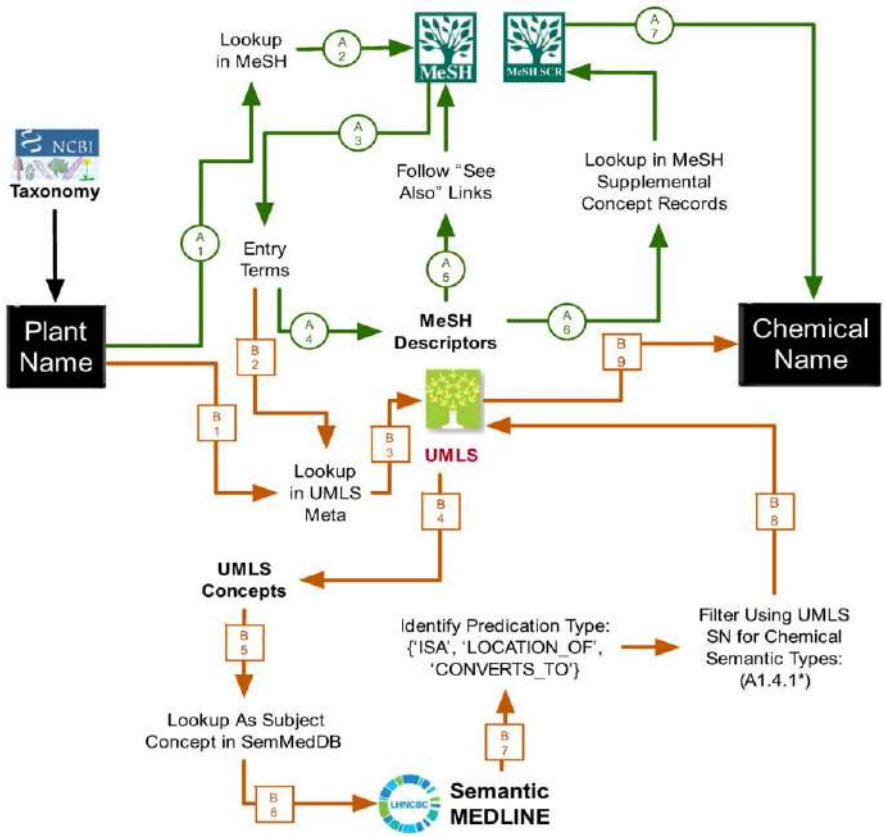

Figure 1. Overview of Approach for Identifying Chemicals Associated with Plants. Two types of knowledge sources were used to identify chemicals associated with plant species as listed in NCBI Taxonomy: (A) MeSH Supplemental Concept Records (SCR); and (B) Semantic MEDLINE. For MeSH SCR, first the full set of MeSH descriptors and entry terms were determined (A1-A5) and then the MeSH SCR was queried to identify associated chemicals (A6-A7). In addition to the NCBI Taxonomy plant species name (B1), entry terms from the MeSH SCR search (B2) were used to identify relevant concepts in the UMLS Meta (B3-B4). These concepts were then searched in Semantic MEDLINE as subject concepts (B6) and restricted to specific predicate types of interest (B7) and filtered for chemical related semantic types (B8-B9).

Table 1: Summary of agreement between chemicals associated with selected plants based on information from Dr. Duke's versus the developed approach (phyotkb_chem). For each of the five plant species examined in detail, the number of chemicals identified by the developed approach from Medical Subject Headings Supplemental Concept Records (SCR) or SemMedDB (SM), as unique to phytokb_chem (u_p), shared by both phytokb_chem and Dr. Duke's (c), unique to Dr. Duke's (u_d), or chemicals that were catalogued in both phytokb_chem and Dr. Duke's but were not identified as either as being associated with a given plant species ($u_{\neg p \neg d}$). For each plant species, respective values for the F-measure (fm), Matthews Correlation Coefficient (mcc), and Cohen's Kappa (κ) are shown.

Plant species (common name)	SCR	SM	u_p	c	u_d	$u_{\neg p \neg d}$	*fm*	*mcc*	κ
Calendula officinalis L. (Marigold)	2	24	24	1	61	5481	0.023	0.103	0.017
Cannabis sativa L. (Marijuana)	42	46	77	9	63	5476	0.011	0.204	0.101
Papaver somniferum L. (Poppy)	5	64	54	14	156	5375	0.118	0.279	0.102
Senna alexandrina Mill. (Senna)	19	10	25	2	29	5518	0.069	0.179	0.064
Solanum lycopersicum L. (Tomato)	0	896	810	85	125	5177	0.154	0.154	0.105

The UMLS Meta CUIs for the objects were retrieved. The candidate objects were filtered for concepts contained within the "Chemical" (T003; 'chem') hierarchy of the UMLS SN (A1.4.1*). The process used to identify chemicals from SemMedDB is graphically depicted in Figure 1 as B1-B11 (orange arrows; bottom half of figure).

Evaluation for Selected Plant Species

For a chosen set of five plant species with known phytochemical properties (*Calendula officinalis* L. [Marigold], *Cannabis sativa* L. [Marijuana], *Papaver somniferum* L. [Poppy], *Senna alexandrina* Mill. [Senna], *Solanum lycopersicum* L. [Tomato]), associated chemicals were retrieved from Dr. Duke's. A complete list of chemicals listed in all plants catalogued in Dr. Duke's was also retrieved.

The full set of Dr. Duke's chemicals were mapped to UMLS Meta CUIs by direct lookup; those chemicals that could not be mapped to a UMLS Meta CUI were not included in the evaluation. The set of chemicals retrieved through the process developed in this study (phytokb_chem) were compared to the set of chemicals from Dr. Duke's for each plant species of interest. In addition to a proportional analysis of the chemicals suggested to be associated with each plant species, three agreement statistics were calculated with Dr. Duke's and phytokb_chem, serving as reference standards to each other:

1. F-Measure (*fm*), which is the harmonic mean of precision and recall for a set of classifications:

$$fm = \frac{2 \cdot c}{(2 \cdot c) + u_p + u_d}$$

2. Matthews Correlation Coefficient (*mcc*), which quantifies the correlation between two classification systems:

$$mcc = \frac{(c \cdot u_{\neg p \neg d}) - (u_p \cdot u_d)}{\sqrt{(2 \cdot c) \cdot (c + u_p) \cdot (u_{\neg p \neg d} + u_p) \cdot (u_{\neg p \neg d} + u_d)}}$$

3. Cohen's Kappa (κ), which ascertains the quality of the relative accuracy of a given classification system as a function of true accuracy compared to random accuracy:

$$\kappa = \frac{\left(\frac{c + u_{\neg p \neg d}}{c + u_{\neg p \neg d} + u_p + u_d}\right) - \left(\frac{\left((u_{\neg p \neg d} + u_p) \cdot (u_{\neg p \neg d} + u_d)\right) + \left((u_d + c) \cdot (u_p + c)\right)}{(c + u_p + u_d + u_{\neg p \neg d})^2}\right)}{1 - \left(\frac{\left((u_{\neg p \neg d} + u_p) \cdot (u_{\neg p \neg d} + u_d)\right) + \left((u_d + c) \cdot (u_p + c)\right)}{(c + u_p + u_d + u_{\neg p \neg d})^2}\right)}$$

Where c represents the number of chemicals in common between Dr. Duke's and phytokb_chem; u_p represents the number of chemicals unique to phytokb_chem; u_d represents the number of chemicals unique to Dr. Duke's; and $u_{\neg p \neg d}$ represents the number of chemicals that are catalogued in either phytokb_chem or Dr. Duke's but not accounted for by u_p or u_d.

Results

A total of 127,597 plant species were searched in MeSH SCR and SemMedDB, resulting in 4,361 plants having at least one chemical. The mean number of chemicals per plant species was 9±100 [95%CI 6-12], with an inclusive range of 1 to 5,589 chemicals per plant species. For the five plant species manually examined relative to Dr. Duke's, there was little overall agreement (summary of agreement statistics shown in Table 1), suggesting that the approach developed here offers potentially synergistic information about chemicals associated with plant species. Detailed results are available as supplementary information at:

Discussion

Identification of phytochemicals is an essential aspect in the study of medicinal plants. In advance of the laborious process of developing and implementing screening programs for ascertaining the phytochemicals for a given plant species, it is paramount to have an understanding of what is known about the plant species. To date, the process of cataloguing known phytochemicals relies on a manual curation process. Screening programs, such as those previously led by the National Cancer Institute [16], have led to the identification of active chemicals that have led to significant drugs (e.g., taxol [17]). A major challenge with such screening programs is the difficulty associated with developing appropriate protocols for reliable extraction of phytochemicals [18].

With recent interest in exploring plants as a potential source for new or complementary therapies [19,20], there is a great need to develop robust methodologies for identifying knowledge about plants lest effort be wasted in identifying already known (but perhaps lost) phytochemical knowledge. As with other sectors of biomedicine that have leveraged biomedical knowledge sources, there is a significant opportunity to utilize automated approaches to determine the latest recorded information. This feasibility study demonstrates that there is a strong discordance between existing resources (e.g., Dr. Duke's) and phytochemicals that can be identified using the MeSH Supplemental Concept Records and SemMedDB.

In considering biomedical knowledge sources that may be of utility for identifying phytochemicals, this study focused on using MeSH SCR and SemMedDB. The results of this study

suggest that MeSH SCR and SemMedDB offer complementary knowledge about chemicals. MeSH SCR data are based on drug and chemical information that appear in biomedical literature and can be mapped to MeSH descriptors. As with the MeSH thesaurus, this well-curated list of associations can generally be trusted as *bona fide* associations. However, like the MeSH thesaurus, it is limited in the scope and range of chemicals listed based principles for indexing MEDLINE. Resources like the MeSH thesaurus and MeSH SCR are primarily designed to facilitate information retrieval tasks (i.e., to identify relevant literature for a given query). Nonetheless, the results of this study demonstrate that there is utility in leveraging SCR information to identify potential phytochemicals.

In contrast to MeSH SCR, SemMedDB consists of a detailed set of predications that have been determined using a natural language processing (NLP) system (SemRep). The predications underpin the Semantic MEDLINE system, facilitating the process of retrieving relevant biomedical literature based on semantic relationships between concepts. SemRep based data have been used in a number of text mining studies (e.g., to identify interactions between drugs [21] or proteins [22] from MEDLINE). There have been previous studies in leveraging NLP approaches for studying medicinal plants [23-25]). The present study is, to the best of our knowledge, the first to leverage a predicate extraction system like SemRep for the identification of plant-chemical associations.

A major limitation in the evaluation of the quality of extracted relationships is the limited availability of suitable reference standards. In this study, the phytochemical candidates identified by the developed system were compared to a popular electronic catalogue of phytotherapy knowledge (Dr. Duke's). However, it is important to note that such resources are not "true" reference standards, the information catalogued is incomplete and also may contain inconsistent errors (e.g., chemicals like alcohol are often listed as chemical components, but these are likely artifacts of the phytochemical extraction process [26]). There is some information about putative medicinal uses, but these are supported by limited primary literature. Other resources, like NAPRALERT, have references to primary literature but also may suffer from incorrectness or incompleteness. In this study, the comparison was done with Dr. Duke's because it is a freely accessible resource. Future work will expand to include comparisons to NAPRALERT (which requires a fee for complete access to data on par with Dr. Duke's).

Ultimately, it is envisioned that the work presented in this study will be seen as complementary to resources like Dr. Duke's and NAPRALERT. However, there are still some areas of potential improvement that we consider essential before the results of the developed system could be seen as a reliable catalogue. The first is addressing the issue of identifying chemicals mentioned in literature that are associated with plants only because of the extraction process (e.g., the aforementioned alcohol). While this only occurs in a small percentage of the extractions, it may be easily addressed through a combination of stop words (which would consist of chemicals commonly used for extractions) and information theoretic approaches to identify chemicals that occur commonly and may not be of interest (e.g., water).

Another area of improvement that is planned includes developing a confidence score for the chemicals identified for each plant species. For example, there may be utility in weighting certain predicates in combination with their relative frequency in order to identify chemicals that are of interest for a particular plant species. A more detailed evaluation is needed for each of the data sources for more than five plant species; five plants was chosen to support a manual assessment to verify potential for species that are known to have phytochemicals. Nonetheless, the results of this initial study suggest that there is promise in leveraging biomedical knowledge sources for identifying phytochemicals that are not currently available in electronic phytochemical resources such as Dr. Duke's or NAPRALERT.

Acknowledging that a given plant species has at least one thousand phytochemicals, another important contribution of automated systems such as the one developed here is a tabulation of reported phytochemicals that may supplement data which are in resources like Dr. Duke's or NAPRALERT. In doing so, one can identify plant species that have been heavily studied (e.g., those with more than 1,000 phytochemicals, such as *Solanum lycopersicum* L. [Tomato] as identified either by the process developed here or in Dr. Duke's) versus those that have not had extensive phytochemical analyses shared in accessible resources (e.g., *Calendula officinalis* L. [Marigold] which had only 86 phytochemicals identified either by the process developed here or in Dr. Duke's amidst its long history of medicinal use [27]). The results of this study may thus be used to continually curate available electronic literature sources and, in combination with electronic resources like Dr. Duke's or NAPRALERT, provide a metric for identifying plant species that have been understudied. This would be especially valuable in the context of studying plants that may have therapeutic indications (e.g., based on ethnobotanical survey knowledge).

Biomedical knowledge sources are principally aimed at cataloguing and retrieving information mostly relative to disease knowledge. This can make it challenging to identify non-traditional biomedical concepts, such as plant species. In this study, a combination of MeSH entry terms, MeSH "see also" entries, and UMLS string lookups were used to identify the array of relevant concepts for a given plant species. The source used for taxonomic plant species name in this study was NCBI Taxonomy, which is limited to organisms that have associated data in other databases within NCBI (e.g., GenBank), and does not necessarily reflect the full set of plant species that are catalogued in more comprehensive resources like the International Plant Name Index [28]. Similarly, the set of chemical names indexed within UMLS Meta is not necessarily the full set of known chemicals (i.e., the 5405±138 catalogued chemicals that could not be mapped to UMLS; these were excluded from the evaluation of this study). Future work will therefore need to utilize a more robust approach for identifying plant species names and chemical names that can be added as source concepts for SemRep. Finally, the three target predicate types ("ISA", "LOCATION_OF", or "CONVERTS_TO") used for this study were determined through manual examination of predications associated with plant concepts within SemMedDB; there may additional predications that could be considered (including those that may be added to SemRep) in future work.

This study focused on analyzing biomedical literature indexed in MEDLINE. It is our expectation that the techniques described here may be used to develop approaches to identify phytochemical knowledge from other sources of electronic knowledge (e.g., PubMedCentral or the Biodiversity Heritage Library).

Conclusions

Knowledge about phytochemicals is embedded across a number of resources, including biomedical literature. This

study demonstrates how semantic biomedical knowledge sources can be leveraged to identify potential phytochemicals from literature based resources, focusing on the MeSH Supplement Concept Records and the Semantic MEDLINE Database. The results suggest that automated approaches, such as developed here, can identify a largely non-overlapping, complementary set of potential phytochemicals compared to an existing manually curated resource (Dr. Duke's Phytochemical and Ethnobotanical Databases).

Abstract

Clinical text de-identification enables collaborative research while protecting patient privacy and confidentiality; however, concerns persist about the reduction in the utility of the de-identified text for information extraction and machine learning tasks. In the context of a deep learning experiment to detect altered mental status in emergency department provider notes, we tested several classifiers on clinical notes in their original form and on their automatically de-identified counterpart. We tested both traditional bag-of-words based machine learning models as well as word-embedding based deep learning models. We evaluated the models on 1,113 history of present illness notes. A total of 1,795 protected health information tokens were replaced in the de-identification process across all notes. The deep learning models had the best performance with accuracies of 95% on both original and de-identified notes. However, there was no significant difference in the performance of any of the models on the original vs. the de-identified notes.

Machine Learning, Data Anonymization, Natural Language Processing

Introduction

The use of electronic health records (EHR) data to support research is growing in the translation research community [1]. Significant amounts of those data are trapped in free-text throughout a variety of clinical notes [2,3]. Provider notes often contain patient names, dates of services, and other types of Protected Health Information (PHI). In the United States, the Health Insurance Portability and Accountability Act (HIPAA) protects the confidentiality of patients [4], and based on the Common Rule, researchers are required to obtain either an informed consent from patients or a waiver of informed consent from an Internal Review Board (IRB) in order to use data for research [5]. As a result, automated de-identification in order to make text data more accessible for research is being investigated [6]. The impact of de-identification on the fidelity of information content as well as the utility of the data for research purposes, and information retrieval are also being evaluated [7,8]. In this paper, we examine the impact of de-identification on machine learning-based text classifiers. This experiment was conducted in the context of an automated approach for the detection of altered mental status (AMS) in emergency department (ED) physician notes for the purpose of decision support in the evaluation and management of pulmonary embolism [9–11].

Methods

This study was approved by the IRB at the Medical University of South Carolina (MUSC) under protocol # Pro00080055. We extracted ED physician notes from the MUSC Research Data Warehouse, which contains data extracted from the EHR system. The text notes span a period of 6 years, exported from one commercial EHR system. The notes were enriched with records from adult patients with concurrent International Classification of Diseases (ICD)-10 codes indicating AMS (e.g. codes under the R41 ICD-10 code hierarchy, which includes symptoms and signs involving cognitive functions and awareness) and an equal number of records from patients without AMS ICD codes as controls or negative cases. Using regular expressions to identify the section headers, a total of 8,194 clinical notes were segmented into the different components of a clinical record including the history of present illness (HPI), physical exam, assessment, etc.

Labeling

The parsed notes were imported into REDCap [12] and made available to clinical members of our research team (two ED physicians, a Pediatrician and a Doctor of Pharmacy) for review and labeling as either AMS or not AMS. The team was instructed to look for any signs or symptoms of AMS in the context of pulmonary embolism as described in the literature [9,10] within the HPI, e.g. disorientation, lethargy, stupor, somnolence, confusion, coma, loss of consciousness, or syncope. They were also asked to drop repetitive notes for patients with frequent ED visits in order to minimize bias in testing the models. Cases that were deemed not clear cut AMS by a reviewer, were labeled by consensus after consultation with other team members. The team completed the labeling on 1,113 HPI text notes from 849 patients, with 487 notes labeled as AMS, and 626 labeled as non-AMS. A sub-sample of 100 notes was labeled independently by two labelers in order to estimate the interrater reliability.

De-identification

For automated de-identification, we used a system based on 'BoB' (best-of-breed clinical text de-identification application) [13,14] with a previously demonstrated precision of 93% and

recall of 76% on MUSC data [15]. This system combines high precision algorithms (e.g., regular expression matching) and high recall algorithms, e.g., Conditional Random Fields (CRF) and Support Vector Machines (SVM). After all models are run on a document, their individual PHI determinations are consolidated into a single coherent output using an ensemble method. Tokens tagged as PHI can be replaced with tags, (e.g. a name replaced with a single generic token "[***PHI***]" or a corresponding PHI-type or class name e.g. "[*** Patient ***]") or "resynthesized" (i.e., PHI is replaced with realistic surrogates so a name will be replaced with a different, randomly sampled name). For the purposes of this study, we selected to use the multi-class token replacements in the de-identified output.

Text Processing

We used R version 3.5.1 [16] for constructing the machine learning pipelines, and Keras [17] and TensorFlow [18] for constructing and training the deep learning models. We ran both the original text (i.e., not de-identified) and de-identified text through several traditional bag-of-words (BOW) text classifiers, and word-embedding (WE)-based deep learning models. Text processing for the BOW models was done using the quanteda package [19] and included lower casing, punctuation removal, stop-word removal, stemming, and tokenization. The BOW word frequencies were normalized using term-frequency, inverse document frequency (tf-idf) a weighted approach for term discrimination [20]. For the WE models, we used Keras for text processing, which included lower casing, sentence segmentation, punctuation removal, and tokenization, followed by sequence padding to ensure that all sequences have the same length.

Baseline Approaches

As a baseline, we used regular expressions (regex) on lowercased notes to identify AMS key words as described in the literature in the context of pulmonary embolism [9,10] (e.g. altered, disorientation, disoriented, lethargy, stupor, confusion, syncope, etc.). The regex algorithm was refined after several iterations of testing against the labeled data to include other patterns based on the root words and abbreviations. We also examined the accuracy of ICD codes against the labeled data.

BOW-based Machine Learning Models

The traditional models included: Naïve Bayes Classifier (NBC) with uniform priors, smoothing of 1; Lasso (LASS) with a default alpha=1 and lambda=NULL [21]; Single Decision Tree (SDT) [22] with a maximum depth of 20; Random Forrest (RF) [23] with 201 trees and the number of variables randomly sampled as candidates at each split (mtry)=150; SVM Type 1 with a radial basis kernel [24]; and a Simple Multilayer Perceptron (SMP) artificial neural network with 64-node input and hidden layers.

Word Embedding - Deep Learning Models

The deep learning model was based on the architecture described by Kim [25]. However, instead of using parallel channels for the embedding layer, we used either a pre-trained layer using word2vec (W2V) [26] or word embedding without pre-training (vectors randomly initialized using a uniform distribution) with either of 50 (D50) or 200 (D200) dimensions per word. The W2V weights were derived by pre-training the W2V skip-gram model on all 8,194 HPI (original, not de-identified) notes using a window of 5 words in each direction and 200 dimensions per word. The next layer was a convolutional layer or convolutional neural network (CNN) with multi-filter sizes (3, 4 and 5), 200 nodes each, with global maxpooling, followed by a merge tensor, a fully connected 200 node layer, then a single sigmoid activation output node. A dropout rate of 0.2 was used after both the embedding layer and the last dense layer. Other deep neural network architectures were tested including Kim's and CNN's with larger window sizes; however, we chose the above architecture due to its superior performance in our hands for the purpose of demonstrating the impact of de-identification.

Training and Evaluation

Due to the relatively small number of labeled clinical notes, all the models were trained and evaluated using 5-fold train/test cycles, i.e. the test set in each of those runs was used as an unseen holdout set. Moreover, in order to ensure further consistency in results, the experiment was repeated 5 times by bootstrap sampling using different random seeds. Therefore, all models were run a total of 25 times on different train/test sets. In order to allow comparison between models, the same train/test sets were used during each cycle for all the models. The same random seeds were used for both the original and de-identified sets, thus ensuring identical partitioning of train/test sets and that the models trained on original notes were trained on the de-identified version of the same original notes. The performance metrics, including area under the receiver operating characteristic curve (AUC), were calculated based on the pooled predictions of the test data from the 25 runs. The caret package was used for k-fold, bootstrap sampling and calculations of the metrics [27].

Results

Dataset Statistics

The BOW matrices generated after lower casing, stop-word removal and stemming had token dimensions of 5,200 and 4,925 for the original and de-identified sets respectively. The WE sequences, which did not undergo stop-word removal and stemming, had vocabulary sizes of 7,260 and 6,923 for the original and de-identified sets respectively. The HPI note sizes ranged from 21 to 716 words with a median of 174 words for both original and identified sets. The corpus of the labeled HPI notes included a total of 207,475 tokens.

De-identification Results

The automated de-identification resulted in the replacement of 1,795 PHI tokens from a variety of types or classes of PHI (Table 1), which is less than 1% of all tokens in the corpus. The most prevalent replacements within our HPI data were related to health care unit names (such as "MUSC" or "Gastrointestinal" unit) and ages. The different PHI classes and their prevalences are listed in Table 1.

Table 1– Breakdown of the Numbers of PHI Tokens Replaced by the De-identification System.

PHI Token Class	n	%
Health care unit names	558	31.1%
Ages greater than 89	512	28.5%
Dates	360	20.1%
Provider names	128	7.1%
Patient names	122	6.8%
Street or City	73	4.1%
State or Country	16	0.9%
Phone numbers	15	0.8%
Other organization names	10	0.6%
Other IDs	1	0.1%
Total	**1795**	**100.0%**

Baseline Analyses

We had a fairly high interrater reliability between labelers (Cohen's Kappa = 0.94). Using the ICD codes listed in table 2, the accuracy of concurrent ICD codes assignments associated with the labeled clinical notes was 81.1% (precision 72.2%, recall 92.4%). The presence of any of these codes was considered as positive for AMS otherwise the note was considered negative for AMS by ICD.

Table 2– List of ICD-9 and ICD-10 Codes Considered to be AMS in the Context of Pulmonary Embolism.

Code Set	ICD Code	Diagnosis Name
ICD9	780.0x	Alteration of consciousness
ICD9	780.2	Syncope and collapse
ICD9	780.97	Altered mental status
ICD9	799.5x	Signs and symptoms involving cognition
ICD10	R40.x	Somnolence, stupor and coma
ICD10	R41.0	Disorientation, unspecified
ICD10	R41.8x	Other symptoms and signs involving cognitive functions and awareness
ICD10	R41.9	Unspecified symptoms and signs involving cognitive functions and awareness
ICD10	R55	Syncope and collapse

The accuracy of classification using the refined regex patterns against the labeled notes was 88.1% (precision 81.3%, recall 94.7%).

Machine Learning Performance

There was no discernable difference in performance of any of the models between original and de-identified text, with significant overlap in the 95% confidence intervals of the AUC's for all the models across original vs. de-identified (Figure 1). Table 3 shows the performance of the models, along with the differences in performance between original and de-identified text (Δ's).

The RF model was the best performer in the BOW models with AUC's of 0.978, in both original and de-identified texts. Both CNN's (D50 and D200) with the randomly initialized word embeddings had the best overall performance with AUC's near 99% and average accuracies near 95% across both original and de-identified text, exceeding those of the W2V model.

Discussion

The de-identification resulted in the replacement of 1,795 PHI tokens out of a total of over 200 thousand tokens in our sample of 1,113 HPI notes. Table 1 demonstrates the extent of de-identification that the notes were subjected to. The results show negligible difference in performance of text classifiers on original vs. de-identified HPI notes, across all types of machine learning models. The deep learning models in particular seem to perform exceedingly well in both environments.

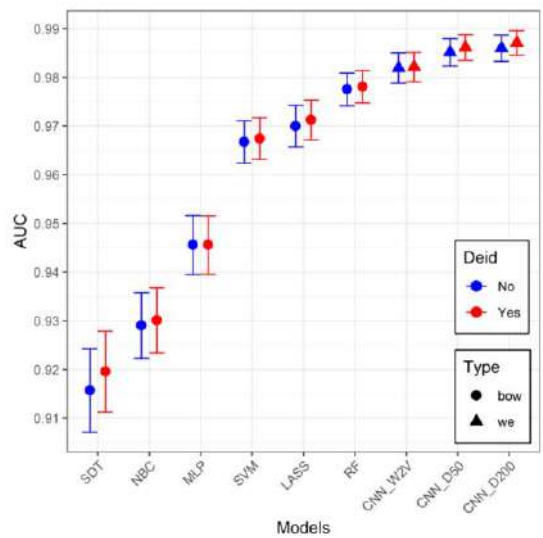

Figure 1. AUC values and 95% confidence intervals for all the models for both original and de-identified (Deid) data.

We hypothesized that the replacement of a number of different named entities with uniform classes of tokens, which slightly reduces the vocabulary size in our corpus and therefore the number of features that the BOW and WE models have to deal with, could potentially improve machine learning performance due to reduced dimensionality and noise in the data. If such an advantage exists, it could not be definitively demonstrated in our results. Several of the models seem to have a slight advantage when applied to the de-identified set, but given the 95% confidence intervals' overlap between original and de-identified, this difference is not significant. It is worth noting that such a result would also be expected if a PHI 'resynthesis' process were used (i.e., replacement of PHI with realistic

surrogates), which is an option in the automatic de-identification system described above, and is based on a large and diverse database of possible surrogates (e.g., all last names found in the U.S. national census). The resynthesis might allow for conservation of diversity of the original PHI.

The fact that automated de-identification did not reduce the accuracy of machine learning performance should be of interest to the translational research community. Clinical text corpora are critical for biomedical informatics research in domains such as machine learning, ontology annotations, predictive modeling and precision medicine, to name a few. Automated de-identification should make such corpora more accessible at scale for such research. While automated de-identification technologies have matured significantly in recent years, regulatory guidelines still lag behind. Looking ahead, we envision several governance models in which de-identified text corpora could be made available with appropriate data use agreements with minimal oversight and review by ethics boards. Institutional research leaders at academic medical centers should work closely with their offices of research oversight and local informatics experts to make such resources more accessible.

Regarding the performance of deep learning vs. the traditional classifiers, the deep learning classifiers seem to significantly outperform the BOW-based classifiers with the exception of RF, which had a performance approaching that of the CNN's. Not surprisingly, all machine learning models outperformed ICD codes on accuracy, which is consistent with reports in the literature on coder errors, such as misattribution, unbundling, and upcoding [28,29]. However, only the better performing models (MLP and above) had better accuracies than the optimized regex classifier. The accuracies of the deep learning models were particularly far superior to the regex accuracy. However, none of the models outperformed the high recall demonstrated by our regex classifier. However, the regex approach required significant fine-tuning specific to the detection of AMS keywords in order to yield this performance. As such, the regex approach is more difficult to generalize to other classification problems. Finally, it should be noted that the W2V initialized WE models, did not outperform the randomly initialized WE models. In fact they seem to have consistently lower AUC's, but with overlapping 95% confidence intervals. The lower performance is possibly due to the relatively small amount of pre-training data, for example, compared to models trained on all of PubMed.

Limitations

Our text corpus represents data from one health system, on a single EHR system making it difficult to draw generalizations about performance in other environments. We also examined the performance of machine learning through the narrow prism of a simple text classifier to identify AMS in one type of EHR clinical text, namely the HPI. Future work should include expanding the study to other institutions and examining other types of notes and machine learning tasks, such as predictions of outcomes.

Conclusions

Despite the limitations outlined above, this simple experiment demonstrates the power of an automated de-identification pipeline, and the preservation of text features that are necessary for the performance of both deep learning models as well as the more traditional machine learning models used in text classification tasks.

Abstract

Different analytic techniques operate optimally with different types of data. As the use of EHR-based analytics expands to newer tasks, data will have to be transformed into different representations, so the tasks can be optimally solved. We classified representations into broad categories based on their characteristics, and proposed a new knowledge-driven representation for clinical data mining as well as trajectory mining, called Severity Encoding Variables (SEVs). Additionally, we studied which characteristics make representations most suitable for particular clinical analytics tasks including trajectory mining. Our evaluation shows that, for regression, most data representations performed similarly, with SEV achieving a slight (albeit statistically significant) advantage. For patients at high risk of diabetes, it outperformed the competing representation by (relative) 20%. For association mining, SEV achieved the highest performance. Its ability to constrain the search space of patterns through clinical knowledge was key to its success.

Keywords:

Data Science, Electronic Health Records, Data Mining

Introduction

The widespread adoption of electronic health records (EHRs)[1] enables new kinds of analytics such as explicitly modeling population heterogeneity or identifying benefit groups for an intervention[2,3]. It is well understood that different analytics tasks and techniques operate optimally on different types of data[4]. For example, association pattern mining requires binary or categorical data[5] and most regression models assume that the predictor variables have an additive effect[6]. Data, as it exists in the EHR, is not ideal for many analytics tasks.

A data representation is a transformation of data into a format amenable to a particular analytic technique. Data transformations are not new, e.g., log or rank transformations of non-normally distributed variables[7] have been a mainstay for decades. The recent success of deep learning in some applications[8] has put data representation into the spotlight and is, at least in part, attributed to the underlying data representation. In this work, we propose a data representation, which is specific to the clinical domain and represents data at a high level and enriches it with clinical knowledge.

Specifically, SEV augments the original data with a set of ordered or partially ordered binary variables, combining information about patients' state from multiple perspectives: therapies, diagnoses, and whether or not the laboratory results or vital signs are normal and/or achieve a typical therapeutic target. These variables are (at least partially) ordered: the variable 'patient is under control with first-line oral therapy', represents a lower severity than the variable 'patient is not under control despite last-line therapy'. These variables are highly interpretable, as they follow clinical reasoning and incorporate clinical knowledge.

To make the discussion concrete, we carry out our study in the context of type 2 diabetes (T2D). Diabetes is a common disease with severe complications[9], affecting 29.1 million Americans. T2D can be prevented or delayed through lifestyle modifications and/or pharmacological treatment[10], hence identifying patients at high risk is of high importance. From a technical perspective, T2D is an ideal evaluation platform, as it exhibits common challenges: T2D is heterogeneous; risk factors are correlated and not necessarily additive; and the time frame between the risk factors and the onset of diabetes can be as long as 20 years, which makes missing data inevitable[2,11].

We encode diabetes risk factors, hyperlipidemia, hypertension, and obesity as SEVs (a set of SEVs for each disease) and perform two clinical tasks related to type-II diabetes. The first task is to predict the onset of diabetes using a Cox model and the second one is to model population heterogeneity in terms of the risk of T2D incidence using association pattern mining. We will compare SEV to five other data presentations, including the original data. The main objective is to study the characteristics of the data representations.

Related Works

Data representations transform the data into a new data set. For a *dimensionality-expanding* representation, the new data has more features than the original data, while for a *dimensionality-reducing* representations, it has fewer. The key concern in dimensionality reduction is information loss. Representations can also be *outcome-specific* or *outcome-independent*. Outcome-specific data representations are specific to a

particular study end point (outcome) and can potentially limit the information loss that is relevant to the outcome, while *outcome-independent* representations do not consider an outcome.

Outcome-specific Representation

A severity score (SS)[12] quantifies disease burden with respect to some outcome of interest. For example, the Framingham diabetes score[13] associates disease burden, defined by a handful of risk factors, with the risk of developing diabetes (an outcome). Severity score is a dimensionality-reducing representation, as it summarizes numerous original risk factors into a single number, which is proportional to the burden conferred by those risk factors on some outcome.

Outcome-independent Representations

Outcome-independent representations transform the original data into a new set of features, typically with a different dimensionality. Many currently existing representations, such as principal component analysis (PCA)[14] and nonnegative matrix factorization (NMF) [15] have the specific aim of reducing the problem dimensionality. PCA is a statistical procedure that transforms a set of features into a new (ordered) set of orthogonal features (called principal components) in a manner such that each subsequent component explains maximal amount of residual variance, and NMF factorizes the original matrix into two matrices having only non-negative values, in a way that each subsequent component captures maximal amount of the residual information. Dimensionality reduction is achieved by using only the first few components.

Deep neural networks (DNNs)[8] are computational models that are inspired by neural networks in animal brains and have recently achieved considerable success. Much of this success is attributed to the data representation of these techniques, which is known as de-noising autoencoders (DAE). DAEs consist of successive layers of transformations, where the outcome of each layer is the input to the next. Each layer is thought to extract features that are higher-level than those of the previous layer. The criterion for the goodness of the transformation is the reconstruction error, which is a measure of how well an autoencoder can reconstruct the original data from its output.

Severity Encoding Variables

Severity Encoding Variables (SEV) is our proposed outcome-independent representation. The purpose of SEV is to summarize the numerous facets of a disease into a single hierarchical variable. Nodes at the same level in the hierarchy are fully or partially ordered.

The construction of the hierarchy replicates the clinical reasoning steps of determining the severity of a certain disease. Reasoning involves a sequence of questions: (i) are lab results and vital signs present and normal, (ii) has an intervention been initiated, and if it has, how aggressive is it (first-line treatment, combination therapy, etc.), and (iii) has a diagnosis been recorded. Accordingly, the first split (at the root) produces three nodes: patient with missing, normal, and abnormal lab results. Next, we reason about medications. Each of the three nodes can be split indicating whether treatment has been initiated and how aggressive those treatments are. The final question splits the nodes based on the presence of diagnoses.

Figure 1 illustrates the SEV for hyperlipidemia. At the root of the hierarchy, we ask whether lab results (LDL, HDL and TG) are normal (if they are not missing) and which (if any) are

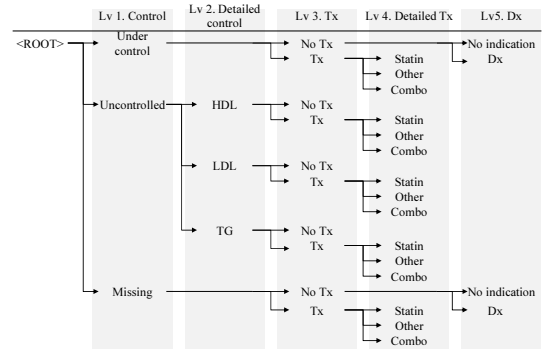

Figure 1: Sample Severity Encoding Variable Hierarchy for Hyperlipidemia. Abbreviations used: Treatment (Tx), Diagnosis (Dx), High-density lipoprotein (HDL), Low-density lipoprotein (LDL), Triglycerides (TG).

Table 1. Categorization of the Data Representations.

	Outcome-Specific	Outcome Independent	
		Data-Driven	Knowledge-Driven
Dimensionality-Reducing	SS	PCA DAE-9	SEV
Dimensionality-Expanding		DAE-34	SEV

abnormal. At the next level, we reason using medications. For example, does a patient under control use medications? If medications are used, are they first-line medications (statins in case of HL), other drugs, or combinations of drugs? On the last level, we reason using diagnoses. Naturally, diagnoses are most helpful if no other indication of disease exists.

For analysis, the hierarchy can be cut at any level and the nodes at that level are taken as binary variables. For example, cutting the hierarchy at the top-most level results in a set of three binary variables: 'patient is under control', 'patient is not under control', and 'laboratory results are missing'. These variables are partially ordered: being under control could (but does not have to) indicate lower severity than not being under control, but 'lab results are missing' is not comparable to the other two in terms of severity. Cutting the hierarchy at the (say) third level yields 10 leaves and incorporates information about medication use. One of these leaves would be 'patient has abnormal LDL despite medication'. By changing the level at which the hierarchy is cut, we can increase the number of leaves (and information content).

SEV is a framework for representing diseases as hierarchies induced by a sequence of clinical decisions; it is not a set algorithm for modeling all diseases. Recall that SEV is outcome independent; once a SEV is constructed, it can be used for multiple study end-points. The diseases that we build SEVs for are predictors of the outcome and the construction of the SEV can (and possibly should) depend on the disease that we build the SEV for. Depending on the disease in question, a different ordering of the same clinical questions could yield a more clinically meaningful hierarchy, and other diseases may incorporate altogether different questions (for example, stage and grade of cancer). We have not observed substantial changes in predictive performance in terms of the ordering of the questions.

Materials and Methods

Data, Cohort Construction and Study Design

Mayo Clinic, located in Rochester, MN, provides primary care to a large population. Resources available at Mayo Clinic are described elsewhere[16]. After IRB approval, a cohort of 75,317 patients aged 18 or older on 01/01/2005 with research consent was constructed. The cohort was followed from the baseline of 01/01/2005 until the end of 2015. To determine patients' baseline status, we retrospectively collected diagnoses of obesity, hyperlipidemia, hypertension, and prediabetes; laboratory test results for lipid panels and fasting plasma glucose (FPG); vital signs (blood pressure, and body mass index [BMI]); demographic information (age, gender); and medications for hypertension and hyperlipidemia. From the cohort, we excluded patients with preexisting diabetes at or before baseline (11,897 patients) and suspicion of diabetes (3 patients with fasting plasma glucose > 125 ml/dL and 2 patients taking anti-diabetic drugs), resulting in a final cohort of 63,415 patients.

Comparative Representation

Severity Scores (SS): A severity score is computed for each diabetes risk factor (obesity, hypertension, hyperlipidemia, pre-diabetes) quantifying the risk factor's contribution to diabetes. While all features could be combined into a single severity score (analogously to the Framingham score), we compute a severity score for each risk factor, combining only the features that are related to the specific risk factor. Modeling the risk factors separately allows us to retain the relationships among them.

For each risk factor, the corresponding SS is the linear prediction from a Cox model, whose independent variables are the data elements that describe the risk factor in question and the dependent variable is diabetes outcome. Missing blood pressure measurements were imputed using mean imputation and a bias-correcting indicator variable signaling whether imputation was performed for each patient was added.

Principal Component Analysis (PCA): In this study, logistic principal component analysis (PCA)[14] is applied to the risk factors, resulting in a single set of principal components. We kept the first 9 principal components because additional components are unable to explain significant amounts of variation. PCA is thus a dimensionality-reducing, outcome-independent representation.

Deep autoencoder (DAE): For this study, we used two configurations, tuned via cross-validation. Both used the hyperbolic tangent activation function, had two hidden layers with 20 nodes on the first layer and had 9 and 34 nodes on the second layer, respectively. The first configuration (DAE-9) has the lowest reconstruction error among configurations that *reduce* the dimensionality of the problem, while the 34-node configuration (DAE-34) has the lowest reconstruction error among all configurations. DAE-9 is a dimensionality-reducing representation, while DAE-34 is a dimensionality-expanding representation.

Severity Encoding Variables (SEV): A severity encoding was constructed for each of the four risk factors of diabetes independently. The hierarchy was cut at the leaf level, making it dimensionality-expanding (there are more nodes in the hierarchy than original features).

The Two Tasks

Regression Analysis: The objective is to measure the impact of the data representations on the predictive performance of estimating patients' 8-year risk of T2D. Risk factors (lab results, vital signs, diagnoses (ICD-9 billing code rolled up into categories), and prescriptions rolled up into NDF-RT pharmaceutical subclasses) are determined at baseline. We use this information transforming into the five new representations. The sixth representation is RAW, the original (untransformed) data. Six Cox proportional hazard models are constructed using age, gender and each of the six data representations as independent variables. Backwards elimination is applied.

Association Pattern Analysis: The central concept in association pattern mining is an *item*, which is a binary variable such as 'presence of hyperlipidemia diagnosis' or 'LDL ≥ 130 mg/dL'. Items are combined into conjunctive sets, called *itemsets* (e.g. 'LDL ≥ 130 mg/dL AND diagnosis of hyperlipidemia'). The association of an itemset with the outcome is measured through *confidence*, which is the fraction of patients presenting with the outcome among patients who present with all conditions in the itemset (fraction of patients who developed diabetes among those with LDL ≥ 130 mg/dL and diagnosis of hyperlipidemia in our example). Association pattern mining systematically enumerates all itemsets and computes their confidence. In the Classification Based on the Association (CBA) framework[17], the risk of diabetes for a patient is the confidence of the highest-confidence rule that applies to that patient.

Continuous variables (age, severity scores, scores from PCA and DAE) are categorized into deciles (with backwards elimination discarding superfluous categories) and laboratory results and vital signs are dichotomized using the American Diabetes Association[18] cutoffs. Of interest are the number of patterns and their predictive performance. A data representation that can achieve higher predictive performance with a lower number of rules is preferable.

Results

Regression Analysis

Figure 2 (a) shows the concordance of the various data representations as box plots. The top, middle, and bottom line in each box correspond to the upper quartile, median, and the lower quartiles of the concordances estimated from the 1,000 bootstrap replications, respectively. The representations are ordered left to right by the number of features they produce.

While all performance differences are statistically significant, some are not substantial. Our population consists of relatively healthy patients, hence all methods achieved high discrimination. A more clinically meaningful question is to accurately estimate diabetes in risk patients who are at relatively high risk and may actually benefit from an intervention. To this end, we consider patients with Framingham score of at least 20 and in Figure 2 (b), we present the predictive performance of the Cox model on the 6 data representations on these 2,493 patients.

Association Analysis

Association rule mining can discover an exponentially large number of patterns, many of which can be coincidental. The parameter that controls the number of patterns is *Minimum Support in Cases (minsupC)*, the number of cases (patients who developed diabetes) to whom the pattern applies. Figure 3

displays the concordance and number of patterns discovered as a function of minsupC.

Discussion

As the paradigm for clinical studies continues to shift toward precision medicine, the range of tasks that clinical data analysis is used for will broaden. Since these newer tasks may operate optimally with different data representations, understanding existing and developing new data representations will become increasingly important. In this manuscript, we proposed a new data representation, Severity Encoding Variables, which represents diseases at a high level and is enriched with clinical knowledge. We compared SEV to five other existing data representations using two clinical tasks.

Assessing the Risk of Incident Diabetes through Regression

The key concern in regression is information loss. The two dimensionality expanding methods, SEV and DAE-34, achieved the highest performance, as they can extract more information (e.g. SEV encodes some interactions and Deep Autoencoders can encode non-linearities). While the performance difference between these two methods in the entire population was minimal (although statistically significant), when we focused on the subpopulation with very high Framingham score (20 or higher), the performance gap widened substantially and SEV outperformed DAE by 20%. Given their high risk of developing diabetes, this is precisely the group of patients for which we need to estimate the risk accurately so that we can effectively target preventive measures to the patients most in need.

Mechanistically, SEV's performance advantage stems primarily from interactions. It can distinguish between patients who have similar lab results at baseline but are in very different states of severity: e.g. patients who are not yet pharmaceutically treated are very different from those who are already undergoing combination therapy at baseline. Despite having similar (abnormal) lab results, the latter patients are at a disproportionately higher risk and interaction among the various facets of the disease are required to model this correctly. Second, SEV can handle missing data without imputation, identifying that the presence of the diagnosis code is more important in patients who have no available lab results than in patients where the lab results already suggest the presence of the disease.

While interactions among various facets of a disease partly explain how SEV achieves high performance, selecting the right interactions is important. Some classification methods, such as decision trees or association rules, are capable of automatically discovering interactions, however, as our experiment with association rules demonstrates, finding the right combination of interactions is non-trivial.

Dimensionality-reducing data representations did not perform well. Dimensionality reduction can reduce noise and can also lead to information loss. Given that our problem is "tall", the number of patients far exceeds the number of variables, dimensionality reduction led to information loss. Among the dimensionality-reducing methods, SS takes the diabetes outcome into account, and hence managed to preserve most of the outcome-related information, achieving a reasonable performance with the smallest number of features. PCA and DAE-9 are outcome-independent, and have suffered greater outcome-related information loss than SS despite having more features.

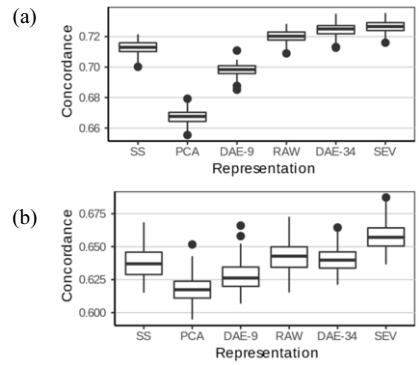

Figure 2: (a) Performance comparison of data representations for the regression task. (b) Comparison of concordance on subpopulation with Framingham score ≥ 20.

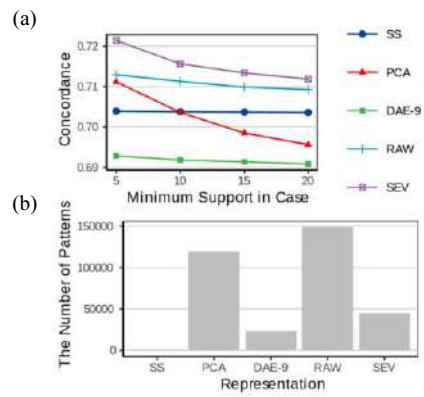

Figure 3: (a) Comparison of the predictive performance of the association patterns discovered using the various data representations as a function of the minimum support in cases (minsupC) (b) The number of association patterns discovered using the various data representations. (minsupC=5)

Modeling Patient Population Heterogeneity through Association Pattern Mining

On this task, SEV performed substantially (and statistically significantly) better than others. The association mining algorithm itself performs dimensionality expansion by forming combinations of the features the data representation provides. To find high-risk patients, we typically focus on patterns that occur in small patient groups, which can yield less reliable risk estimates and higher predisposition to overfitting (finding patterns that happen to randomly *coincide* with diabetes). Different data representations offer different mechanisms to reduce overfitting. The severity scores reduce the number of items an itemset can have. For example, for SS, there are only 5 axes (demographics, obesity, hypertension, hyperlipidemia and prediabetes), each of which is categorized into multiple bins. Since a patient cannot fall into two different bins along the same axis, the maximal number of conditions in a pattern is 5, which seriously limits the number of patterns. Some patterns have as many as 11 conditions in the RAW representation.

SEV, the data representation that achieved the highest performance on association pattern mining, applies a different mechanism. SEV uses the same dichotomization as RAW, but SEV combined these dichotomized variables into predefined "sub-patterns". For instance, the SEV item 'lipids under

control' is a combination of three RAW items: LDL is normal AND HDL is normal AND TG is normal. These higher-level items constrain the space of possible patterns (based on clinical knowledge) and thus reduce the tendency for overfitting.

Generalizability

We tested the data representations with a regression model and association pattern mining to highlight certain characteristics of the SEV representation. We believe that these results generalize to other classification methods, as well. First, the SEV representation offers a high-level clinical description of the diseases enhancing clinical interpretability of the models. Second, SEV can improve predictive performance by automatically handling missing lab results and by incorporating clinically meaningful high-order interactions. Third, as we have mentioned earlier, some methods have the ability to discover interactions, and discovering high-order interaction is non-trivial. Currently, there are no classification methods that can do all three well.

Limitations

Unlike the data-driven representations, the construction of the SEV requires clinical expertise. Most of the effort is spent on classifying diagnoses into categories and determining pharmaceutical subclasses for drugs. This effort is not specific to SEVs; even the RAW representation had access to these higher-level categorizations. The effort that is specific to SEV is determining whether lab results and vital signs are normal and whether a drug is first-line or last-line medication. This information is often readily available from practice guidelines, such as the American Diabetes Association guidelines for diabetes. The effort to include this information is small, but non-negligible. However, SEV is outcome-independent, thus once a hierarchy for a risk factor or disease is defined, it can be used for numerous outcomes without the need to change it.

Conclusions

For both regression and association pattern mining, SEV provides the highest performance, substantially higher than the other data representations in a high-risk subpopulation, where accurate risk assessment is particularly important to appropriately target preventive measures. Besides having the highest performance, SEV produces clinically interpretable models and can also handle missing values.

Abstract

Several indices exist to classify Congestive Heart Failure (CHF) patients' propensity for early mortality; however, they are primarily based on limited data and are not intuitive to use at the point of care. We investigate a novel, data-driven, risk assessment and visualization approach to investigate mortality prediction of CHF patients using data retrieved from an intensively digitized hospital's data repository. Combining well-known, computationally efficient, dimensionality reduction (DR) methods with 2-d information visualization, the method classifies and visualizes CHF patients into high and low risk groups, contextualized by the factors driving their classification. The DR method performed similar to logistic regression (LR), but visualized the classification and its significant factors at the population level, individual level and the potential impact of interventions for an individual patient. These are encouraging results in favor of the proposed visualization approach, and contributes to the current focus on advancing patient care via large-scale visual analytics.

Keywords:

risk assessment, computer graphics, heart failure

Introduction

The widespread adoption of Health Information Technology (HIT) by healthcare organizations in many parts of the world has generated vast repositories of detailed patient-level data as a result of routine care delivery [1]. Efficient and effective use of multi-dimensional, multi-sourced data for clinical decision support at the point of care is further exacerbated by the time-constrained and stressed environments where most of health care is provided – in the general practitioner (GP)'s office, hospitals and emergency care institutions [2]. Visually intuitive methods and tools that support clinicians for early identification of high-risk patients with Congestive Heart Failure (CHF), as well as patients with better adherence to treatment recommendations and shared decision-making, can improve both clinical decision-making and patient health outcomes. The objective of this study is to demonstrate a multi-level visualization of CHF patients' disease risk classification that combines statistical dimensionality reduction (DR) methods with innovative information visualization to enhance efficient and effective clinical decision support at the point of care. The visual presentation provides a simple, intuitive tool for clinicians to quickly identify high-risk patients and understand key factors affecting their condition at a snapshot in time.

Congestive Heart Failure (CHF)

Based on recent data, nearly 5 million US adults are currently living with CHF as are more than 25 million adults worldwide [3]. CHF affects people of all ages, from children and young adults to the middle-aged and elderly. Almost 1.4 million individuals with CHF in the U.S are under 60 years of age. CHF is responsible for 11 million physician visits each year in the US, and more hospitalizations than all forms of cancer combined (https://www.emoryhealthcare.org/heart-vascular/wellness/heart-failure-statistics.html). In fact, CHF is the leading cause of death for both men and women, and the most common diagnosis in hospital patients age 65 years and older. More than half of those who develop CHF die within 5 years of diagnosis, and sudden death is common in patients with CHF, occurring at a rate of six to nine times that of the general population [4, https://www.cdc.gov/heartdisease/facts.htm].

Several indices exist to classify CHF patients' propensity for early mortality. Among the most popular are the Enhanced Feedback for Effective Cardiac Treatment (EFFECT) [5]; the Emergency department-based models of Society of Chest Pain Centers, and the Ottawa Heart Failure Risk Scale [6].

Current prediction tools are largely based on limited data, rather than on patient-level big data derived from various data sources [7, 8]. Furthermore, most prior studies either used explanatory rather than predictive statistics, or utilized traditional, albeit sometimes complex, statistical models [9, 10].

Visual Analytics (VA)

Data or information visualization refers to graphical *presentation* of complex computerized results in formats that enable rapid comprehension of complex situations by the viewers, but does not necessarily involve *analysis* tasks or *interactivity* [11]. In contrast, VA requires collaborative interaction between the user and the computer. It is defined as the science of analytical reasoning facilitated by interactive visual interfaces [12]. VA combines automated analysis techniques with interactive visualizations for an effective understanding, reasoning and decision-making on the basis of very large and complex data sets. Using VA, the results are presented via visual interactive platforms for decision makers to explore and gain insights and new knowledge. The approach is to marry the big data processing capabilities of analytics with the human intuitive capabilities of interactive visualization.

Benefits of using visualization tools

Innovative algorithms and tools that combine statistical machine learning and optimization with information visualization and electronic health data may reduce clinicians' information processing load and improve their ability to assess risk of disease onset and related complications at the point of care [2, 13]. Information visualization utilizes the high bandwidth processing capabilities of the human visual system to more efficiently perform interactive data exploration and glean important insights [14, 15]. A critical element in visualization is the incorporation of an expert user, such as the clinician decision-maker, in the interpretation of the data. This may make visualization methods particularly useful for cardiology care where clinicians desire flexibility for customizing assessments to the needs of their unique patient

populations. To the best of our knowledge, this is the first study on computationally driven visualization techniques for improving CHF risk assessment.

We applied the visual analytics method to two subsets of the uniquely comprehensive cardiology dataset from a major academic medical center in Israel. We compare the risk visualization approach with Logistic Regression (LR) results to highlight the unique value of visual analytics in clinical decision making for complex health conditions.

Methods

Study setting and data

The Sheba Medical Center is the largest Israeli hospital, located in the center of the country. It is a leading public academic medical center, annually handling over a 1.5 million patient visits and ~200K emergency visits, and conducts more than two million medical tests of all types. Sheba is an extensively computerized hospital, where an integrated EMR system is used in the ED and all inpatient departments, fully replacing paper-based medical records. In recent years, Sheba has established a research-focused data warehouse which collects data describing imaging results, manual monitored parameters keyed into the clinical information system in the intensive care unit (patient temperature, blood pressure, pulse, blood oxygen saturation, weight, height, etc.), medical devices data (ECG, Echocardiography examinations, Cardiac Catheterization, Nuclear Imaging), the National Population Registry, the National Cancer Registry and the Sheba Executive Survey data.

Each patient admitted to the hospital, via the ED or otherwise, who is diagnosed with a cardiovascular condition as a primary diagnosis, has data uploaded to the data warehouse. All patient information is then retrieved from the other systems using the unique patient ID as it appears in the Israeli Population Registry. This unique identifier allows accurate location of patient data. The records have the potential to contain above thousand features for each patient, albeit sparsely populated. Such a health data repository is both rich and unique for large-scale data analysis, but there are many data challenges. While return of investment of such data integration projects is uncertain [16], one of the use cases proposed for health data is to improve clinicians' decisions at the point of care.

In this preliminary study, we use a subset of the uniquely comprehensive Sheba data warehouse for our analysis, which provides many relevant variables affecting readmissions and mortality and covers all possible patients treated at Sheba over the recent five years. Consequently, this represents the whole population of interest instead of a limited, skewed sample.

Data sample

We employed k-means cluster analysis on a dataset of 7,168 patients hospitalized at the Sheba Medical Center for heart disease between 2010 and 2017. For the demonstration of the visual analytics approach, we selected two specific clusters: younger (N= 204, average age 63 (±15.5)) and older patients (N=367, average age 79.12 (±10.57). Table 1 shows the descriptive statistics of the younger cohort. The other cohort is omitted due to page limit constraints.

Logistic regression to predict patients' propensity for early mortality

Among the many analytical methods currently available, we chose logistic regression (LR) as a baseline method to compare with the visual analytics approach. LR is a widely used and accepted statistical method in clinical medicine [17].

Visual analytics approach

We apply prior work on dimensionality reduction and information visualization for disease risk assessment [2, 13] to CHF data. Specifically, the visual analytics approach incorporates Principal Component Analysis (PCA) and Fisher's Linear Discriminant Analysis (LDA) to develop informative two-dimensional (2-D) projections of multi-dimensional patient data and classify them for CHF-related risk assessment [2, 13]. Included in this step are the identification of appropriate data normalization procedures for the dimensionality reduction methods and the disparate measurement of the data attributes. A set of feasible methods for pre-processing and projecting high-dimensional patient data to 2-D plots are incorporated into the framework so that multiple visual enhancements that may augment a user's analysis can be obtained. Prior results show that the framework may generate models which visually classify a large patient population with accuracy comparable to that produced by common statistical methods [2, 13].

Starting with a d-dimensional space (the d features of interest in the current study), PCA uses an eigenvalue decomposition to find d orthogonal linear combinations that explain the most variance in the data [18]. The principal components are ordered based on the amount of variance explained. LDA, on the other hand, is explicitly concerned with classification and takes into account data labels [19]. In a dataset labeled with k classification levels, LDA finds a k-1 dimensional projection of the d-dimensional data that maximizes the ratio of between-class variance to within-class variance. LDA was chosen because it stratifies patients into risk groups. PCA ensures that patient observations are maximally scattered in the reduced space. The data are projected into 2-D space as scatter plots using the optimal linear combinations found by PCA and LDA, with LDA finding a decision boundary for classifying patients into high and low risk categories. Contextualization of the scatter plot is critical for ease of use and interpretability, and is provided by anchoring the risk factors around the scatter plot, effectively circumscribing them in a circle. Each anchor's direction of attraction (θi) is defined using the ratio of that feature's weights on the vertical and horizontal components of the two-dimensional space:

$$\theta_i = \begin{cases} \tan^{-1}\ (d_{i1} / d_{i2}) & d_{i2} \geq 0 \\ \pi + \tan^{-1}\ (d_{i1} / d_{i2}) & d_{i2} < 0 \end{cases} \qquad (1)$$

where d_{i1} is the weight of feature i on the vertical axis component, and d_{i2} is the weight of feature i on the horizontal axis component. Finally, the significance of each anchor can be represented by the size of the anchor (S_i), computed, for simplicity, as proportional to either d_{i1} or d_{i2}. Further details of the method and its evaluation with diabetes data are reported in [2, 13].

These methods have been implemented in an RShiny-based platform (https://shiny.rstudio.com/) that allows loading, viewing, descriptive analyses, predictive analyses and visual analytics of any dataset. We employ these methods and tools to a subset of the Sheba data sample with a set of selected features to investigate the population distribution between low- and high-risk patients, and examine factors emerging as most critical for high-risk patients. The risk prediction results from this phase are compared against the results from LR to generate additional insights, particularly to identify patients who are noted to be at the boundary of high and low risk levels by the two approaches.

Results

The two data subsets represent older group (OG) and younger group (YG) of CHF patients, on average, that are randomly retrieved from the large dataset. In the future, we intend to use the complete dataset, possibly even over a longer duration, and include additional data on demographics, diagnoses and current and past health indicators, medications, and lab and imaging results.

Descriptive statistics

The mean and proportion of indicators that differed significantly between the younger group (YG- alive and deceased) are highlighted in Table 1 (The older group (OG) is also discussed but the table is not included due to page limits). As evident in Table 1, among factors affecting significantly likelihood of mortality are age (older more likely), prior CHF, dyslipidemia, hypertension and diabetes mellitus. Among lab tests, patients with lower level of hemoglobin in the first test (indication of anemia), and lower GFR MDRD (measure of renal function) were more likely to die. Additional factors were lower systolic and diastolic blood pressure among patients who died. Among the older patients (not shown as a table), age was a significant factor (older more likely to die), lower GFR MDRD and lower systolic and diastolic blood pressure. For this cohort, however, two unique factors affected the likelihood of older patients' mortality: higher sodium level in the blood and lower level of hematocrit. Interestingly, factors significantly affecting the likelihood of mortality in younger patients were derived from medical history and risk factors, whereas for older patients they were derived mainly from lab tests and physical examination.

Table 1: Data description of the younger population

Indicator and Description	Total	Alive (0)	Deceased (1)	P value
N:Total admissions included	204	160	44	
Patient age (mean ± sd)	63 (15.6)	61 (15.5)	70 (13.4)	<0.001
Male (%)	144 (71)	114 (71)	30 (68)	0.835
Ejection fraction (mean ± sd)	38.08 (17)	37.38 (17)	40.66 (16)	0.266
Past Percutaneous Coronary Infusion (%)	48 (23)	36 (22)	12 (27)	0.645
Past Myocardial Infarction (%)	55 (27)	44 (27)	11 (25)	0.889
Congestive Heart Failure (%)	117 (57.4)	90 (56.2)	27 (61.4)	0.663
Past Stroke (%)	15 (7.4)	13 (8.1)	2 (4.5)	0.632
Peripheral arterial disease (%)	7 (3.4)	5 (3.1)	2 (4.5)	1.000
Dyslipidemia (%)	82 (40.2)	58 (36.2)	24 (54.5)	0.044
Hypertension (%)	101 (49.5)	73 (45.6)	28 (63.6)	0.052
Diabetes Mellitus (%)	64 (31.4)	43 (26.9)	21 (47.7)	0.014
Chronic Obstructive Pulmonary Disease (%)	10 (4.9)	6 (3.8)	4 (9.1)	0.290
FIRST Hemoglobin (mean ± sd)	12.49 (1.91)	12.76 (1.81)	11.52 (1.96)	<0.001
Left Ventricular Function (%)	133 (65.2)	107 (66.9)	26 (59.1)	0.435
SPAP (mean ± sd)	47.33 (13.00)	47.09 (13.46)	48.23 (11.25)	0.606
Glomerular Filtration Rate MDRD (mean ± sd)	60.39 (30.35)	67.40 (29.10)	34.91 (19.24)	<0.001

Not died / Low risk patients (TN)	124	141	167	231

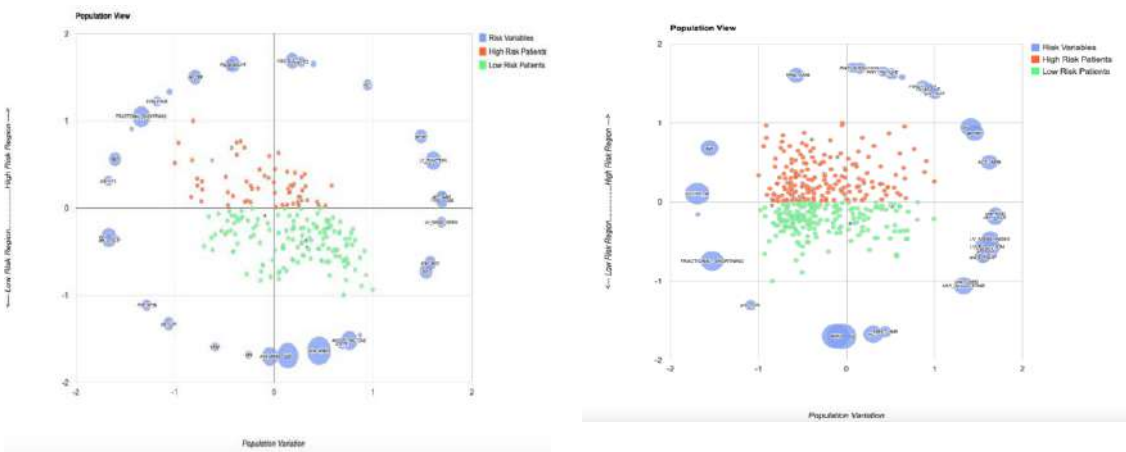

Figure 1: Population-level mortality risk prediction for younger (top) and older (bottom) patient clusters

Dimensionality reduction and population risk visualization

Figure 1 displays the population-level mortality risk prediction for younger and older patients, respectively, using the statistical dimensionality reduction approach described above. It is interesting to note that the distribution of mortality risk in the respective patient cohorts (indicated by red points for high risk and green for low risk patients), the factors driving risk in each group (indicated by the blue circles at the top of the displays and listed in Table 2) and protective factors (indicated by the blue circles at the bottom of the displays – compliance with medications) are distinct and different for each subset. These visualizations provide new insights about customized, cohort-driven population risk management. Individual patient-level and intervention-level analysis can be performed analogously, as described in [2, 13].

The DR technique classified almost 70% of the younger group to have low-risk of mortality, while 30% were classified as high-risk (Figure 1, top). In this cohort, there are seven factors in the high risk region (top of the graph) that are driving risk for this population while eight factors at the bottom of the graph are protective.

Comparison of DR and LR

Table 2 shows factors that have been determined to be statistically significant in driving the classification as high or low risk. It is interesting to note that that DR identifies a different set of factors for the younger vs. the older populations whereas the factors are quite similar in the LR solution. DR also identifies a larger group of modifiable factors that clinicians can intervene on compared to LR. These findings need to be evaluated with larger data sets and validated extensively with practicing clinicians and the clinical literature.

We compared the two methods using three measures (Table 3): Accuracy (TP + TN divided by the number of participants), Recall (TP divided by TP + FN) and Precision (TP divided by TP + FP). DR outperformed LR on the Recall measure for both cohorts, an important indicator for mortality.

Discussion

The DR analysis provides a visual classification of the patient cohort into low- and high-risk regions. Factors affecting the specific classification can be derived and visualized as anchors around the scatter plot (circles), as can the magnitude of the effect of individual anchors (size of the circle). It is important to demonstrate the validity of this classification method in the context of multiple disease conditions. This has been done by comparing the visual analytic results to those of logistic regression, a common classification method. As presented in Tables 1, 2 and 3, DR outperformed LR in discriminating high risk patients (TP), while LR performed better in identifying low risk patients (TN). Although results of other comparison measures (accuracy, precision) were inconclusive, the capacity of DR to more precisely identify high-risk patients, without likewise increasing the falsely identified patients (especially FN) is encouraging (Table 3). Minimizing the FN is the major criterion in actual practice. Moreover, DR identified a higher number of significant factors affecting high-risk patients specifically for older, readmitted patients (Table 2).

While expert physicians are generally able to classify regular patients to low- or high-risk categories, patients with multiple comorbidities often are more difficult to classify correctly. We found that the DR tool was able to classify patients as either low- or high-risk, thus aiding the clinician to refine their assessment. Both options are important: classifying low-risk patients as high-risk is costly and causes unnecessary worry and inconvenience for the patients, and classifying high-risk patients as low-risk may be dangerously life threatening. This approach offers a unique opportunity to deliver cognitively-guided capabilities that have the potential to move statistical risk models closer to the frontlines of clinical practice using visualization techniques, and facilitate the goal of meeting clinician and patient information needs to improve care quality and health outcomes. The demonstrated visualization techniques may benefit multiple stakeholders, including patients, clinical practitioners, researchers and policy-makers, with generalizability to many risk assessments in clinical practice.

Conclusions

We have demonstrated the promise of an innovative statistical model-based approach to create a visualization tool (dimensionality reduction and 2-D visualization). The advantages are evident in the lower number of FNs and identification of modifiable significant factors that differ between younger and older populations. In terms of model characteristics, such as accuracy and recall, results are not conclusive. Additional analyses with larger patient cohorts need to be carried out.

Future research includes many avenues such as extending the methodology to allow time-varying risk factors, optimizing feature selection and decision boundary alignment and evaluation against several other statistical and machine learning methods.

Abstract

Research data generated in large projects raise challenges about not only data analytics but also data quality assessments and data governance. The provenance of a data set – that is the history of data sets – holds information relevant to technicians and non-technicians and is able to answer questions regarding data quality, transparency, and more. We propose an implementation roadmap to extract, store, and utilize provenance records in order to make provenance available to data analysts, research subjects, privacy officers, and machines (machine readability). Each aspect is tackled separately, resulting in the implementation of a provenance toolbox. We aim to do so within the context of HiGHmed, a research consortium established within the medical informatics initiative in Germany. In this testbed of federated IT-infrastructures, the toolbox shall assist each stakeholder in answering domain-specific and domain-agnostic questions regarding the provenance of data sets. This way, we will improve data re-use, transparency, and reproducibility.

***Keywords*:**

Data Accuracy, Metadata, Research, Reproducibility of Results

Introduction

In addition to the variety of hospital information systems, university hospitals and academic medical centers operate specialized systems, each one serving specific use cases in a best-of-breed manner to support research [1]. Furthermore, a hospital runs multiple software systems in order to serve medical care, generating vast amounts of heterogeneous data. Using information that is contained in healthcare and research systems requires cleansing, harmonizing, and integrating the data sets – typically referred to as extract, transform, and load (ETL) processes. Finally, an integrated data pool can be generated for further analysis. As the numbers of data sets and systems grow, for example by federating systems from multiple sites, the complexity of performing ETL related tasks grows as well. This makes the assessment of data quality a tedious task. Moreover, data reuse is oftentimes difficult and then neglected, which results in recaptured and regenerated data sets per research project [2]. Thus, creating reusable data sets represents an important focus in current research [3]. The FAIR principles require data sets to be findable, accessible, interoperable, and reproducible in order to ensure high-quality data sharing and enable data reuse [4] both for humans and machines. Fine-grained documentation of processes, transformations, and influences on an object – also known as provenance – from data sources, data integration pipelines, and data repositories can be exploited to enable data reuse and improve data quality [5,6]. Provenance is used to enhance reproducibility, transparency, presentation, meta-analysis, and machine-readability [7].

Capturing, storing, and utilizing provenance have shown to provide valuable insights within biomedical research projects [8] – technical experts inspect provenance in order to assess data quality and gain insight into data processing across multiple sites. We aim to implement a generalized toolbox focused on provenance using our experience, providing instruments to capture, store, and utilize provenance for technicians and non-technicians alike. More discipline-specific experience on how to handle provenance in federated research projects is available from the geographic information systems (GIS) [9], bio-informatics [10] or the physics domain communities [11].

We will implement and test the provenance toolbox in the context of the HiGHmed platform, which aims to implement a federated platform of medical data sets in order to improve healthcare and medical research at multiple institutions [12]. Conforming to the HiGHmed principles, the toolbox needs to be scalable, compliant to local data safety and privacy regulations, sustainable, federated, and focused on improving patient healthcare. This toolbox should be applicable by different stakeholders in medical research projects.

We propose this implementation roadmap towards a provenance system architecture describing how we intend to develop solutions to capture provenance appropriately, store provenance securely embedded into a heterogeneous IT-infrastructure, and implement the means to utilize provenance for each relevant stakeholder in medical research.

Methods

A thorough literature review was conducted as a basis for our work [13]. Additionally, surveys of Moreau [14], Herschel et al. [15] as well as Pérez et al. [16] were considered. These works present background knowledge regarding provenance research as well as several solutions that implement provenance.

We will use the provenance definition by the W3C PROV-DM specification: “provenance is defined as a record that describes the people, institutions, entities, and activities involved in producing, influencing, or delivering a piece of data or a thing.” [6] Provenance is captured in several granularities, ranging from provenance meta-data to data provenance as depicted in Figure 1 [15]. Provenance meta-data refers to a generic, hardly utilizable type of provenance,

e.g. a free-text description of a method in a research paper. Workflow and information system provenance refer to more specific types of machine-usable data, for example, a definition and execution of a workflow defined in a workflow management system. Distinguishing between these two types of provenance is not always possible. Data provenance refers to the most specific type of provenance, which is usually tailored to the precise context the data describes. Dublin Core, for example, describes several elements of the provenance of digital resources [17].

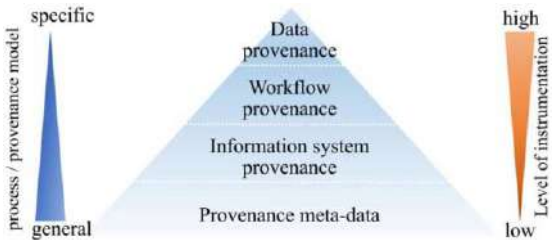

Figure 1 – Provenance Types Hierarchically Ordered by the Provenance Model and the Level of Instrumentation [15]

Capturing provenance manually is considered ineffective [18]. Workflow management systems enable capturing data based on predefined workflows, resulting in workflow-based provenance containing domain-specific insights on processing steps. Process-based (or activity-based) methods require a system or application itself to collect relevant provenance data. Operating-system-based (OS-based) methods allow to capture provenance based on OS functions, like file reads [13]. Similarly, captured provenance based on service-oriented architectures results in service-based provenance. Finally, provenance capturing in the context of relational database systems is considered as a specialized approach to collect provenance [16].

Tracing provenance is performed by two approaches: lazy and eager [16]. Lazy describes collecting provenance after the data processing took place, for example by scraping logs or reverse engineering database queries. The eager approach aims to collect provenance data during data processing (or immediately after), for example by wrapping data processing applications.

PROV-DM is a data model for provenance on the web, defined by the W3C in an effort to summarize and consolidate existing provenance models [6]. It models provenance as an acyclic directed graph, consisting of nodes and edges which represent provenance. Entities, Activities, and Agents represent objects, processes, and influences respectively.

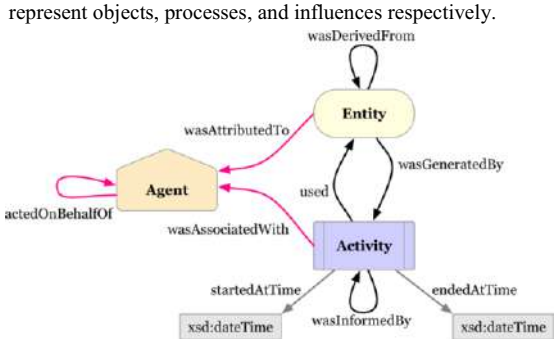

Figure 2 – W3C PROV-DM Depicted as an Acyclic Directed Graph, Showing the Three Starting Point Classes Entity, Activity, Agent in Yellow, Blue, Orange Respectively, Connected by the Relations Defined by PROV [21] and Two Activity-specific Properties are Visualized in Grey

These three nodes are connected by different relations as depicted in a general overview in Figure 2. PROV-DM is highly extensible, allowing to tailor general concepts to more specific constructs. The W3C also provides different serializations for PROV like XML [19] as well as general guidelines on how to use PROV-DM data, like access and query mechanisms [20].

Results

Using provenance from heterogeneous medical research information systems requires considering three aspects: extraction, storage, and utilization. Extraction (or capturing) of provenance is the documentation of data processing steps. Storage of provenance involves a data store, a data format and the means to query the stored provenance data. Finally, utilization generates knowledge from stored provenance data, enabling possible uses from provenance like meta-analysis or reproducibility of computing steps.

Extraction of provenance

As a first step, coordination-points – central computing systems which process high loads of data – will be tackled in order to extract provenance [22]. PROV@TOS has been implemented to capture provenance from data integration jobs based on Talend Open Studio for Data Integration [23]. In combination with version control systems, full-featured provenance documents for data integration pipelines will be extracted [24]. As a part of HiGHmed, the Medical Data Integration Center at the University Medical Center in Göttingen (UMG MeDIC) will use an IHE compliant infrastructure that will use Audit Record Repositories defined by IHE ATNA [25]. These will serve as sources to extract provenance besides data integration pipelines. Upon enabling provenance-awareness for those two coordination-points, existing IT-systems are tackled. In addition to wrapping, log-scraping or creating provenance templates [26], a concept to categorize different provenance sources regarding the quality of produced provenance data will be defined and used to prioritize the implementation of capturing techniques per system. Although the impact of different capturing techniques on provenance quality has been investigated [18], we intend to tailor a comparison to the medical domain in order to prioritize the implementation of per system provenance capturing mechanisms.

Solution to store provenance

Storing, accessing and querying provenance are made possible at a centralized provenance store [27] utilizing the standardized W3C PROV data model [6]. A neo4j NoSQL database (https://neo4j.com/) with an appropriate W3C PROV connector (https://github.com/DLR-SC/provneo4j) will serve as the provenance store. It will be a part of an IHE-compliant IT-infrastructure, hard linking provenance records to the actual data they represent [28]. User access rights are defined via the IHE Consent Profiles (BPPC/APPC) where applicable. The definition of appropriate access rights needs to consider data privacy (i.e. General Data Protection Regulation (EU) 2016/679 (GDPR)). Concepts analogous to the "Cross-Community" profiles defined by IHE will be created and implemented. As a basis, the PROV-AQ [20] mechanisms can be used and extended to fit the needs within a medical context. Furthermore, FHIR Resources for PROV (http://hl7.org/fhir/provenance.html) are available for usage, enabling captured provenance to be used across a whole data sharing community.

HiGHmed's architectural framework relies on the openEHR standard for semantic modeling of clinical information [12]. This standard provides the Feeder Audit (https://www.openehr.org/releases/RM/latest/docs/common/common.html#_feeder_system_audit) which enables linking or directly storing provenance information on different granularity levels even for single data entries where desired.

Visualization and exploration of provenance

On a per stakeholder basis, tools to access provenance records are – if no ready-to-use solutions are available – developed and evaluated, each serving the specialized needs of a stakeholder regarding provenance questions. As a starting point, three stakeholders are taken into account: domain experts (medical informaticians) that perform data analytics, data privacy officers that need to assess regulatory questions and laymen (patients) that seek informational value from provenance records. As intended, use case and domain specific knowledge varies greatly among these three stakeholders, therefore stakeholder-specific access and interaction interfaces to provenance must be designed. A stakeholder analysis needs to be performed prior to implementing the tools followed by validation of the implemented tools against the requirements previously gathered [29]. The PrIMe methodology can serve as a starting point for this task [30]. Tools visualizing such metadata to researchers preparing data analysis can benefit from the availability of standardized provenance information. In order to assist in tasks like data analysis effectively, the planned tools should be embedded into other applications (for example, tranSMART (http://transmartfoundation.org/) for data analysis). As other research fields have already implemented solutions for their respective fields (for example, DataONE [9]), an analysis of those implementations will be performed. Additionally, gaining insight from provenance records is not limited to visualizations, as network analytics are currently evaluated within the provenance research community [31]. To contribute to this research, the metrics that are defined by the authors can be put to use within controlling and monitoring systems.

Discussion

Solutions to capture, store, and use provenance data are scarce. DataONE [9] implements provenance capturing, storing, and usage to recall processing steps related to the data objects that are stored in DataONE, enabling reproducibility. Similarly, platforms like Galaxy [10] or CRISTAL [11] aim to make processing workflows reproducible and recallable. In the Software Evolution domain, the means to utilize provenance data within source code versioning solutions for domain specific needs exist, e.g. defect prediction [32] or simulation of software evolution processes [33]. Our aim will be to learn from these solutions and create the possibility to use provenance to answer domain-specific questions regarding reproducibility of results, assessing data quality, presentation of results, and meta-analysis of all processes within the context of medical research as Curcin et al. suggest [8].

Extraction of provenance

Several software solutions to capture provenance are available, most of them based on workflow management systems [16]. This makes it difficult to tailor them to the needs within the HiGHmed MeDICs. Moreover, the client-server architecture defined by the IHE profiles [25] makes the use of OS-based provenance capture mechanisms less viable. The majority of data sources are only available by proprietary software, urging us to choose an approach similar to PLUS [22]: we will focus on provenance from coordination-points first and tackle single systems second, employing PrIMe [24] to wrap or extend systems. Data privacy needs to be considered when extracting provenance from medical data sets due to GDPR. Where applicable, fine-grained domain-specific provenance data will be extracted from source systems in order to represent the whole data capturing process within the provenance store [11].

Audit logs compliant to the Good Clinical Practice (GCP) showed to yield valuable information regarding provenance [5]. Hence, the audit logs captured based on the ATNA IHE-profile specification may yield comparable data from a coordination-point. Source systems that forward audit logs compliant with ATNA could also be addressed this way. Further investigation is needed to validate this assumption, being an integral part of establishing provenance-aware medical research IT-infrastructures.

Solutions to store provenance

As W3C PROV-DM is modeled as an acyclic directed graph [6], the neo4j graph database is a primary candidate to store PROV data in contrast to commonly used relational database storage systems [8]. Neo4j provides a reliable and scalable solution to store and query graph data [34] and is also used by established provenance recording systems [22,35].

Data privacy within provenance is oftentimes regarded as the need to ensure access rights to provenance data [8,14]. Albeit an important consideration, restricting access to provenance is insufficient to meet both, data privacy regulations and interests of data analysts. Chapman et al. introduce the use of surrogates to mask sensitive data to unprivileged users [22]. This enables the use of sensitive data without violating privacy rights. Under the umbrella term "secure (data) provenance", Torra et al. summarize four requirements [36]: distribution of provenance, integrity of provenance, availability of provenance and privacy and confidentiality of provenance. Tailoring these requirements to the medical research domain will be an important part of future research and the implementation in the UMG MeDIC and other Data Integration Centers.

Provenance data is considered essential within big data applications [37]. Although medical research IT-infrastructures are not necessarily big data applications [1], some characteristics (variety, veracity and, to some degree, volume of data) remain important in data integration in translational research. Within the GIS community, distributing data with its provenance is common practice [38]. Hence, federating provenance across multiple sites in ways similar to the federation of medical data sets is an important focus which needs to be addressed when implementing data federation infrastructures. FHIR, as a standard for medical data exchange, incorporates W3C PROV and provides a starting point to focus on provenance federation.

Visualization and exploration of provenance

Utilizing provenance usually comes in two steps: visualization and analysis. Several solutions to visualize provenance exist, primarily an acyclic directed graph defined by PROV-DM [6]. Prov-O-Viz by Hoekstra and Groth is another graph-based visualization that focuses on the data flow within activities and entities [39]. Schreiber and Struminski present a solution to make provenance understandable for laymen using a representation with comics [40]. The latter solution will serve as a starting point to implement provenance visualization solutions for all stakeholders. In combination with the data

itself, provenance is able to assist visualization of medical records in a similar approach to EVLIN [41].

Due to the nature of PROV-DM, analysis of provenance – that is, computations utilizing provenance without visualizing it – are closely related to network analysis techniques. Huynh et al. tailored several metrics established within network analysis to provenance data, demonstrating the usefulness of such techniques [31]. The usage of provenance templates may add insight in combination with network analysis [26].

Provenance insight serves different purposes [7]. Tackling all purposes in a single application would result in a highly complex tool that requires not only a deep understanding of provenance itself but also of the data it describes. To circumvent this challenge, insights from research regarding data quality of medical data sets can be exploited. Kahn et al. recommend utilizing provenance to improve data quality and data reuse of observational and administrative data [42]. Also, the term "fitness for purpose" was coined to describe that every use case requires a specialized view on data sets to gain optimal performance [43]. Following this paradigm, we aim to make provenance usable for each stakeholder by selecting relevant provenance data sets and by using a specialized applications, tailored to a small set of provenance questions.

As an example, the GCP-compliant data capture software secuTrial (https://www.secutrial.com) implements a function to review audit trails within the application itself, bringing provenance directly into the context of the data itself.

Conclusions

The means to extract, store, and utilize provenance have been tackled individually by several tools within the provenance community. Solutions that grant all of these features are scarce but show great potential to improve reproducibility, recall, insight, presentation, and enable meta-analysis of processing steps within heterogeneous IT-infrastructures. We aim to learn from successful implementations in other disciplines (GIS [9], bio-informatics [10] and software evolution [32,33]), and harness this knowledge to jump start provenance applications in medical research implemented in a provenance toolbox that pools all features related to extraction, storage, and utilization of provenance. This will improve reproducibility, re-use, interoperability, and overall quality in medical research [8,44].

What a Comprehensive, Integrated Data Strategy Looks Like: The Population Level Analysis and Reporting (POLAR) Program

Christopher Pearce[a,b], Adam McLeod[a], Natalie Rinehart[a], Jason Ferrigi[a], Marianne Shearer[c]

[a] *Outcome Health, East Burwood, Victoria, Australia,*
[b] *Department of General Practice, Monash University, Victoria, Australia*
[c] *Gippsland Primary Health Network, Victoria, Australia*

Abstract

In Australia, general practice (GP) acts as the gatekeeper to the rest of the healthcare system, and therefore the vast majority of the population have an electronic medical record. It follows that the largest database of the population is therefore on the distributed GP computers. Informed by a comprehensive system-wide data strategy, the Population Level Analysis and Reporting program extracts data from the GP electronic medical records and repurposes it for multiple uses. The program requires the data to be coded and then structured for multiple uses clinical care, clinical governance, research, and policy.

Keywords:

Primary Health Care, Electronic Health Records, Medical Record Linkage.

Introduction

With 85% of the population seeing a general pratice (GP) at least once a year [2], GP currently contains the most comprehensive database of health data in Australia. Hospital systems contain largely episodic data, and national projects contain limited project-specific data. For instance, the national schemes Medicare (the national health insurance scheme) and Pharmaceutical Benefits Schedules (subsidised medicines), contain only data collected for administrative purposes. Some organisations rely on registries – purpose-built data collections around specific diseases – and often based on hospital settings. Others use small, practice-based research networks.

The described project occurs in the context of a worldwide move to use the data from electronic medical records for research [4; 5], although significant barriers apply, including data extraction [9], and data quality.

Australia has meso-level organisations designed to assist general practice to deliver population-based care. Formerly called GP networks [15], these Primary Health Networks (PHNs) fulfil a critical role as the chosen delivery platform for elements of key health reforms and initiatives and are now embedded in the primary health care landscape as drivers of quality, efficiency, coordination and improved access to health services. PHNs have adopted a comprehensive program to supply their general practices with a multi-faceted approach to help them provide patient centred care, improve their data quality, and take a population-based approach to analytics, based on common principles.

The Population Level Analysis and Reporting (POLAR) program and its research arm, POLAR Data Space, represent an attempt to bridge the power of the former with the needs of the latter, by creating a useful environment to understand the health needs of the population using Australian GP derived data. POLAR is a platform designed primarily to improve quality of care for the Australian population. It does so at several levels – acknowledging a data hierarchy [14] designed to take the use of health data beyond the term 'secondary use of data' – to a position where all uses of data are important. Just because a piece of information is recorded for the care of a patient, does not mean uses of it beyond that are 'secondary'. Indeed, the most significant impact of the data could be from the use of data beyond the individual clinical record.

The program is informed by the principles of an 'organisational wide data quality management program' [8] which expands the data hierarchy to be:

- Identification of the patient
- Clinical care
- Coordinate and integrate services (clinical governance)
- Care of populations
- Research, evaluation, and monitoring of safety and quality
- Policy and strategy
- Administration and logistics

The objective of the POLAR program is to construct a data quality platform that allows data to be 'fit for purpose' across all of these possible uses.

Lacking often in consideration of a data strategy is a theoretical basis of the interaction of data with the business of health. While society has been extensively altered by the arrival of the Internet and the digitization of society – creating the term 'Digital Revolution' to mirror the 'Industrial Revolution' – its effects have been delayed in health, in part because health remains heavily reliant on human-to-human interactions.

Relatively under-theorised, the patient-doctor relationship has been characterised using grounded theory [1], and complexity theory [10]. More recently, the patient-doctor-computer relationship has been described using the frameworks of both dramaturgy [20] and the work of Habermas [11]. These frameworks were created at a time when the potential of data to alter the interaction was not fully appreciated. Early work focused on the role of the computer as an agent, whereas increasingly the computer is a conduit for data to influence care. The focus now needs to be on data as the active agent. Data from multiple sources now influences the patient in their healthcare interactions. In developing this integrated strategy, we looked to extend the use of Habermas.

Habermas framed the world according to the actions of the *lifeworld* and the *system* [6; 7]. *Lifeworld* represents the individual and cumulative actions of individuals – through what is known as communicative action. As the actions of individuals, communicative action represents their expression as aspects of personality, culture and even society. Importantly in our context, it is the result of communication that creates this.

By contrast, *system*, and the concomitant *strategic action* represents the actions of the created society on the individual. This creates for us a tension when considering a framework to examine data – for data is generated by the micro-interactions that represent communicative action, yet is also utilised by the system, and represents a means by which stratifications can be implemented. This is big data at work.

By example – a consultation (or other healthcare interactions) represents communicative action based on of the *lifeworld*. In past work, this would be understood as understanding the whole person in developing a plan [17]. Now, however, such an interaction may be influenced by the actions of the computer – which may be the conduit for the strategic action of the system – recommending specific actions based on national initiatives and allowing for the passage of information to inform the system [12]. The conduit for this activity is the data codes generated by the system.

So in describing the data hierarchy below, in effect it represents a ladder from communicative to strategic influence – from changing the communication between individuals though working between individuals and the system, and to the system itself. This creates the data as a mediator between the two worlds, and the organisation wide governance framework is a means of making that work.

Methods

At the initial level, GPs (and practice nurses, other practice staff) collect and record data in their Clinical Information System (CIS) primarily for the care of an individual patient. Thus a blood pressure, test result or social history recording helps an individual GP with an individual patient.

Data in the systems is collected in a variety of formats. Within the record, there is both structured and unstructured data. Unstructured data can be found in the clinical notes section, in incoming and outgoing correspondence, and other documents such as discharge summaries. At the time of writing, because of the potential of identifiability, unstructured narrative data is not collected.

Next is structured data – which may or may not be coded. Structured data includes elements such as diagnoses, medications, and measurements. This data is extracted and processed, de-identified, and placed in a data repository (see figure 1).

The POLAR extraction tool (called Hummingbird) extracts data into the POLAR database and then de-identified data is sent outside the practice to the POLAR data warehouse, where it is framed and processed for the various uses – including feedback to the practice.

At POLAR we now have a multi-layered approach to cleaning and rationalising data to be used at multiple levels. Medication data is organized according to the World Health Organizationav's Anatomic and Therapeutic Coding (ATC) system. Diagnoses are extracted and undergo an automated process to apply a SNOMED-CT-AU code. Use of this process allows a code to be applied to 95% of data extracted from the diagnosis field. Most of the remnants are not diagnoses, but either administrative or other notes recorded in the diagnosis section. Once the diagnoses are coded, there are further overarching groups created – all diabetes codes into a single diabetes category. Key chronic disease groups are utilised as a qualifier as well.

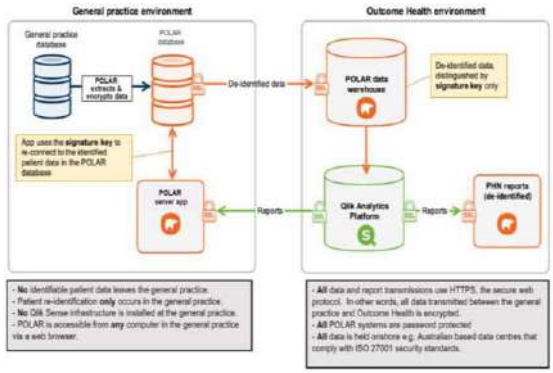

Figure 1– Extraction Environment

Pathology codes are recorded in the system generally using LOINC codes, but again there are many variations across the laboratories and inconsistent naming conventions. We have gone through the extractions and grouped them according to clinical utility (hepatitis testing, etc.) [18]. A similar process has been used for radiology investigations, where no current coding schema is available.

Governance

Governance is just as important as technical ability. Outcome Health provides the POLAR program to the PHNs, and the PHNs provide the service to the practice. As part of accreditation requirements, practices must inform patients of the potential uses of their data.

Ethics approval has been granted separately for the collection and storage of data for the POLAR program, and also for linkage activities. The ethics approval is not project-based, but standing ethics for the underlying processes.

Outcome Health then acts as the data custodian. Various groups then oversee the uses of the data. The research governance group consists of the representative PHN CEOs and reviews applications for research using specific de-identified data fields. The POLAR Data Governance Committee oversees the program as a whole and is made up of a range of internal and external experts. This group is guided by a Data Governance Framework through regular meetings to ensure that the data and processes are ethical, secure and beneficial for all stakeholders.

Other working groups that oversee the presentation of the data to the practices and the PHNs help ti ensure that the tools provided meet the needs of the end users.

Results

Using the data hierarchy described above, the data is repurposed for use at multiple levels. Importantly, this is not secondary use of data – each use of the data is as valid as any other.

Identification of the patient

At the core of the program is the necessary data to identify the individual concerned. At the practice level this includes basic demographics such as: date of birth, sex, address, government derived individual health identifier, etc. However, one of the

principles of POLAR is that no identifying information leaves the practice, for privacy and security issues. Therefore, Outcome Health has created a linkage process, called ORCA. For any given patient record ORCA creates 3 Hash keys based upon a combination of identifiable data. ORCA uses both AES encryption and SHA256 hashing combined with a salting process to protect the integrity of the hash key.

The linkage process allows patient data to leave the practice, but if necessary be returned to the practice and be re-identified during analytics conducted by the general practice staff. For example, a practice may want to identify all their patients with an active diagnosis of diabetes to ensure they are all participating in a Diabetes Cycle of Care.

In addition, through the use of the HASH keys, de-identified patient data can then be linked across practices and with other sources of data. This mechanism allows for innovative research projects across other data sets such as hospital, mental health, etc. to trace and better understand patient journeys through the health system.

Clinical care

The reason the data is collected is to provide a longitudinal view of the patient for all the treating clinicians in the practice. This EMR began as an electronic representation or reflection of the paper record – but has evolved beyond that. Digital health data has allowed the system to more efficiently manage clinical/administrative items such as recalls, tracing of results chronic disease management and many other items. [19] It also has made for more complete information on communications such as referrals [3].

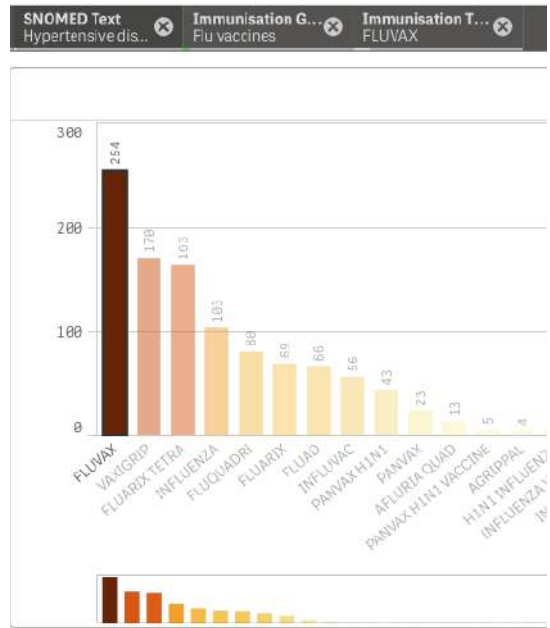
Coordinate and integrate clinical services (Clinical Governance)

Within the practice, the coding and classification of data allow GPs to easily identify cohorts of patients. POLAR then extracts the data from the GP system for clinical governance – allowing GPs to look at their practice population – how many patients have untreated blood pressure, or abnormal test results. Alternatively, sophisticated calculations such as CHADS2-VASC scores. This allows individual GPs to monitor their populations and ensure consistency of care. System-wide recalls (such as adverse reactions to new drugs, or ensuring over 65s receive an influenza vaccination) are easily handled in batches.

Care of Populations (Population Health)

De-identified data is presented at the Primary Health Network level to allow the PHN to look at it at the population level – both in clinical and geographical measures. This becomes crucial to allow both population planning and also benchmarking back to the practices. Such programs have been in place for many years [15], but the level of sophistication has improved with the creation of the organised and coded values. It is essential for PHNs to understand what issues are crucial and in what areas to best leverage and administer their health program funding to improve the health system and the health outcomes for their communities.

Figure 2, for instance, can be replicated at the PHN level, giving valuable information on individual practice performance (for feedback and development initiatives) or for the PHN to design population-based interventions.



ALL IMMUNISATIONS BY PATIENT & TYPE

Patient ID	Full Name	Immunisatio
327	Abanades, Abdellali	FLUVAX
10289	Abar, Abdelmalek	FLUVAX
30235	Abaygar, Abdenabi	FLUVAX
30235	Abaygar, Abdenabi	FLUVAX

Figure 2– All hypertensive patients immunisation status

Research, evaluation, and monitoring of safety and quality

One feature of the program is POLAR Data Space, essentially a governance framework involving the PHNs that allows for the data to be used for research. With the focus of the PHNs on making a difference in primary care – the emphasis is on collaborative research with an intent to create practical outcomes through better primary care but also better-integrated care. Quality data can inform many different modes of research, from traditional descriptive methods through to advanced analytics.

Descriptive studies currently being undertaken or completed include:

- Analysis of after hours-presentations [22]
- Prescribing and antibiotic patterns [23]
- Cardiovascular screening in musculoskeletal disorders. [21]

More advanced research involves using the GP data for real-time monitoring of immunisation adverse events, with a trial project underway. Even mora advanced is using machine learning/artificial intelligence to provide advice at the GP consultation on the risk of emergency deparment (ED) attendance in the next 30 days. Using both linked data (mapping the GP journeys of 5 years worth of patients who attended local ED's) and using machine learning on the GP data [16], this tool can accurately predict the risk 75% of the time [13].

Policy and Strategy

Good data is what should inform strategy and policy. It is impossible to plan if you do not know the landscape in which you are planning. The completeness of the data, its longitudinal nature, and the ever-increasing degree of linkage provide the PHNs significant opportunities to plan service delivery in their local areas, as well as influence policy at a state and national level.

Uniquely, the involvement of the PHNs as change agents allows the finding of the research groups to be rapidly implemented into practice, where appropriate, therefore closing the circle of learning. Examples of these are shown in figures 3, 4 and 5

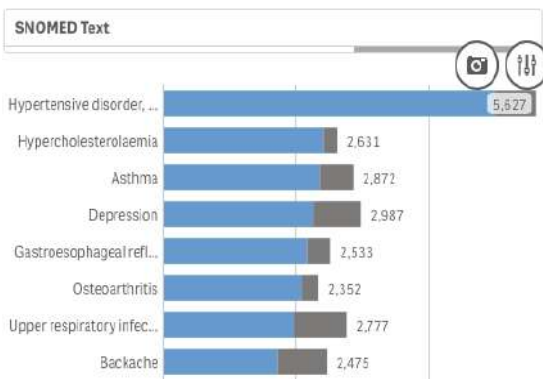


Figure 3– Top 8 diagnoses of active patients who have attended more than 12 times in a year.

Figure 4– Same patient cohort as figure 3, but counting the number of active diagnoses per patient.

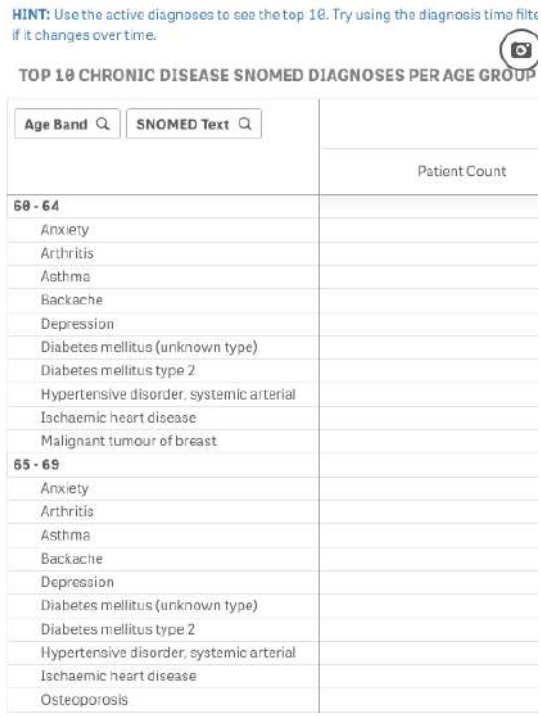

Figure 5– Example of PHN level data visualisation: Top 10 Active disease groups in specific age groups

Administration and Logistics

Within the practice, the data can be used for business and strategic planning to monitor appropriate billing for future service availability, or ensure clinician rostering is appropriate to meet the needs of their patient cohort, address waiting times or anticipate peaks in demand.

For the PHN, the de-identified data enables regional and local level planning to achieve better whole of system care. PHNs need data on health issues in order to understand the needs of communities, target and invest in services to address those needs, prioritise health system improvements, or evaluate performance and outcomes. With their emphasis on making a measurable difference, logistical analytics informs the journey of care so that fragmentation can be reduced by measuring integration and coordination of health services.

Discussion

That which is readable by humans is not by a computer, and the challenge here is to make the data easily exchangeable by the system. Data in an electronic medical record exists in many forms. Free text is the free-flowing writing that exists in many areas such as narrative notes, and many individual data types may be mixed. Advanced computing techniques such as Natural Language Processing (NLP) are required to interpret these notes. Next comes structured text – in which the free text is at least placed in a recognisable area. Writing in a designated 'diagnosis' field fits into this category. Finally comes coded text – in which a specific term has been used to link to a computer readable code.

In order to make the data useable beyond the GP environment, POLAR has chosen to concentrate on the structured text that exists in the system. Narrative data contains much identifying information, and the commitment is that no identifying

information shall leave the practice. Focusing on the structured data, we first concentrated on the diagnosis fields. Using a combination of automated and manual processing, we have been able to apply SNOMED-CT-AU codes to the vast majority of diagnoses. Once coded, we have been able to group relevant diagnoses into clinically meaningful areas. So all instances of diabetes, for instance – or a broader classification of chronic diseases. This makes manipulation of data for clinical governance and population health all the more manageable through the business intelligence analytics dashboards provided to general practice and PHNs for analysis.

Medications have been mapped to the Anatomic and Therapeutic Classifications (ATC) system, which applies five different levels, from 'all cardiovascular' down to individual drugs. This grouping, again, makes manipulation and interpretation of medications much simpler. A similar process is underway for pathology and radiology testing.

Conclusions

The key to making digital data understandable by the system, and useful for multiple purposes, is a multi-pronged strategy of coding, grouping and iterative analysis, underpinned by robust governance structure and a clear strategy.

Abstract

Exploring the topical evolution patterns and temporal trends of hypertension can promote knowledge communication among experts, and is of great significance to understand the profile and frontiers of chronic disease. Current popular topic detection mainly focuses on two directions: one is based on social network analysis (SNA), the other is based on the topic models. Aiming at distinguishing their similarities and differences, this paper adopts the community detection method and expanded topic model Dirichlet-multinomial regression (DMR) respectively to detect the topic distribution and evolution trends of hypertension research. A total of 26,717 articles in the PubMed database were used as examples to construct the MeSH Terms co-occurrence matrix. It is found that hypertension literature is mainly concentrated on three communities and five research topics. MeSH Terms obtained from SNA are more specific and clearer, while the DMR has an advantage in exploring the evolution patterns of various themes.

Keywords:

Hypertension, Medical Informatics

Introduction

Hypertension is one of the most common chronic diseases and the main risk for cardio-cerebrovascular disease. Some 9.4 million people die of hypertension worldwide every year, in which the complications (such as stroke and heart disease) can lead to about half deaths. Thus, an increasing number of scholars have begun to devote themselves to the study of hypertension. As of May 12, 2017, 284322 articles related to hypertension were retrieved in the PubMed database. However, such large-scale medical literature has caused great trouble for researchers. It is difficult to present a comprehensive overview of the profile and frontiers of Hypertension. As the bibliometric method was widely used to analyze the medical literature, some scholars [1-3] have concentrated on the macro level (including major research countries, institutions, authors, etc.) of hypertension research, without in-depth analyzing their topic distribution and evolution patterns at the medium or micro levels.

Existing literature mainly focused on two directions to detect the topic distribution and evolution patterns: one is based on social network analysis (SNA), the other is based on the topic model [4]. The SNA is widely used in data mining, knowledge management, information dissemination, and knowledge network. It can show the relationship of subject terms clearly and visually and can provide effective support for analyzing the location and association of topic words in the network. M. L. Wallace et al.[5] utilized two case studies to demonstrate that the SNA method (such as community detection) helps in identifying research directions, and can reveal more structural details of the knowledge domain than traditional co-citation analysis.

Meanwhile, the topic model, which was widely used in natural language processing [6], information retrieval, text mining, and other fields, is based on the probability and statistics model in the machine learning field. D. Mimno and A. McCallum [7] proposed the Dirichlet-multinomial Regression (DMR) model extended and derived from the LDA model. M. Song et al. [8] utilized the DMR model to detect the topic distribution and evolution patterns of Alzheimer's disease and achieved good results. Compared with the co-word analysis and citation analysis, the topic model can better reflect the relationship between "words-topics-documents." It has great advantages in topic detection.

The purpose of this study is to detect the topic distribution and evolution patterns of hypertension research and distinguish the similarities and differences among topics obtained by the SNA method and Dirichlet-multinomial regression topic model. To illustrate the process of the methods, 26717 articles related to Hypertension in PubMed database are taken as an example to construct the co-occurrence knowledge network.

Methods

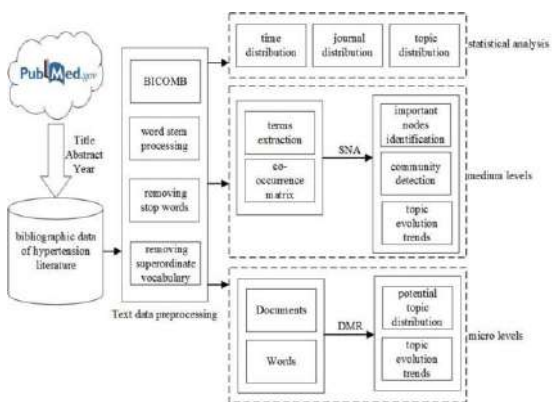

Figure 1– Research Framework

As shown in figure1, the process of our research includes data collection and preprocessing, basic statistical analysis, topic, and community detection by SNA and DMR, comparison of the analysis results.

Data Collection and Processing

The search strategy "Hypertension[MeSH Terms] AND ("2000/1/1"[PDat]: " 2017/5/1")" is used to retrieve the literature of hypertension in the PubMed database. 99252 articles were retrieved. After removing unrelated literature, we finally obtained 26717 articles containing both abstracts and full texts. Then this data was imported into the Bibliographic Items Co-occurrence Matrix Builder (BICOMB) to generate a co-occurrence matrix of bibliographic data. We can find that the 26717 articles were distributed in 1701 journals, involving 171637 authors and 9978 keywords through the extraction and statistics of journals, authors, and keywords.

In order to determine the high-frequency MeSH Terms, the frequency threshold of the subject words is obtained as 77 according to the formula of high and low-frequency word boundary [9]. The high-frequency MeSH subject terms are obtained from the bibliographic data, and the word co-occurrence matrix is constructed in the BICOMB.

Community Detection Based on Optimized Network Modularity

Social network refers to the collection of social actors and their relationships, mainly developed to measure, analyze, and predict the structure and attributes of relationships between various entities in the network [10]. In the academic literature, scholars always use the same or similar words to express the hot-spots in a certain field. The relationship between massive text data can be linked through the subject words of the text to form a huge network. The community is a common phenomenon in social networks composed of a group of highly aggregated and closely connected nodes. Nodes belonging to the same community are more likely to have similar functionality, and community structures can indicate the relationship between network structure and functionality. The most representative community identification algorithm is the optimized network modularity method proposed by M. E. J. Newman [11]. Module degree is an index that can measure the quality of network partitioning, also called Q value. In essence, the modularity-based algorithm performs community identification based on changes in the intermediaries and modularity of the edges.

Since the nodes in the word co-occurrence network are the topic words, the process of determining the community representative topics transformed into the process of finding the core nodes. A few core nodes represent the scientific research themes corresponding to the community. In complex networks, there are many important indicators of nodes such as centrality and PageRank values. These indicators consider the calculation of the number of edges, centrality, and connections with other nodes to determine the core nodes from the global level of the network.

Dirichlet-multinomial Regression Topic Model

The Dirichlet-multinomial regression topic model, as shown in figure 2, mainly obtains the distribution of topics under different conditions by adjusting the characteristics of the observed documents. This paper takes the time of publication of hypertension literature as a variable to explore the trend of the topic over time.

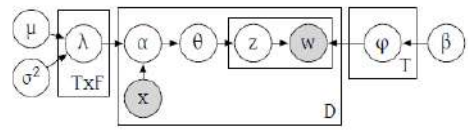

Figure 2– DMR topic model

In the document set D, for each document d, x_d represents the feature vector of the metadata, α is a function of the observable document feature, represents the prior probability distribution of the subject; given a prior probability distribution $\mathrm{N}(0,\Sigma)$, hyperparameters β , documents and words are generated as follows:

For each topic t, draw $\phi_t \sim Dir(\beta)$. $Dir(\beta)$ is a different topic-word distribution from the previous Dirichlet distribution.

For each document d, draw $\theta_d \sim Dir(\alpha_d) = \mathrm{Dir}(\exp(\tau_d))$, $\tau_d \in \tau$. For α_d of each document, the parameter of Dirichlet distribution and τ_d is covariance functions $\mathrm{f}(y_d, x_k)$, where y_d is the observed attribute vector of documents, and x_k is the vector of metadata.

For each word w, draw $z_{d,w} \sim Multi(\theta_d)$. $z_{d,w}$ is the subject allocation of the word t_w and θ_d is the proportion of the document d belonging to a certain topic, draw $T_{d,w} \sim Multi(\phi_{z_{d,w}})$. $T_{d,w}$ is the w-th word in document d, ϕ_t is the preference of topic t, $\Sigma_n \phi_{t,n} = 1$.

In the DMR topic model, three fixed parameters are set including the variance of the previously distributed parameter values σ^2, Dirichlet topic-word distribution β and the number of topics |T|.

Results

Topic Detection and Evolution Trend Analysis Based on SNA

In order to achieve better visualization, the nodes with the frequency no higher than 77, and the isolated nodes are deleted. 632 nodes are obtained to construct a co-occurrence matrix of high-frequency words. To reduce its complexity, the top 100 nodes are selected, and 4950 edges are included. A node is a biological entity derived from articles. The edge represents the relationship between the entities. The weight of the edge indicates the frequency at which the two entities co-occur in the specific sentence of the article. The data is imported into Gephi, and the community detection algorithm [12] is used for visualization, as shown in Figure 3.

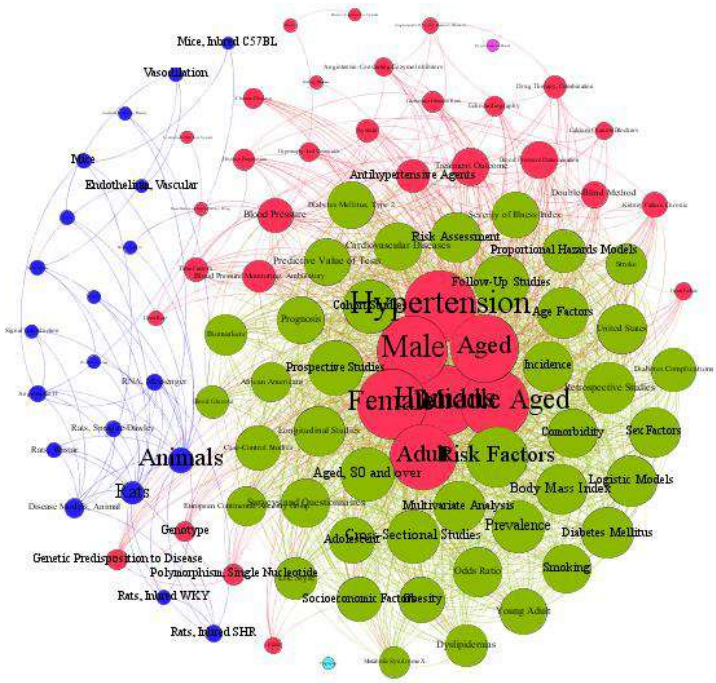

Figure 3–community detection (SNA)

To identify the most important biological entities in the literature of hypertension, four well-known centrality indicators including PageRank value, weighted centrality, closeness centrality, and betweenness centrality are calculated. Detailed centrality measurements are made by S. Wasserman [13] and S. Brin [14]. The top-ranked biological entities with PageRank values are similar to the top entities with weighted centrality rankings. Moreover, PageRank has unique biological entities, such as rates that only appear in the PageRank values top 10. The risk factor, prospective studies, and follow-up studies, only appear in the weighted centrality top 10, while Blood Pressure, Animals, and Body Weight only appear in the betweenness centrality top 10. The top 10 words in closeness centrality are exactly the same as the weighted centrality. In general, the nodes that are at a critical position in the entire network are mainly Hypertension, Male, Female, Age, Adult, Human, Risk factors, Body Weight, Blood Pressure, Animals, Prospective Studies, etc. These nodes are also at the core of the community distribution map.

The modular algorithm proposed by V. D. Blondel [12] is used for community detection and the resolution is set to 1 [15]. 5 modules are detected including 3 main modules (shown in red, blue, and green in Figure 3). The modular value Q is 0.187. The average path length is 2.645, and the diameter is 6. Choosing the Fruchterman Reingold layout, the two communities of light blue and purple in the picture account for only 1% of the total communities and are negligible. Therefore, communities of red, blue and green are mainly considered. The largest green community accounts for 42% of the network, including Risk Factors, Aged, Prevalence, Sex Factors, Prospective Studies, Follow-Up Studies. The second largest community (red part) accounts for 36% of the network, including Hypertension, humans, female, middle-aged, Treatment Outcome, Antihypertensive Agents, etc. The third largest community (blue part) accounts for 20% of the network, including animals, Rats, Inbred SHR, Messenger, Mice, etc. Through manual judgment and expert identification, the three communities can be initially divided into five topics.

Topic 1 mainly includes words related to risk factors for hypertension, such as age, pregnancy, gender, smoking, obesity, myocardial infarction, etc. Topic 2 mainly includes research methods and models related to hypertension, such as prospective studies, follow-up studies, Lateral studies, cohort studies, retrospective studies, etc., also includes some indicator parameters for hypertension research, such as morbidity, disease severity index, experimental expectations, and so on. Topic 3 mainly includes the basic elements of hypertension, such as gender, age, blood pressure, heart rate, renin, glomerular filtration rate, etc. Topic 4 mainly includes disease diagnosis and treatment, such as diagnostic effects, antihypertensive drugs, blood pressure measurement, drug dose response relationship and so on. Topic 5 mainly includes animal, rat, RNA, and Inbred SHR. That is to verify the indicators of hypertension through animal experiments. In general, the biological entities within each community are closely linked to form a variety of specific research topics relevant to the hypertension literature.

According to the time distribution, the hypertension literature was divided into three stages: 2000-2005, 2006-2010, 2011-2017. After data processing, they are imported into Gephi and visualized by a community detection algorithm. According to the visual distribution map and various parameters, the three stages of hypertension topics are distributed in three communities, and the proportion of each community is relatively average. The proportion of communities in the period from 2000 to 2005 was 38%, 33%, and 29 %, the proportion of each community in the period of 2006-2010 was 40%, 38%, 22%. In 2011-2017, the proportion of each community was 42%, 37%, 21%; compared with the MeSH Terms obtained in the three stages, the most frequent occurrences of the three stages are hypertension, male, and female. Most of the terms appear in three stages at the same time, but the distribution of the theme communities in each stage is slightly different. The topic community distribution parameters at each stage are shown in Table 1. The average degree, graph density, and modularity in these three stages are constantly increasing,

indicating that the number of MeSH erms in each stage is increasing with time and the distribution of subject communities is constantly changing. However, this method is very labor intensive, and it is difficult to accurately detect the proportion of each topic in each time period and the path that the theme evolves over time.

Table 1–Parameters at Each Stage

	2000-2005	2006-2010	2011-2017
Average degree	13.94	16.88	20.4
Graph density	0.141	0.171	0.202
Modularity	0.126	0.158	0.175
Average clustering coefficient	0.891	0.438	0.869

Topic Detection and Evolution Trend Analysis Based on DMR

The bibliographic data of 26717 articles were processed as follows: word stem processing; removing stop words, words of length 1 and words with a frequency less than 5 times; removing the superordinate vocabulary in hypertension field. Each bibliographic data generates a text file as a document for the DMR topic model. The data is then processed through an open source machine learning language processing package Mallet [16], according to the DMR model and algorithm. In order to contrast with the topics detected by SNA, the number of topics |T| is set to 5, while adjusting the σ^2 and β values, the resulting five topics and related subject terms. In order to make the identified topics and terms more meaningful, the numbers of terms in the topic-vocabulary distribution of each topic are set to 10, 20, and 30. 10 words that appear more frequent and meaningful are selected, as shown in Table 2.

Topic 1 contains mice, angiotensin, renin, vascular, response, effects, receptor, rats, etc., mainly to describe animal experiments related to hypertension; topic 2 contains risk, factors, age, obesity, gene, women and other words Mainly used to describe the risk factors of hypertension, including age, diabetes, obesity, gender, genes, etc. Topic 3 includes systolic, diastolic, group, compare, rate, invalid, significant, etc., mainly used to describe and hypertension related research methods. Topic 4 contains patients, blood, gene, treatment, results, and other words, mainly used to describe basic elements of hypertension. Topic 5 contains treatment, antihypertensive, therapy, coronary, mortgage, medication, care, control, etc., mainly used to describe the diagnosis and treatment of hypertension.

Table 2–Topic Distribution (DMR)

Topic 1 animal experiments	**Topic 2** risk factors	**Topic 3** research methods	**Topic 4** Basic elements	**Topic 5** Diagnosis Treatments
Mice	Risk	Systolic	Patient	Patient
Renal	Age	Group	Blood	Antihypertensive
Vascular	Prevalence	Significant	Treatment	Coronary
Effects	Blood	Rate	Results	medication
Expression	Disease	Pressure	Finding	clinical
Angiotensin	Factors	Diastolic	cardiovascular	Treatment
Proteins	Diabetes	Compare	Gene	Therapy
Response	Obesity	Invalid	Association	Mortality
Receptor	Gene	Term	Evidence	care

Then the time of publication of the hypertension literature is taken as a variable to explore the trend of the topic over time. The relative distribution of each topic from 2000 to 2017 is shown in Figure 4 below. In general, each topic is constantly evolving over time. In 2000, topic 1 (animal experiment) and topic 4 (basic elements) accounted for a relatively large proportion, and topic 5 (diagnosis and treatment) research was relatively weak; over time, topic 1 (animal experiment) The trend of gradual decline, the topic 4 (basic elements) first decline and then rise, but it has been in an important position; and the proportion of topic 5 (diagnosis and treatment) has increased year by year. It had a relatively important proportion in 2017. Topic 2 (risk factors) has developed relatively stable and has been in a relatively important position; topic 3 (research method) has slightly fluctuated and its proportion has increased year by year since 2007.

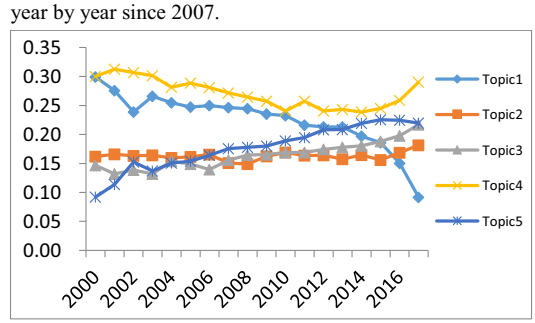

Figure 4– Trend of the Topic Evolution (DMR)

Discussion

The results show that the topics obtained by the SNA are almost the same with those detected by the DMR, both including risk factors, research methods, basic elements, diagnosis, and treatment as well as animal experiments. From the macroscopic view, the MeSH Terms obtained using the SNA method are more specific and more precise, while the DMR are broader. For example, in the topic risk factors, the MeSH Terms determined by SNA, including age factors, Diabetes Mellitus, sex factors, smoking, cardiovascular disease, obesity, and lifestyle can represent relatively concrete risk factors. On the contrary, the term identified by DMR, including age, Diabetes, obesity, and gene, are wider, only to illustrate each general categories of risk factors. In addition, in research methods part, SNA can not only recognize the terms covering prospective studies, logistic models, surveys and questionnaires which stand for research methods, but also include targets such as risk assessment, odds ratio, severity of illness index while DMR recognizes the terms including group, compare, rate and significant. This is because the dataset is too large. Those objects selected by SNA are the top 100 highest-frequency MeSH Terms, while DMR focuses on the entire document. Different research objects thus result in the dissimilarity in the outcome. The number of community topics is also different. SNA sets the number subjectively, and DMR adjusts the number of topics and terms in advance as well. Besides, the relation among 'terms-topics-documents' can be better displayed by DMR so that the probability distribution of the topics can be figured out in any document.

In the comparison in evolution trends, SNA can merely detect the distribution of topic communities for a specific period, hard to compare the evolution trends happening in every duration. However, DMR can detect the ratios of different topics in every period and the evolution trends of topics depending on time,

and it has advantages in exploring the process of topics evolution trends.

In general, the SNA method and DMR method pay different attention to detecting community and evolution trends. The MeSH Terms obtained by SNA are more concrete and precise while terms obtained by DMR are more widely, which need interpretations but are more advantageous in exploring the evolution trends of every topic. Given that combining these two methods together, exploring the community and evolution trends of knowledge network from both the medium and micro view. As a result, they can supplement each other.

Conclusions

Firstly, it is found that the hypertension literature is mainly concentrated on three communities, which can be divided into five research topics, such as risk factors, research methods, basic elements, diagnosis and treatment, and animal experiments. Secondly, the topic changes constantly with time going by. The basic situation of patients has always occupied a high proportion of research. Researches of animal experiments have decreased yearly. Development of risk factors analysis has accounted for a relatively important ratio steadily. The percentage of research topics have been increasing since 2007. Third, it is also found that the topic obtained from SNA and DMR are basically similar. But the MeSH Terms obtained using the SNA method are more specific and precise, while the DMR are broader and have an advantage in exploring the evolution of various themes. If they are applied jointly, the result will be better.

These investigations can help researchers who just start to explore hypertension study to understand the field overview, discover research hot-spots and predictive research frontiers in the field, and promote knowledge exchange within and between domains among experts to help decision makers follow up the flow of knowledge in the field of hypertension. At the same time, the analysis methods of community detection and topic evolution trends in this paper can be extended to other areas of chronic diseases, such as diabetes, coronary heart disease, etc.

Based on the results of this study, PubMed and other databases can provide such information services, helping researchers to obtain a global understanding of relevant fields in the literature search, and improve the relevance and efficiency of the literature search.

This paper also has some limitations. Some Mesh Terms are wildly used in the PubMed publications and are not specific to hypertension, such as “humans”, “female”, “middle-aged”. The accuracy of this research will be further improved by means of filtrating these terms by normalizing their frequency in the target corpus with their overall frequency in PubMed. The DMR topic model needs to preset the number of topics when detecting potential topics. But the number of topics identified by DMR in this paper is subjectively determined; In addition, “a direction for future work is analyzing the internal structures and correlations of communities and topics, which is the next step of our study.

Abstract

In sub-Saharan African countries the prevention and control of epidemic diseases requires the improvement of the surveillance system for these diseases. Biomedical ontologies are a growing field that can improve health information systems. Indeed biomedical ontologies allow semantic support, data integration, automated reasoning. We are building a meningitis ontology to assist filtering messages relevant to meningitis domain on social media in order to predict a possible epidemic. Indeed, the messages filtered are used for data and event extraction that serve as input for a meningitis surveillance system. In this paper we focused on the modeling and formalization of different perspectives of the meningitis disease such as biological perspective, clinical perspective, epidemiological and public health perspective. This paper presents the three modules in the global Infection Disease Ontology for Meningitis (IDOMEN) and at the end, we illustrate a case of reasoning with our ontology.

Keywords: Knowledge, Infectious Diseases, Meningitis

Introduction

Meningococcal meningitis is an infectious disease that causes an inflammation of the meninges surrounding the brain and the spinal cord [1]. It is due to a gram negative bacteria called neisseria meningitidis. Our work focuses only on meningitis, called meningococcal meningitis.

Since two decades the situation of meningitis is not clearly under control. Nearly one million of meningitis suspected cases and over 100 000 meningitis death are reported in the *African meningitis belt* [2] made up of 26 countries from western Senegal to eastern Ethiopia, via Mali, Burkina Faso, Niger, Chad, Nigeria and other countries.

Unfortunately, in the sub-Saharan countries in general there is no real-time data collection tools for the meningitis surveillance systems. Therefore, the risk analysis for early detection of the meningitis epidemic is delayed.

In this work we propose an approach of early detection of epidemics based on social networks analysis. Our approach is justified by the fact that the work of [3] shows how social media analysis can improve better health monitoring in terms of availability of information for risk analysis and patient support. As stated in social media analysis, health monitoring is conducted through 3 main steps: data collection, semantic analysis, and results sharing with users or decision makers. In this work we use the social media platform Twitter as data source to improve early detection of meningitis epidemic risk in Burkina Faso. We are interested in Twitter because of it increasing use Africa. Indeed, in, the report 2015 “How Africa Tweets”, Portland Communications analyzed 1.6 billion tweets from Africa during this year. They show that African people adopt more and more social media. At December 2017 Internet users in Burkina Faso exceeded to 3 million, with internet growth more than 36 percent.

However, the tremendous of stream of data generated by social media requires filtering while collecting data. It requires the use of a domain-controlled vocabulary to assist data filtering. A domain ontology for meningitis could act as better candidate for this task since ontologies provide at first a domain terminology and secondly axioms describing relations across terms. Our ontology for meningitis is built as an extension of infectious diseases ontology (IDO) [4]. As existing domain ontologies extending IDO, the meningitis ontology is called IDOMEN as Infectious Disease Ontology of/for MENingitis. The scopes of IDOMEN cover the classic views on the disease such as the biologic aspect, clinical aspect, and public health aspect.

In the following of this paper we first present the global architecture of IDOMEN in Methods. Then we highlight the knowledge modeling and formalization of the different meningitis aspects covered by our ontology in the Results.

Finally, we conclude and draw the perspectives of our work.

Methods

Ontologies define a set of basic terms and relations which exist in the vocabulary of a given domain, as well as the rules and axioms that apply on these ones. Gruber has given a fairly comprehensive of "what is an ontology" : « An ontology is a formal, explicit specification of a shared conceptualization ». Depending on the level of abstraction and the object of conceptualization we distinguish three kinds of ontologies :

- The **top level** (upper-level) **ontologies** are characterized by ontologies that model universals, general knowledge;
- The **core ontologies** or generic ontologies describe generic knowledge that are not specific to one domain but are common to several domains ;
- The **domain ontologies** represent knowledge from a specific domain.

The IDOMEN is designed as domain specific ontology since it represents knowledge of the meningitis disease domain.

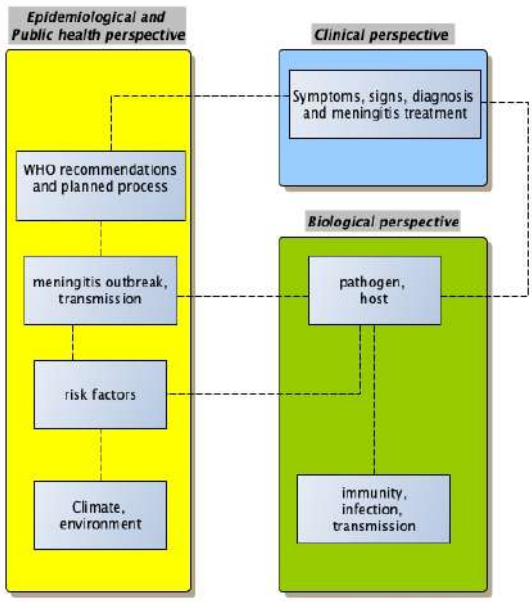

Figure 1 – Modular perspectives design of IDOMEN

The goal of IDOMEN is to assist extracting data and events from text messages published in social media, and to allow data integration, domain knowledge sharing and efficient communication between actors within the epidemiological surveillance system [10]. Therefore, to satisfy these requirements, the scope of IDOMEN covers the disease aspects related to the biology, clinical manifestation and care, public health, prevention and control, biomedical research, and epidemiological studies.

The different aspects have been packaged in three modular perspectives that are biological perspective, clinical perspective, epidemiological perspective and public health perspectives (figure 1) :

- The **biological perspective** focuses on biology and microbiology of organisms implied in the disease course. In this perspective we model immunity, virulence factors, pathogen and host biology, etc. ;
- The **clinical perspective** focuses on clinical manifestations (signs, symptoms), complementary examination (laboratory test, laboratory findings, etc.), diagnosis, treatment, etc. ;
- The **epidemiological and public health perspective** focuses on topics related to the disease spread/outbreak such as risk factor, transmission, climate, environnement, etc. ; and deals with standard strategies of preventing or fighting against meningitis outbreaks.

This organization of the knowledge allows us to design our ontology in modular perspectives. Modularity makes it possible to build ontologies of large or small sizes and offers the possibility of easily reusing existing ontological resources. In the field of biomedical ontologies the reuse of existing ontological components is a best practice that is strongly encouraged.

This leads to the principles of the Open Biomedical Ontologies (OBO) Consortium [6] which are best practices and recommendations that promote interoperability. There are many biomedical ontology repositories containing ontology of different types and level of abstraction that can be freely reused. IDOMEN is designed and built upon this principle.

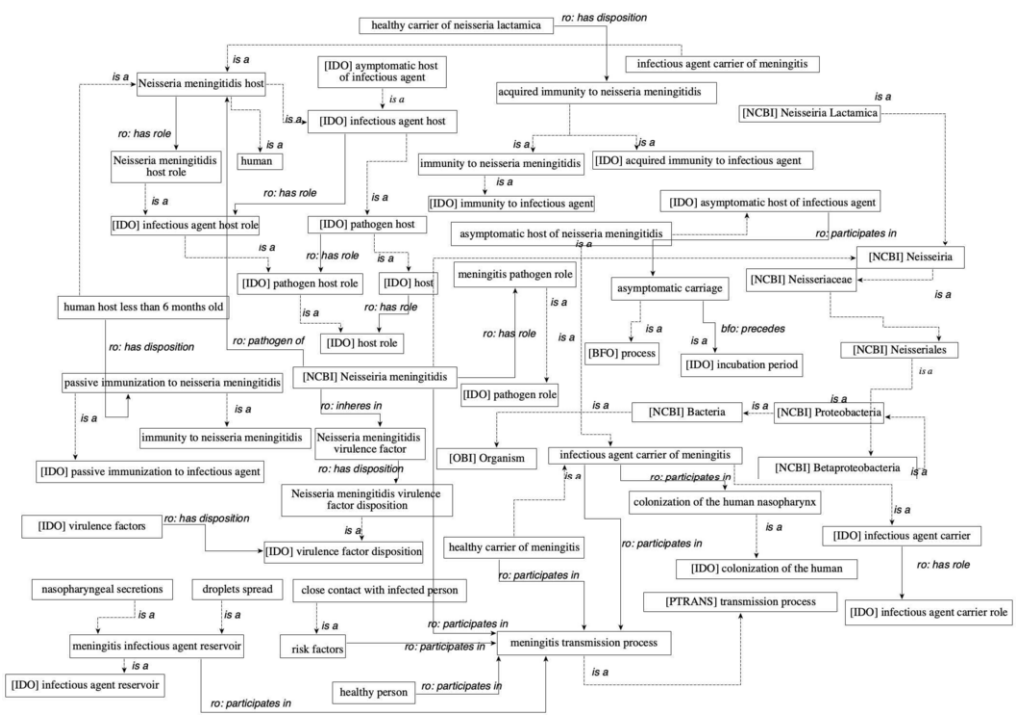

Figure 2– Conceptual model of the biological perspective of the meningitis disease

Results

Modeling biological perspective in IDOMEN

Pathogen and host

In figure 2, we present the knowledge modeling of the pathogen agent of meningococcal meningitis called *Neisseria meningitidis.* We use the classification of NCBI Taxonomy to provide a classification of the organism *neisseria meningitidis* in IDOMEN. The species *Neisseria meningitidis* in the taxonomic classification of NCBI is of the genus

Neisseria, and the *Neisseria* are from family of the *Neisseriaceae*. In the Figure 2 this is represented by *"[NCBI]Neisseria meningitidis"* is a *"[NCBI]Neisseria"*, followed by the relation *"[NCBI]Neisseria"* is a *"[NCBI]Neisseriaceae"*. Browsing further in the hierarchy of the NCBI Taxonomy, we found that *Neisseria Meningitidis* is also a subclass of *Proteobacteria*. *Proteobacteria* is a phylum of bacteria consisting of the purple bacteria *"[NCBI]Proteobacteria"* is a *"[NCBI]Bacteria"*. Bacteria is an organism. *Neisseria meningitidis* being the pathogen agent of meningitis, it plays a *"pathogenic role"* (*"meningitis pathogen role"*) in the human body : *"meningitis pathogen role"* ***is a*** *"[IDO]pathogen role"*. Thus, we have *"[NCBI]Neisseria meningitidis"* ***bearer of*** *"Meningitidis pathogen role"*. *Neisseria meningitidis* has the capability under specific conditions to trigger a pathogenic process, we say that it has a *"pathogenic disposition"*. A disposition is an intrinsic attribute of an entity that allows it to trigger itself a specific process or processes when particular conditions are satisfied : *"[NCBI]Neisseria meningitidis"* ***has disposition*** *"[IDO]pathogenic disposition"*.

Pathogenesis

The pathogenesis of meningitis refers to the process or processes responsible for triggering and developing meningitis. The pathogenesis of meningitis occurs in three (03) sequences that are: transmission, acquisition, colonization.

There are two (02) modes of transmission of meningococcal. The aerosol mode and the contaminated secretions one. A person who caught the pathogen agent Neisseria meningitidis but who has not any manifestations (symptom and sign) of the meningitis is called *"healthy carrier of meningitis"*. We translate this by *"healthy carrier of meningitis"* **is a** *"infectious agent carrier of meningitis"*. *"Asymptomatic carriage"* is a process during which the infected person develops no symptomatic manifestation of meningitis. This state of fact is described by 3 relations: : *"healthy carrier of meningitis"* ***is a*** *"[IDO]asymptomatic host of neisseria meningitidis"*. *"[IDO]asymptomatic host of neisseria meningitidis"* ***is a*** *"[IDO]asymptomatic host of infectious agent"*. "[IDO]asymptomatic host of infectious agent" **participates in** "asymptomatic carriage" and "asymptomatic carriage" **is a** "[BFO]process". This process asymptomatic carriage precedes the phase of colonization in the nasopharynx, what is transcribed by these two relations *"asymptomatic carriage"* precedes *"[IDO]incubation period"* and *"infectious agent carrier of meningitis"* ***participates in*** *"colonization of the human nasopharynx"*.

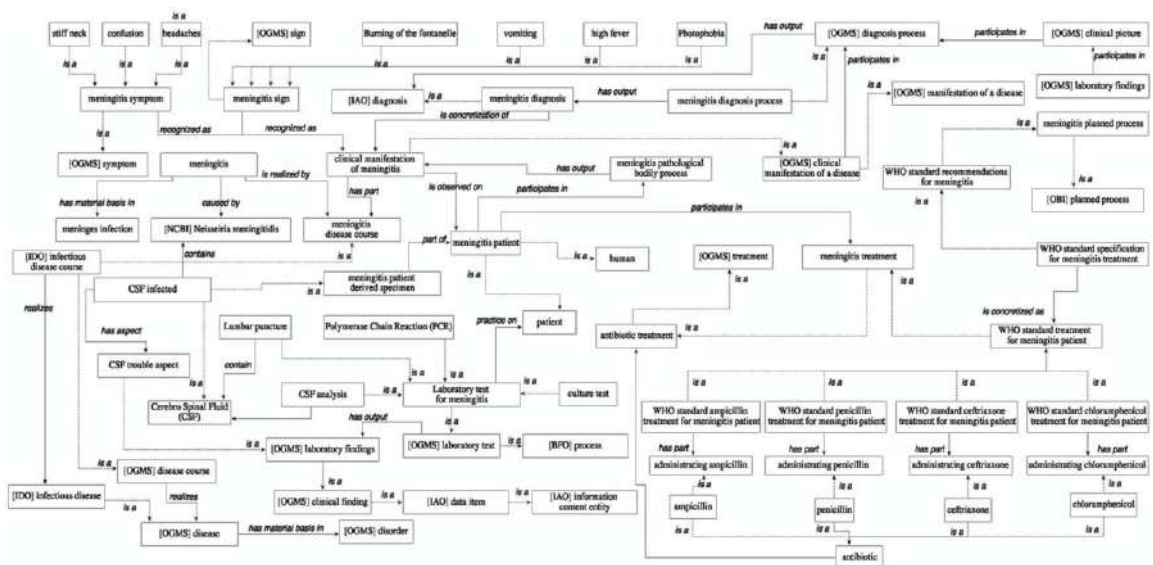

Figure 3– Conceptual model of the clinical perspective of the meningitis disease

Modeling clinical perspective in IDOMEN

Signs and symptoms

Meningitis symptoms and signs are clinical features of meningitis. The most common symptoms of acute meningitis are high fever, headache, stiff neck, vomiting, irritability or confusion, photophobia (sensitivity to light), Kerning signs, lethargy seizures. *"meningitis symptom"* and *"meningitis sign"* are perceived or noticed on patient. They are formalized as follow *"meningitis sign"* is a *"[OGMS]sign"* and *"meningitis symptom"* is a *"[OGMS] symptom"* by reusing existing concepts in OGMS. For instance, we can also infer the following relations *"headaches" is a "meningitis symptom"*, *"headaches" is a "meningitis symptom"*, *"photophobia" is a "meningitis sign", "Kernig sign" is a "meningitis sign"*.

Meningitis patient is a patient presenting clinical manifestations of meningitis. "Meningitis patient" is a subclass of *"patient"* and a *"clinical manifestation of meningitis"* ***is a*** *"[OGMS]manifestation of a disease"*. Therefore *"meningitis symptoms"* ***recognized as*** *"clinical manifestations of meningitis"* and *"meningitis signs"* ***recognized as*** *"clinical manifestation of meningitis"*.

Diagnosis

The first step in the diagnosis consists mainly in the recognition of clinical manifestations.

In terms of diagnosis, *"meningitis diagnosis" is concretization of "clinical manifestation of meningitis"*, *"meningitis diagnosis" is a "[IAO]diagnosis"*. *"meningitis diagnosis process" is a "[OGMS]diagnosis process"*. and *"meningitis diagnosis process" has output "meningitis diagnosis"*.

After seeing clinical signs, we can perform a CSF sample to further the diagnosis. In case of the observation of CSF ("*CSF analysis"*) reveals a cloudy or purulent appearance after macroscopic examination, this indicates a probable case of bacterial meningitis. CSF analysis can be extended by other laboratory tests such as Polymerase Chain reaction, antibiogram, etc., used to diagnose meningitis are organized in class called "Laboratory test for meningitis".

Finally, only the detection of the bacterial agent in the CSF at the laboratory level makes it possible to effectively define a *confirmed case of meningitis*.

"Laboratory test for meningitis" is a *"[OGMS]Laboratory test"*. The results of the laboratory tests are subclasses of *"[OGMS]Laboratory findings"*.

Treatment

Meningitis is a disease whose evolution is very fast in the patient, which necessitates a quick diagnosis in order to start the treatment. The different treatments for meningitis are specified in WHO standard protocols called "*WHO standard specifications for meningitis treatment*". Here are some treatments recorded in the standard protocol: "*WHO standard ampicillin treatment for patient meningitis*", "*WHO standard penicillin treatment for patient meningitis*", "*standard WHO ceftriaxone treatment for patient meningitis*", *"WHO standard chloramphenicol treatment for patient meningitis*". All of these different treatments are based on antibiotic administration [7], so we have for example "*WHO standard ampicillin treatment for meningitis patient*" ***has part*** "*ampicillin*" and "*ampicillin*" ***is a*** "*antibiotic*".

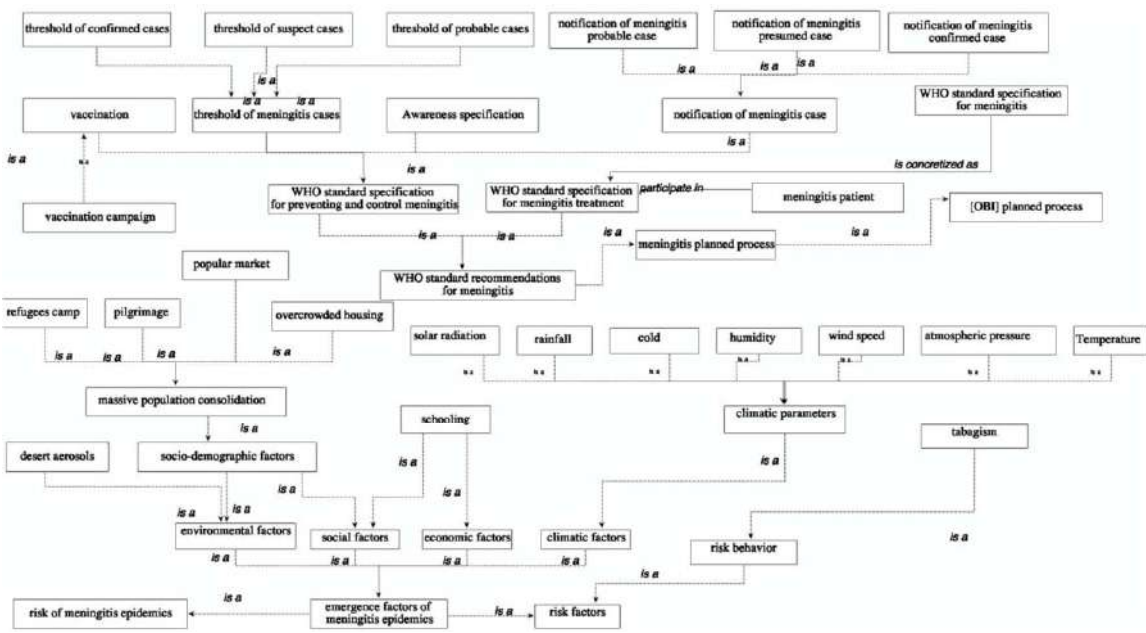

Figure 4– Conceptual model of the epidemiological and public health perspective of the meningitis disease

Modeling epidemiological and public health perspective in IDOMEN

In the figure 4, we describe different aspects related to disease spread/outbreak such as surveillance, prevention, epidemic emergence factors (risk behaviours, climate and environment).

Prevention

The prevention and control of meningitis is based on vaccination, vaccination campaigns and awareness : *"vaccination"*, *"vaccination campaigns"* and *"awareness"* are subclass of *"WHO standard specifications for preventing and control meningitis". "WHO standard specifications for preventing and control meningitis"* ***is a*** *"meningitis planned process". "meningitis planned process"* ***is a*** *"[OBI]planned process"*. To control and prevent the occurrence of an outbreak there is a mechanism called *"cases notification"* consisting in systematically notifying the different cases encountered in health facilities (*"presumed case of meningitis"*, the *"probable case of meningitis"* and the *"confirmed case of meningitis"*). We have represented this notification mechanism in IDOMEN as follow *"presumed case of meningitis notification"* ***is a*** *"meningitis case notification", "probable case of meningitis notification"* ***is a*** *"meningitis case notification"*, *"confirmed case of meningitis notification"* ***is a*** *"meningitis case notification".* As soon as one of the thresholds (*"threshold of presumed cases"*, *"threshold of probable cases"* and *"threshold of confirmed cases"*) are reached an alert that corresponds to the level of the situation is launched in order to bring appropriate measures.

Epidemic emergence factors

The recurrence of meningitis outbreaks is linked to a complex combination of several factors of kinds economic, social, climatic and environmental [8] [9]. We defined a class *"meningitis epidemic emergence factors*" which is a parent classes of following subclasses *"environmental factors*", *"social factors*", *"economic factors*", *"climatic factors*". The population dynamics (movements of populations and communities) are

considered to be factors influencing the intensity of meningitis epidemics in the African meningitis belt : *"massive population consolidation" is a "socio-demographic factors*". *"socio-demographic factors*" is a subclass of *"environmental factors*" and *"social factors*". For example of *"massive population consolidation"* in the meningitis belt we have : *"pilgrimage", "popular market"*, *"refugees camp"* and *"overcrowded housing"*. The "climatic parameters" are : *"atmospheric pressure", "wind speed"* , *"humidity", "cold", "rainfall" and "solar radiation"*.

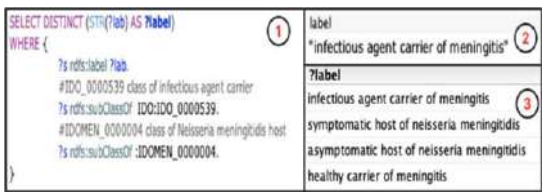

Figure 5– Use case reasoning

Conclusions

In this first stage of the IDOMEN ontology building, we provided formalization in OWL2 using the Protege editor which also allows us to experiment reasoning use cases on the ontology. For example, the Figure 5 presents (1) a SPARQL query about ***"Which are the infectious agent carriers that also are Neisseria Meningitidis hosts ?"***, (2) the result without launched inference engine, and (3) the results by activating the reasoner FaCT++ 1.6.5 engine in the Protégé editor. This explains that we obtain more complete results by deductive inferences on classes and subclasses. In the case of our query the deduction is based on the transitivity properties from the classes inheritance.

In this work we modeled the knowledge relating to the biological perspective, clinical, epidemiological and public health perspectives of the meningitis disease. A usable version is available for download at https://github.com/cedricbere/IDOMEN/blob/master/Ontology/idomen.owl.

Our future work will focus on validating and evaluating the ontology before using for filtering on social media.

Improving Mechanical Ventilator Clinical Decision Support Systems with a Machine Learning Classifier for Determining Ventilator Mode

Gregory B. Rehm[a], Brooks T. Kuhn[b], Jimmy Nguyen[b], Nicholas R. Anderson[b], Chen-Nee Chuah[a], Jason Y. Adams[b]

[a] University of California Davis, Davis CA 95616, USA
[b] University of California Davis Medical Center, Sacramento CA 95817, USA

Abstract

Clinical decision support systems (CDSS) will play increasing role in improving quality of medical care for critically ill patients. However, due to limitations in current informatics infrastructure, CDSS do not always have complete information on state of supporting physiologic monitoring devices, which can limit input data available to CDSS. This is especially true in use case of mechanical ventilation (MV), where current CDSS have no knowledge of critical ventilation settings, such as ventilation mode. To enable MV CDSS make accurate recommendations related to ventilator mode, we developed a highly performant machine learning model that is able to perform per-breath classification of five of most widely used ventilation modes in USA with average F1-score of 97.52%. We also show how our approach makes methodologic improvements over previous work and is highly robust to missing data caused by software/sensor error.

Keywords:

Artificial respiration, clinical decision support systems, machine learning

Introduction

Mechanical ventilation (MV) is life-saving intervention delivered in intensive care unit (ICU) to patients with acute respiratory failure. When delivered properly, MV allow injured lungs heal while ventilator performs majority of work of breathing for patient. When delivered improperly, MV has been associated with variety of adverse clinical outcomes including patient discomfort, increased sedative dosing, longer ICU length of stay, increased chance of ventilator-induced lung injury, and lower survival [1,2]. New generation of clinical decision support systems (CDSS) promises to reduce chances of delivering improper MV by automating aspects of ventilator configuration, and providing clinically accurate and relevant alerts to providers. However, key detriment to these systems is lack of access to configured state of ventilator and therefore lack information that may improve efficiency of these CDSS [3].

One such piece of information that many MV CDSS lack is choice of ventilation mode (VM) that determines pattern of flow and pressure delivery with each breath (Figure 1 B-D). This information is generally unavailable to CDSS due to lack of interoperability and information exchange between CDSS and ventilator or electronic health record [3]. CDSS knowledge of VM is important because changing VMs may be a necessary procedure in course of patient care [4]. For example, if CDSS determines that patient is breathing asynchronously with ventilator, it may be able to make recommendation that providers choose a different VM that provides more comfort and flexibility in breathing to patients [5-8]. Another example would be that CDSS could provide alerts to clinicians if patients continually violate safe volumes of air to inhale. This would be especially important in cases where patients have acute respiratory distress syndrome and need limited tidal volumes [9,10]. In this case CDSS could recommend patients be placed on VM that limits tidal volumes such as volume-control.

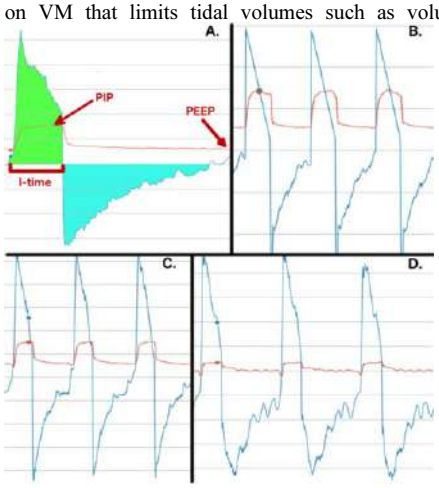

Figure 1- Displays visualizations of ventilator waveform data (VWD). Flow measurements represented in blue, and pressure in red. A.) Here we display examples of how to extract information from VWD. Positive End Expiratory Pressure (PEEP) is noted as minimum pressure supplied by ventilator, and peak inspiratory pressure (PIP) is maximum pressure supplied during inhalation. Inspiratory time (I-time) is amount of time patient breathes in. Total amount of air breathed in represented in green, and air breathed out shown in teal. B.) Shows canonical example of volume control (VC), mode patient receives fixed volume of air for each breath. C.) Shows example of pressure control (PC). In PC, pressure is fixed during inhalation. D.) Example of continuous positive airway pressure (CPAP). Here minimal pressure support is given, and all breaths initiated by patient.

If MV CDSS lacks knowledge of VM from more traditional methods, it may still be able to access it by utilizing information derived from streams of flow and pressure readings that comprise ventilator waveform data (VWD). To the best of our knowledge, only one previous effort has developed rule-based classifier using analysis of VWD for providing hourly VM classifications. However, its use of closed dataset, limited temporal resolution, and accuracy of model represent potential limitations both for research and decision support [3,5]. Having

highly granular temporal resolution VM classification results is important because in practice providers may change VM frequently based on changes in clinical state or patient tolerance of VM. These changes may cause specific VM to remain constant for as low as minutes of time. To improve upon previous work, we note that machine learning (ML) has proven capable of accounting for highly variable nature of physiologic data such as VWD on temporally granular time scales [11,12]. So we created a ML model that could identify different VMs on per-breath basis, with freely accessible dataset, using only VWD as input.

In this paper, we detail multiple important considerations for modeling ML classifier that can classify VM. First, we discuss how we created one of the largest datasets of per-breath labeled information, extraction of features from VWD, and performance of our resulting ML model that can determine five of most widely used ventilation modes in USA [4]. Second, we discuss experiments of how well our model performs in presence of missing training data. Finally, we discuss experimentation we conducted for reducing size of our training dataset by nearly 72% while maintaining generalizability of our classifier to our testing set. To allow reproducibility of our work, our code and dataset are publicly accessible and published on GitHub. Thus, we hope that our work will serve as catalyst for continuing to improve capabilities and efficiency of MV CDSS.

Methods

In this study, we used dataset of VWD collected from 103 subjects (IRB# 647002) within intensive care environments of University of California Davis Medical Center (UCDMC) consisting of MV flow and pressure measurements sampled at 50 Hz [13,14]. Ventilation mode was not recorded in course of VWD data collection. We then randomly selected 2-4 hour epochs of VWD from the 103 subjects. All VWD was stored in data files of 2 hours in length, and approximately 2,000 breaths were stored per data file. Each breath in these epochs was annotated by three expert clinicians (JYA, BTK, JN) for presence of one of five VMs: volume control (VC), pressure control (PC), pressure support (PS), continuous positive airway pressure (CPAP), and proportional assist ventilation (PAV) (Table 1). Many patients had 2-4 hour periods selected where VM was switched multiple times, other modes such as pressure regulated volume control (PRVC), volume support, and airway pressure release ventilation (APRV) were found, and annotated within these epochs, but were excluded in our final analysis because of their rarity of use at UCDMC.

Table 1-Descriptive statistics for our dataset for each ventilator mode analyzed. Also analyzed number of patient ventilator asynchrony (PVA), suction, and cough breaths found [14]. While these breaths do not represent normal breathing, they are typical in clinical practice.

	Volume Control	Pressure Control	Pressure Support	CPAP	PAV
Patients	23	37	55	28	22
Total Breaths	61,662	78,635	92,360	14,795	36,303
PVA Breaths	7,714	4,570	6,924	2,373	7,669
Suction Breaths	750	136	681	350	373
Cough Breaths	229	117	178	56	96

Given VWD is so heterogeneous it can be difficult for even expert clinicians to make consistent classification of breathing patterns [15]. Thus, in performing classification of VM we ensured that each breath was dual clinician adjudicated, meaning that two clinicians would independently annotate a single breath, and if classifications disagreed they would be resolved through communication between the two [14]. To further account for breathing heterogeneity, we included regions containing pathologic patient-ventilator interactions such as patient-ventilator asynchrony (PVA), routine clinical events such as suctioning and cough, and regions of noisy data caused by moisture/blood/mucus in ventilation circuit tubing [14].

Table 2-Set of proposed features for our model. Features were segmented into per-breath and multi-breath time frames.

Feature	Description
Inspiratory Flow Slope Variance (per breath)	This feature measures variance of successive, 0.08-second long slope measurements of inspiratory flow curve of a single breath. This feature was effective for classifying volume control.
Variance of Pressure (per breath)	This feature takes variance of all pressure measurements for a single breath. This feature was helpful for classifying CPAP which typically utilizes low pressures relative to PEEP on inspiration.
Variance of Per-Breath Inspiratory Flow Slope Variance	The inspiratory flow slope variance was found on per breath basis, and this feature takes variance of inspiratory flow slope variance across a 10 breath window.
Inspiratory Time (I-time) Variance (10 breath window)	The amount of time that patient inhales for single breath is called I-time. This feature calculated variance of 10 successive breaths.
Pressure-Based I-time Variance (10 breath window)	We defined pressure-based I-time as amount of time (seconds) that pressure is elevated by [0.4 * (PIP - PEEP)] above PEEP. This was an important variable to measure in pressure control and pressure support, where flow-based I-time can be shorter than ventilator's set I-time, which may occur in delayed cycling asynchrony.
N Plateau Pressures (20 breath window)	A plateau pressure is taken on ventilator when inspiratory flow is set to 0 for a certain amount of time, during which ventilator can read residual pressure in respiratory system. PAV will repetitively take plateau pressures in order to adjust ventilation to patient's needs.
Pressure-Based I-time Variance (100 breath window)	In this feature, pressure-based I-time statistic is also calculated for 100-breath window. This feature was necessary to provide capacity for differentiating between pressure control and pressure support in synchronously breathing patients.

With this dataset, we utilized 55 patients and 140,928 breaths for our training cohort, and 48 patients and 165,988 breaths for our testing cohort. There was no patient overlap between testing and training cohorts. Testing set was chosen to be approximately as large as training set because initial modeling

yielded strong results, and we wished to utilize large testing set as further validation for our approach. Using both Scikit-learn and Pytorch ML libraries [16,17], we evaluated use of multiple ML algorithms including: support vector machine (SVM) [18], multi-layer perceptron (MLP), long-short term memory recurrent neural network (LSTM RNN) [19], logistic regression, and random forest (RF) classifier [20]. All models performed classification on per-breath basis, highest possible level of granularity possible in VM classification. Based on model investigation, we settled on usage of RF with parameterization of 30 classifier trees for our final model (see online supplemental).

Our feature set is composed of 7 items of expert-guided information derived from raw VWD, and is described in Table 2. Our features are derived from both per breath and multi-breath analytic time frames. Per-breath time frames occur over single breath, while multi-breath time frames are composed of windows of short, medium, and long periods of breathing. Short window is 10 breaths long, medium window 20 breaths, and long window 100 breaths. Tuning of features and hyperparameters was guided by performing 10-fold cross-validation of our training data. After tuning model hyperparameters during the validation phase, we evaluated our model on our testing set. No additional changes to our feature set, or model hyperparameters were performed after model development was completed in training set. Model performance is primarily reported through F1-score because it is more representative of class-imbalanced classifier performance than accuracy is. F1-score is calculated as harmonic mean of precision (PPV) and recall (sensitivity):

$$\text{F1-score} = 2\frac{precision * recall}{precision + recall}$$

Limitation to using RF to classify ventilator mode is RF classifier assumes that all breaths are independent of each other. However, ventilator mode is a continuous setting that does not vary over time, unless it is manually changed by provider. Therefore, one breath's mode is often predictive of next breath's mode. This modeling incongruity causes RF classifier to sometimes perform incorrect VM classification even in periods where classifier correctly predicts correct VM for a majority of breaths. To smooth these incorrect predictions, we implement an algorithm we term "look-ahead smoothing" which operates as second pass heuristic on all per breath RF breath predictions. More specifically, once RF is finished, look-ahead smoothing examines each breath VM classification sequentially, and if it determines breath's classification is not in accordance with previous n breaths then it will look ahead at next n breaths in sequence. The breath will then be re-classified in accordance to majority x percent of subsequent n breaths. Both n and x are configurable parameters that we set at $n = 50$ and $x = 60$, parameters which were found via sensitivity analysis. In real-time classification, assuming average respiratory rate of 20 breaths per minute, this technique results in latency of at most 2.5 minutes between a given breath and availability of its final classification.

Finally, we implemented experiment to test how well our classifier would generalize to larger dataset if random breaths in our training dataset were missing due to some technical error. So we conduct experiment where we ablate (i.e. remove) data observations at random from our training dataset in equal proportion for VC, PC, PS, CPAP, and PAV. We do not perform any ablation on the testing set. We then report results of this experiment by recording F1-score for each class with respect to percentage of dataset that simulated as missing.

Results

Using RF model with feature set defined in Table 2, we initially performed 10-fold cross validation with our training set to test performance of our VM classifier. We found that during cross validation our model consistently performed within 98-99% for F1-score, recall, and specificity for all VMs. We then evaluated our model on withheld test set. CPAP suffered largest drop in performance because it confused PS for CPAP for an entire patient. VC/PAV suffered no drop in performance and PC/PS only suffered slight declines in performance (Table 3).

Table 3-Performance of our Random Forest model when applied to our withheld testing set.

Mode	F1-Score	Accuracy	Precision	Recall	Specificity
VC	0.999	1.0	0.998	1.0	1.0
PC	0.989	0.993	0.983	0.996	0.992
PS	0.975	0.981	0.993	0.958	0.996
CPAP	0.85	0.988	0.767	0.952	0.989
PAV	0.994	0.999	0.99	0.998	0.999

We hypothesized that since the model performed well on both training and testing sets that it would also be robust to scenarios in which breath data went missing due to reason of sensor or software failure. We report results for this experiment in Figure 2. We found model is robust to missing data until approximately 90% of data is removed. After this point PC and PS F1-score performance begins to decrease and other classifications begin to fluctuate. After 99% of data is removed our classifications lose clinical utility.

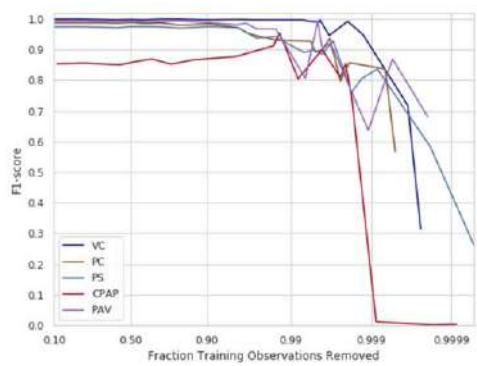

Figure 2-Here we simulate scenario where percentage of training observations is missing due to some kind of software/hardware error.

Given results of random ablation experiment, we hypothesized that we may have created too large a training set. To reduce the size of our training set in generalizable, non-random way, we hypothesized we only needed to keep the first of certain number of contiguous breaths from each VM per data file, and still maintain performance of our original model. In this respect, we could make recommendations to physicians to only annotate first $m$breaths in a series and just leave the rest alone. This could also decrease amount of time necessary to annotate VM on future patients. So, we performed a sensitivity analysis to determine what the optimal number of contiguous observations to keep per ventilator mode is. We do this by sequentially iterating over each VM in our training set and only picking first m breaths in a file while keeping number of observations from other VMs constant. Our analysis (Figure 3) showed that it was

most optimal to only use first 450 VC observations, first 120 PC, 1,200 PS, 160 CPAP, and 80 PAV observations in a file. Using this methodology, we ablated overall number of training observations by 71.41% from 140,928 to 40,285 observations, while still maintaining generalizability of our training set to our withheld test set, and largely improved CPAP performance (Table 4). By performing ablation we were able to boost average F1-score of our classifier to 0.9752 from 0.9614 that was reported in Table 3.

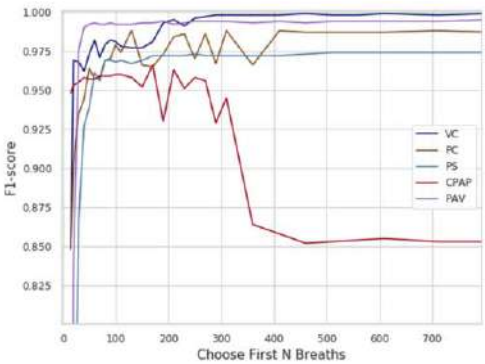

Figure 3-Results from our sensitivity analysis for choosing first N contiguous breaths for a given mode in a data file.

Table 4-Final results of our ablation experiment where we only keep first 450 VC, 120 PC, 1,200 PS, 160 CPAP, and 80 PAV observations in a data file. We note final number of training observations that we kept, and report how much of reduction that was in contrast to original training set. Performance improvements/degradation over results listed in Table 3 are bracketed alongside final performance metrics. E.g. performance increase of 2.0% is denoted as (+.02).

Mode	Training Observations	F1-Score
VC	6,079 (-83.65%)	0.998 (-0.001)
PC	2,154 (-92.77%)	0.964 (-0.025)
PS	27,892 (-26.81%)	0.967 (-0.008)
CPAP	3,040 (-73.55%)	0.955 (+0.105)
PAV	1,120 (-94.46%)	0.993 (-0.001)

Discussion

In this paper, we highlighted how we created dataset of 308,957 breaths annotated for VM on per-breath basis and how we developed highly accurate, ML-based VM classification model that only utilizes raw VWD to perform classifications. Our VM classifier was highly performant in detecting five of most widely used VMs in USA, even in presence of signal noise, episodes of PVA, and routine clinical events such as cough and suction [4]. Using our approach, we were able to achieve methodological and performance improvements in VM classification compared to current state of art [3]. In this regard, Murias reported 89% accuracy at detecting per-hour VM classification, and we report average accuracy of 98.05% of per-breath VM classification (Table 3). Finally, we examined how robust our model is to presence of missing training data, and additional experimental results that suggested how we can decrease the size of our dataset while still maintaining generalizability of our classifier.

We took multiple measures to ensure we were not overtraining our classifier. First, we utilized a relatively large and diverse sampling of patients to create both our testing and training sets. This created one of the largest available datasets of per-breath labeled VWD. Two to four hour epochs were chosen at random from each of these patients. Our testing set included almost as many patients as our training set, and was composed of more breaths than our training set. There was no overlap of patients between training and testing sets. Finally, all model features and hyperparameters were evaluated on the training set using K-fold validation, and were frozen after initial evaluation of our testing set.

Our ablation experiments deserve additional consideration. Results of the random ablation experiments highlight multiple things: 1) RF is extremely performant with our featurization approach, and is also able to perform VM classification with small amounts of data. 2) Our ablation results also illustrate that it may not be necessary to create very large training datasets of information to create performant ML classifiers for VM. 3) Our size reduction experiments did see some decreases in performance in PC and PS because of the manner in which we performed our sensitivity analysis. In our analysis we only modified observations from a single VM type while keeping other VM observations constant, so it was not possible to determine side effects from simultaneously ablating several modes at once. Future experiments could perform more computationally demanding task of ablating multiple modes at once to further explore the issue. 4) Our size reduction experiment showed that first 160 breaths seem to be most representative of CPAP breathing patterns. We hypothesize this can be explained by the fact that some patients tire quickly when on CPAP, and thus their breathing can become more irregular. In this case, later breaths in CPAP sequences may more closely resemble asynchronous breathing from other ventilator modes instead of CPAP.

This work had several limitations. Our use of "look-ahead smoothing" introduced small latency of 2.5 minutes to real-time ventilator mode predictions. This time delay in classification would not likely be of clinical consequence since CDSS recommendations requiring VM state information would rarely be executed over such short time frames to ensure that transient changes in waveforms do not trigger frequent false alarms. If latency is not desired then "look-behind smoothing" can be used as alternative approach. Our study was also confined to a single academic medical center and single ventilator type. There are also additional ventilator modes such as PRVC that we were unable to add to our model due to their paucity of use at UCDMC. We welcome additional collaboration and inclusion of multi-center data and have publicly released our code and dataset.

Conclusions

In conclusion, we created a highly-performant ML classifier for detecting five of most commonly used ventilator modes in USA, using only raw VWD as input. Our use case further demonstrates utility of ML analysis of physiologic waveform data to improve CDSS characterization of patient state when state is missing due to limitations of available informatics infrastructure. We also illustrated usage of dataset ablation to characterize how missing data affects generalization performance of our classifier, and how we can restrict size of our training set while maintaining model generalization to our test dataset. Our classifier will facilitate development of more advanced automated MV CDSS to improve management of patients experiencing respiratory failure.

Abstract

Despite the high consumption of dietary supplements (DS), few reliable, relevant, and comprehensive online resources could satisfy information seekers. This research study aims to understand consumer information needs on DS using topic modeling, and to evaluate accuracy in correctly identifying topics from social media. We retrieved 16,095 unique questions posted on Yahoo! Answers relating to 438 unique DS ingredients mentioned in sub-section, "Alternative medicine" under the section, "Health". We implemented an unsupervised topic modeling method, Correlation Explanation (CorEx) to unveil the various topics in which consumers are most interested. We manually reviewed the keywords of all the 200 topics generated by CorEx and assigned them to 38 health-related categories, corresponding to 12 higher-level groups. We found high accuracy (90-100%) in identifying questions that correctly align with the selected topics. The results could guide us to generate a more comprehensive and structured DS resource based on consumers' information needs.

Keywords:
Dietary supplements, social media, topic modeling.

Introduction

Dietary supplements (DS) usage has gained popularity in recent years with almost 52% of U.S. adults reporting the use of one or more supplement [1]. This high DS usage is especially common among adults aged ≥60 years, where 70% have reported using one or more DS [2]. In spite of this escalating trend in DS consumption across a wide range of consumers, there are not many online resources that consumers could refer to for DS information that is personalized, reliable, succinct, up-to-date, and in a language that is easily comprehensible by a lay-person.

In recent years, the internet has emerged as an important source of health-related information providing an opportunity for people to search online for free health information. According to a Pew Research Center report, 80% of internet users have looked for health information online [3, 4]. This would be especially true in the case of DS as its use is primarily self-initiated rather than based on clinicians' recommendations [5]. Existing online DS health information resources in the U.S. can range from open access, publicly available databases, e.g., Food and Drug and Administration (FDA) [6]; Office of Dietary supplements (ODS) [7]; Dietary Supplement Label Database (DSLD) [8], to commercial databases that often require a paid subscription, e.g., Natural Medicines (NM) [9]. When it comes to personalized queries from consumers, the information is often consolidated under online resources such as "Frequently Asked Questions". However, the information dissipated from such resources is often very basic, non-specific, and not very helpful.

The rapid growth of digital data in today's world, especially in the healthcare domain, offers great opportunities for secondary use in clinical research. Topic modeling [10] has been an area of great interest and to date, several studies have been conducted to make use of electronic data and utilize this novel methodology. The reason for topic modeling's growing popularity is the area's ability to reveal the latent structure and groupings of the underlying corpus without any prerequisite knowledge. Some of the applications of topic modeling in healthcare research include: analyzing clinical notes from Electronic Health Record (EHR) data; discovering and understanding health care trajectories [11]; identifying medication prescribing patterns [12]; mining adverse events of DS from product labels [13]; and discovering health topics in social media [14, 15] among various others.

There are various social Questions and Answers (Q&A) sites and online forums within health communities, e.g., Yahoo! Answers, allowing one to seek information through posting questions and receiving answers from others users (e.g., consumers, health professionals) [16]. Previously, we have used Yahoo! Answers data in several studies e.g., to investigate the terminology and language gap between health consumers and health professionals [17]; to mine consumer friendly medical terms to enrich consumer health vocabulary [16]; and to understand the information needs for diabetes patients about their laboratory results [18].

The purpose of this research study is to understand the information needs of DS consumers by analyzing questions coming directly from consumers and in their own language. The goal is achieved by using Correlation Explanation (CorEx) - a topic modeling algorithm on the title and body of each question under the Q&A section of the Yahoo! Answers database in order to unveil the "topics" around DS information needs. We generated a list of coherent topics that more accurately represent the areas of DS-related information and associated DS ingredients that consumers are most interested in. We will also evaluate the accuracy of the CorEx method in correctly identifying the topics from social media. In the future, the knowledge gained from this study could be used as a guide for developing more meaningful DS resources for consumers that are better aligned with their information needs.

Methods

Figure 1 illustrates the overview of the methods. We extracted and pre-processed questions retrieved from the Yahoo! Answers database, focusing on questions around DS. We performed topic modeling using CorEx in order to understand DS-related topics and categories that consumers are most interested in. We then evaluated the accuracy of the topic modeling methodology by manually reviewing a subset of top ranked questions. We further investigated the actual DS ingredients associated with all the questions under each topic.

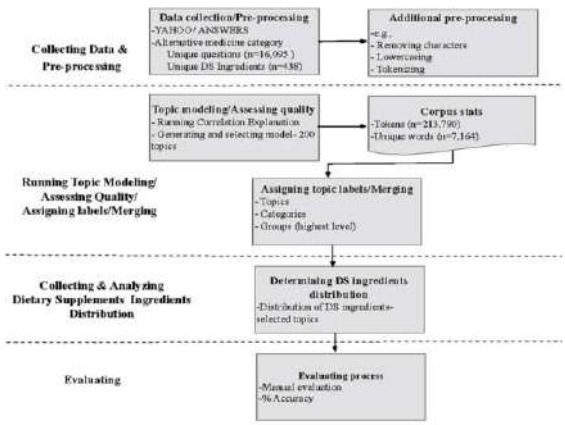

Figure 1— Process overview

Collecting and Pre-processing Data

We collected in total 2,820,179 Yahoo! Answer questions and the corresponding answers posted under 21 sub-categories belonging to the main category "Health". We further extracted 112,090 questions (including their titles and contents) from one of the sub-categories "Alternative Medicine". We then matched the preferred DS names in "iDISK", the first Integrated Dietary Supplements Knowledge base where DS related information is represented in a comprehensive and standardized form [19], with the DS ingredient name in the questions. After two assessors (YW, RR) had manually reviewed the matched preferred names, we cleaned up the DS ingredient names list based on the following rules: 1) only including ingredients with more than 5 matched questions; 2) excluding commonly consumed everyday food/drink items, e.g., fruits, vegetables, wine, caffeine, and water; 3) excluding body parts, e.g., adrenal cortex, brain, and stomach; and 4) excluding recreational drugs e.g., marijuana, poppy seed. Only the questions that exactly matched the DS ingredient names on this list were kept.

These questions were further pre-processed by subject matter experts (TN, JV) and used for topic modeling. We removed all ingredient mentions within the questions to understand the information needs non-specific to certain DS. Each question was then lower-cased and tokenized. Special characters, hyperlinks, and common stop-words (e.g., 'I', 'you', etc.) were removed, and each word was normalized using the normalized string generator (Norm) from the SPECIALIST NLP tool [20]. We only considered words that had at least 3 characters, since any word shorter than that was usually not meaningful. We also removed words that occurred fewer than five times, or more than 85% of the time, as they might not contribute much to the question.

Identifying Topics for DS Questions

In our preliminary investigation of different topic modeling strategies, we found that Correlation Explanation (CorEx) [21] discovered the most coherent topics compared to Latent Dirichlet Allocation (LDA). In contrast to LDA, which defines a generative model for inferring topics, CorEx discovers topics by maximizing the mutual information between words and topics. A subjective assessment of topic quality was performed by two assessors/co-authors and subject matter experts (YW, RR). A topic was considered "coherent" by the experts if assessors found a clear semantic criterion that unites the words under a particular topic. In total, we evaluated several results corresponding to various CorEx models on different numbers of topics (n = 100, 150, 200, 250). Comparing topic modeling results from 100 to 250 topics, we found the model with 200 topics yields the most coherent topic categories.

The selected model was further analyzed and assigned topic names after mutual agreement between two assessors (YW, RR). The "topics" with similar themes were then merged into "categories" (e.g., gastrointestinal disorders, psychiatric disorders) that were further condensed into higher level "groups" (e.g., "uses and symptoms"). For the group, "uses and symptoms", we utilized System Organ Classification (SOC) created by the Medical Dictionary for Regulatory Activities (MedDRA), a medical terminology used to classify adverse event information associated with the use of biopharmaceuticals and other medical products [22].

Topic Evaluation

To evaluate the accuracy of the topic modeling, we selected 15 topics and extracted their corresponding 10 questions with highest ranked probabilities. Manual review (RR, YW) was conducted to determine if the extracted questions correctly aligned with topics generated by the above topic modeling methods. The measure of correctness was reported as percentage accuracy. We also extracted the DS ingredient names corresponding to each topic in order to explore the distribution of ingredients names across various topics. We also reported the DS ingredients associated with most questions for selected topics.

Results

Question Data and Topic Analysis

The final list consisted of 438 unique DS terms in total associated with 16,095 unique matching questions. After data pre-processing, our corpus contained a total of 213,790 tokens, which made up of 7,164 unique words.

From the 200 topics generated by CorEx modeling method, the domain experts (RR, YW) identified topics with similar themes and classified them into 38 unique categories by (Table 1). The 38 unique categories were further summarized into the following 12 higher level groups: uses or adverse effects, product-related, healthy lifestyle, information resources/scientific evidence, addiction, time of use qualifier, sleep disorder, interventions, adverse effect in general, health benefits, mind and body, and population qualifier. The distribution of higher-level groups and number of their associated categories is provided below (Figure 2).

After evaluating the top 10 ranked questions for selected topics, we reported accuracy as number and percentage of questions that correctly aligns with the generated topic. Table 1 lists examples of selected topic groups, their associated categories along with the top 15 most probable words and common ingredients mentions.

Table 1— Selected Topic Categories with Associated Features and Accuracy of Topic Modeling

Topic Groups	*Topic categories (Topic Index)*	*Representative key words*	*Question example*	*Number of correctly matched (accuracy)*	*Representative supplements*
Uses & adverse effects	Gastrointestinal disorders (65)	constipation, laxative, fiber, enema, suppository, constipate, dulcolax, docusate, insoluble, poop, saline, fleet, along with, bum, fecal	Want to take magnesium for health, but it irritates my IBS? Does anyone have any advice for taking Mg?	10 (100%)	Magnesium, Senna, Castor, Probiotics, Glycerin
	Musculoskeletal disorders (93)	arthritis, bracelet, rheumatoid, knee, magnetic, anabolic, steroid, juvenile, sheet, gout, rheumatism, mattress, wonderfully, bangle, supplemental	Is hyaluronic acid supplement safe for children with juvenile rheumatoid arthritis?	10 (100%)	Copper, Fish Oil, Vitamin D
	Psychiatric Disorders (11)	john, anxiety, depression, wort, htp, antidepressant, calm, social, root, 5htp, sam, tryptophan, zoloft, ssri, withdrawal	Is there alternative solution for anxiousness. I'd like to know is if anybody has any feedback on Buspar, Kava root, Passion flower & St. John's wort?	10 (100%)	Valerian, St. John's Wort, SAM-e
	Respiratory, thoracic/ mediastinal disorders (1)	remedy, throat, sore, home, lemon, salt, hot, cure, natural, gargle, warm, epsom, voice, soothe, homeopathic	How can I soothe my sore throat? I have been drinking warm tea with honey & gargle some salt water but it doesn't work.	9 (90%)	Honey, Ginger, Vitamin C, Garlic
	Skin & subcutaneous tissue disorders (23)	skin, face, acne, wash, foot, hand, red, spot, itchy, facial, cream, wrinkle, mask, oily, swell	What are some natural ways to get rid of pimples (home remedies)? I have heard about Aloe	10 (100%)	Apple cider vinegar, Fish oil, Honey, Tea tree oil
	Cardio-vascular/blood & lymphatic system disorders (2)	blood, level, low, pressure, high, normal, cholesterol, , cause, heart, disease, diagnose, raise, thin, flow	Does anyone know about an alternative medicine way of treating high blood pressure? I have heard of l-arginine to be effective.	9 (90%)	Iron, Fish Oil, Sodium
	Endocrine disorders (68)	thyroid, hypothyroidism, synthroid, levothyroxine, hypothyroid, gut, patient, syndrome, leaky, radioactive, testimony, underactive, iodide, success, advisable	Are there natural alternatives after having radioactive iodine treatment for Graves' disease?	10 (100%)	Iodine, Kelp, Vitamin D
	Infections & infestations (31)	infection, yeast, bladder, antibiotic, treat, kill, bite, mannose, parasite, mosquito, coat, douche, poultice, intestinal, frequent	Home remedies for yeast infections? I have heard where diluted apple cider vinegar in a bath tub could provide temporary relief	10 (100%)	Cranberry, Garlic, Apple Cider Vinegar,
	Pregnancy, puerperium/ perinatal conditions (40)	control, birth, period, pregnancy, pregnant, miscarriage, irregular, headache, hormone, tension, 1st, abortion, fertility, defect, endometriosis	Is it safe to drink penny royal tea along with parsley tea to induce a miscarriage?	10 (100%)	Vitamin C, Iron, Dong Quai
	Dental & gingival conditions (124)	pot, tooth, eliminate, desperate, prune, brush, resistant, walnut, wisdom, piss, neti, dentist, dependency, swish, tonsillitis	I am getting my wisdom teeth out & I would like to know if clove oil will help in pain in my gums?	10 (100%)	Apple Cider Vinegar, Silver, Garlic, Clove
Addiction	Smokables (21)	smoke, weed, marijuana, cigarette, legal, pipe, bowl, roll, tobacco, illegal, bud, blunt, smoker, kush, hash	What is the difference between Salvia-A & Salvia divinorum? I smoked salvia divinorum	10 (100%)	Damiana, Catnip, Mullein, Salvia divinorum, Kratom, Clove
Product-related	Dose/dose form/ preparation (43)	mcg, 1000, complex, omega, 5000, 2000, 2500, multiple, adult, 2000iu, standardize, milligram, cla, strength, gnc	Is the dose of vitamin A 2500 IU? Why can I not find that in a supplement?	10 (100%)	Biotin, Vitamin D, Vitamin C, Fish Oil, Vitamin B12, Folic Acid, Vitamin A
Sleep disorder	Sleeping (50)	fall, asleep, 2am, cry, couch, 3am, deaf, sleeper, category, pulmonary, carpet, regardless, proportion, haven't, recreational	Need more info about Melatonin? I have trouble falling asleep	8 (80%)	Melatonin, Valerian
Frequency/ Time	Frequency/Time reference (9)	even, month, since, may, though, well, always, never, pretty, end, fine, mean, without, course, quite	Chromium supplements... do they work? I have been taking them for a few weeks now	7 (70%)	Iron, Vitamin D, Cranberry
Health life style	Weight control (19)	weight, lose, gain, loose, berry, cardio, primarily, weight, workout, lift, shed, cambogia, underweight, usda	Would it be safe to take a weight loss pill with the supplements?	9 (90%)	Acai, Apple Cider Vinegar, Honey, Garcinia,

We found the percent accuracy for most of the selected topics is between 90% - 100%, except sleep (80%) and frequency/time categories (70%). "Use and adverse effects" is the most dominant topic group and accounted for 50 topics out of 200. Under this topic, there were 15 categories classified based on MedDRA SOC (Figure 3).

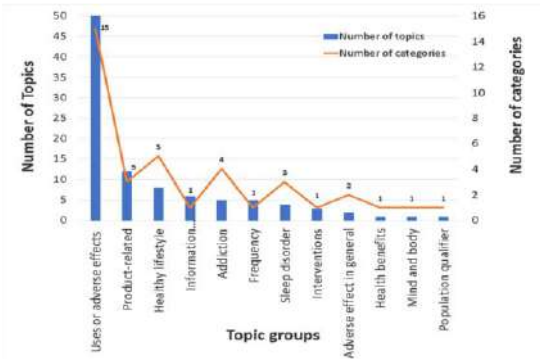

Figure 2— Distribution of TopicGgroups and the Associated Number of Categories.

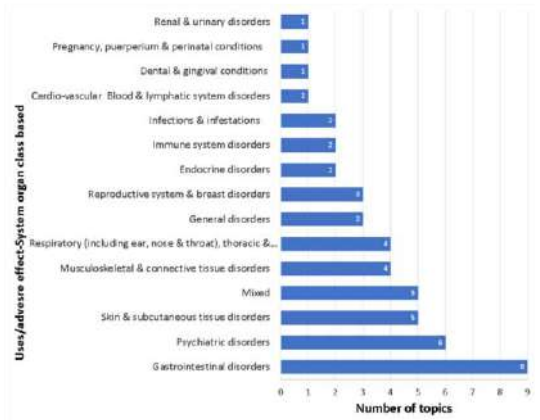

Figure 3— Distribution of uses/adverse effects related categories based on system organ class (SOC)

Dietary Supplements Associated with Most Questions

We also extracted the DS ingredient names associated with most questions corresponding to a particular topic in order to explore the distribution of most commonly discussed ingredients. Only DS ingredients associated with ≥10% of questions under a specific topic were reported (Table 2).

Discussion

In this study, we employed CorEx topic modeling over user-generated questions coming from the Yahoo! Answers data in order to better understand the information needs of consumers. We also discovered interesting information on the distribution of DS ingredients across topics of special interest to consumers. This research effort further validates the feasibility of topic modeling to extract important information hidden in large corpus of social media data.

Applying CorEx topic modeling methods, we were able to accurately identify 12 topic groups. The top three groups with the most number of respective assigned categories and topics, which can be regarded as the information most sought by consumers, are: "use and adverse effects", "product-related", and "healthy life style" (Figure 2). Extracted information pertaining to any symptom or sign could either be an indication or an adverse event of a DS, (e.g., diarrhea, abdominal pain, palpitations, headaches); therefore, uses and adverse effects were combined as one group, "use and adverse effects". We found a higher number of topics and the associated number of questions concerning: gastrointestinal system (specifically diarrhea and constipation); psychiatric (mainly anxiety and depression); and skin and subcutaneous tissues (primarily acne and UV protection). We also had a "mixed group", having keywords corresponding to more than one system. For "product-related groups", we merged categories like dose, dose from, preparation because of their co-occurrence under one topic (e.g., Topic #43). Under the "healthy life style" group, the topics were mostly around eating healthy and weight control/exercise.

Table 2— Total Number of Questions Matched for Each Topic The representative ingredient is the one that matched the most questions. The percentage of the questions that mentioned the representative ingredient is shown in the parenthesis. The text in bold represents the ingredient with high percentage of associated questions.

Topic categories Topic Index)	Number of questions matched	Representative Ingredient	Questions containing Representative Ingredient
Gastrointestinal disorders (65)	145	Magnesium	24 (16.55%)
Musculoskeletal disorders (93)	45	Copper	11 (24.44%)
Psychiatric disorders (11)	256	Valerian	45 (17.58%)
Respiratory (including ear, nose & throat), thoracic & mediastinal disorders (1)	**476**	**Honey**	**226 (47.48%)**
Skin & subcutaneous tissue disorders (23)	84	Apple Cider Vinegar	17 (20.24%)
Cardio-vascular/blood & lymphatic system disorders (2)	264	Iron	38 (14.39%)
Endocrine disorders (68)	48	Iodine	11 (22.92%)
Infections & infestations (31)	160	Cranberry	37 (23.12%)
Smokables (21)	134	Damiana	11 (8.21%)
Dose/dose form/preparation (43)	98	Biotin	35 (35.71%)
Sleeping (50)	**45**	**Melatonin**	**29 (64.44%)**
Weight control (19)	171	Acai	26 (15.20%)

We found high accuracy when we identified questions that correctly align with the topic categories/groups (Table 1). We found few low matching accuracy topics also having questions related to other topics, e.g., sleeping disorders topic with questions related to recreational drug, anxiety/depression. We also reported actual DS ingredient names associated with most questions for a particular topic (Table 2). We found a substantially higher percentage of questions for the ingredients "Honey" under respiratory disorders and "Melatonin" under sleep disorders. This information provides essential knowledge on the use of DS for various specific reasons and needs further exploration.

This research study had several limitations. We analyzed only questions belonging to alternative medicine sub-category under "health" section and might have missed dietary supplement occurrences under other sub-categories, e.g., mental health conditions, general health care. We only used preferred DS ingredient names and not their synonyms (e.g., scientific names, common names) to extract the corresponding questions. Also, there are inherent limitations to topic modeling e.g., topics were generated based on the statistical word distribution within the questions and thus topics with incoherent topic keywords were also generated.

Conclusions

This research provides essential insights on extracting and understanding the information needs of consumers around dietary supplements using CorEx-based topic modeling that could identify the relevant topics embedded in a large corpus of Yahoo! Answers data with high accuracy. The knowledge gained here could be used to generate a more comprehensive repository of resource for consumers around dietary supplements usage. Thus, this study is an important contribution in further accentuating the potential benefits of using social media data in the clinical research.

Abstract

***Objective**: To characterize the scientific reproducibility of biomedical research studies by query and analysis of semantic provenance graphs generated from provenance metadata terms extracted from PubMed articles. **Methods**. We develop a new semantic provenance graph generation algorithm that uses a provenance ontology developed as part of the Provenance for Clinical and Health Research (ProvCaRe) project. The ProvCaRe project has processed and extracted provenance metadata from more than 1.6 million full text articles from the PubMed database. **Results**. The semantic provenance graph generation algorithm is evaluated using provenance terms extracted from 75 selected articles describing sleep medicine research studies. In addition, we use eight provenance queries to evaluate the quality of semantic provenance graphs generated by the new algorithm. **Conclusion**. The ProvCaRe project has created a unique resource to characterize the reproducibility of biomedical research studies and the semantic provenance graph generation algorithm enables users to effectively query and analyze the provenance metadata in the ProvCaRe knowledge repository.*

Keywords:

Knowledge Bases; Biomedical Ontologies; Health Information Systems

Introduction

Provenance metadata describes the history or origin of data, and therefore plays a critical role in supporting the reproducibility of results from scientific experiments. Scientific reproducibility has received increasing attention in the biomedical research community, including clinical research, drug development, and basic science research, with the publication of the U.S. National Institutes of Health (NIH) "Rigor and Reproducibility guidelines" [6; 15]. Reproducibility of results from biomedical research studies is critical to ensure that valid results are used when designing new research studies, developing new drugs with less likelihood of failing during clinical trials, and ensuring the allocation of limited funding resources to rigorously designed research studies [13; 21]. Provenance metadata therefore represents essential information about research studies, including protocols, data acquisition methods, and statistical analysis models.

However, there has been limited work in the use of provenance metadata to support reproducibility in biomedical research. Therefore, as part of the Provenance for Clinical and Health Research (ProvCaRe) project, we are developing a framework to use semantic provenance metadata for characterizing the reproducibility of biomedical research studies [23]. We have developed a provenance-focused natural language processing (NLP) pipeline to extract provenance metadata terms from more than 1.6 million full-length articles in the National Center for Biotechnology Information (NCBI) PubMed database consisting of 28 million citations [1]. The extracted provenance information is stored in a structured form in the ProvCaRe knowledge repository.

The ProvCaRe knowledge repository is a unique resource for sudying and characterizing the reproducibility of biomedical research studies using a systematic and exhaustive approach. Provenance metadata is intuitively modeled as a graph consisting of nodes and edges, for example *ResearchStudy* → *hadCohortSizeOf* → *5861(participants)*, where *ResearchStudy* and *5861(participants)* are nodes and *hadCohortSizeOf* is an edge [8]. The World Wide Web Consortium (W3C), which is the organization for Web technology standards, developed the PROV specifications to facilitate interoperability and interchage of provenance metadata in data management and Web-based information systems [16; 19]. The PROV specifications can be extended to biomedical domain to model provenance as a graph with formal semantics and terms mapped to ontologies. We used this approach to generate semantic provenance information in the ProvCaRe knowledge repository with terms mapped to a provenance ontology to support queries related to scientific reproducibility.

In this paper, we investigate the generation of provenance graphs from the structured provenance information stored in the ProvCaRe knowledge repository. In particular, we describe a new method to transform structured provenance information into a W3C Resource Description Framework (RDF)-based semantic provenance graph. We also describe an approach to query and analyze the provenance graph using a test case of provenance information from 75 selected articles.

Background

Resources

W3C PROV Specifications

The W3C PROV specifications consists of: (1) the core model called PROV-DM, which defines a common terminology system for representing interoperable provenance metadata [19]; (b) the PROV Ontology (PROV-O) that represents PROV-DM in the W3C Web Ontology Language (OWL2) [12; 16]; and a set of constraints (PROV-Constraints) to define valid forms of provenance conforming to the PROV specifications [4]. We extended PROV-O in the ProvCaRe project to model provenance terms associated with biomedical research studies. In particular, we extended the three core concepts of PROV-O,

namely "prov:Agent", "prov:Entity", "prov:Activity"; and its properties, namely "prov:wasDerivedFrom", "prov:wasGeneratedBy", and "prov:used". The namespace *prov* refers to "*http://www.w3.org/ns/prov#*".

ProvCaRe Knowledge Repository

The provenance terms extracted by the ProvCaRe NLP pipeline are currently stored in the ProvCaRe knowledge repository as a set of three related provenance terms (for a detailed description of the NLP pipeline, please refer to [23]). For example, we stored provenance terms extracted from an article describing a study on sleep-disordered breathing and hypertension by O'Connor et al. [20] as "hypertension status of participants", "was ascertained at", "second follow-up exam" in the ProvCaRe knowledge repository. However, this representation of provenance metadata has some limitations, for example (1) it is verbose (making it difficult to query efficiently); and (2) it cannot be modeled as a RDF graph structure. Given a user query, "*How was the hypertension status of participants determined in this research study?*", the ProvCaRe query interface uses keyword-based matching together with ontology-based "expansion" of query expression for retrieving query results. Therefore, we address these challenges by developing a new algorithm to map the provenance information in the ProvCaRe repository to a semantic provenance graph.

Related Work

Provenance metadata has long been used in fine arts, library management, and computer science to track art items, literary resources, and data elements. In particular, provenance metadata plays a critical role in ensuring data quality [3] and reproducibility of experiment results [17]. Provenance terms describing the context of biomedical research experiments, for example sample size of the experiment, randomization techniques used, protocol used for selection of participants in a research study cohort, are critical for enabling the reproducibility of research study results [15].

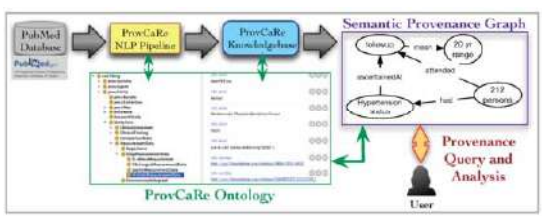

Figure 1: Architecture of the ProvCaRe framework and its components, including the ProvCaRe ontology

Although previous work in the biomedical research domain had limited or no focus on provenance metadata for reproducibility, a number of guidelines and best practices have been adopted to improve reporting of research studies to support reproducibility, for example the NIH "Rigor and Reproducibility guidelines" [10] and the Ontology for Clinical Research (OCRe) project, which developed a formal model of clinical research studies [24]. Projects that have explored the role of provenance in scientific reproducibility in other domains include work by Chirigati [5] and [18]. Many projects have also explored querying of provenance graphs using query language for workflow provenance [2] and Semantic Web technologies such as SPARQL [17; 22].

To the best of our knowledge, ProvCaRe is first project to generate a semantic provenance graph from unstructured text to support queries for scientific reproducibility.

Methods

An overview of the ProvCaRe platform and its components is shown in Figure 1 illustrating a provenance-focused NLP pipeline, storage of provenance triples in the knowledge repository, and the creation of semantic provenance graphs. The ProvCaRe ontology plays a central role as the reference knowledge model during both the extraction of provenance metadata and generation of provenance graphs.

ProvCaRe ontology for biomedical provenance metadata

The ProvCaRe ontology was developed by extending the classes and properties of the W3C PROV ontology using OWL2 description logic [16]. The two key design objectives of the ProvCaRe ontology are: (1) modeling the essential components of a research study, and (2) incorporating terms from existing domain ontologies for terms specific to different medical disciplines to provide appropriate level of granularity for provenance terms. Example terms modeled in the ProvCaRe ontology to meet the first objective are: the method used to conduct the study, the instruments used to record or analyze data in the study, and the different types of data used in the research study. Similarly, to meet the second objective, the ProvCaRe ontology currently models terms specific to sleep medicine, endocrinology, and neurological disorders. Example terms in the ProvCaRe ontology include: polysomnogram (sleep medicine), electroencephalogram (neurology), and Hyperaldosteronism (endocrinology). These terms are mapped to existing biomedical ontologies, such as SNOMED CT, National Cancer Institute (NCI) Thesaurus, and Gene Ontology (GO).

These mappings allow the provenance terms mapped to ProvCaRe ontology classes to reference terms in existing biomedical ontologies, which supports interoperability of the ProvCaRe knowledgebase with existing biomedical databases, such as NCBI Gene and Protein database. The ProvCaRe NLP pipeline uses the ProvCaRe ontology to identify and extract provenance terms from full-text articles in the PubMed database. At present, the ProvCaRe ontology consists of about 300 classes and 40 object properties. The ProvCaRe ontology plays a key role in the generation of the semantic provenance graphs from the provenance terms as it provides the schematic model to represent the nodes and edges of the graph structure.

Generating semantic provenance graph

The W3C Resource Description Framework (RDF) is a widely used Semantic Web technology for representing graph structures [11]. A RDF graph consists of "subject", "predicate", and "object". For example, *ResearchStudy* → *wasApprovedBy* → *EthicsCommittee*, where *ResearchStudy* is the "subject", *wasApprovedBy* is the "predicate", and *EthicsCommittee* is the "object" of the RDF triple. Two or more RDF triples can be aggregated to form a RDF graph. The RDF graphs can be queried using the W3C SPARQL query language that also supports reasoning to infer new knowledge from RDF graphs.

We use RDF syntax to generate the semantic provenance graph in the ProvCaRe project. Figure 2 illustrates a new algorithm developed in the ProvCaRe project to transform structured provenance metadata extracted from unstructured text into graph structures with "subject", "predicate", and "object" mapped to ontology terms. The algorithm uses the output of the ProvCaRe NLP pipeline, which consists of the constituents of the sentence such as nouns, verb ("chunked sentence"), and output of the named entity recognition (NER) as listed in Line 1. The provenance-focused NER module has an important feature that uses the ProvCaRe ontology together with existing

biomedical NLP resources such as the Unified Medical Language System (UMLS)-based MetaMap and the National Center for Biomedical Ontologies (NCBO) annotator for entity recognition [14]. This comprehensive approach to provenance NER ensures that the ProvCaRe NLP pipeline is able to effectively identify and extract provenance terms from unstructured text.

In Line 3, 4, and 5 of the graph generation algorithm (Figure 2), we use mappings between structured provenance and ProvCaRe ontology classes to generate concise representation of provenance terms, which can be used to generate

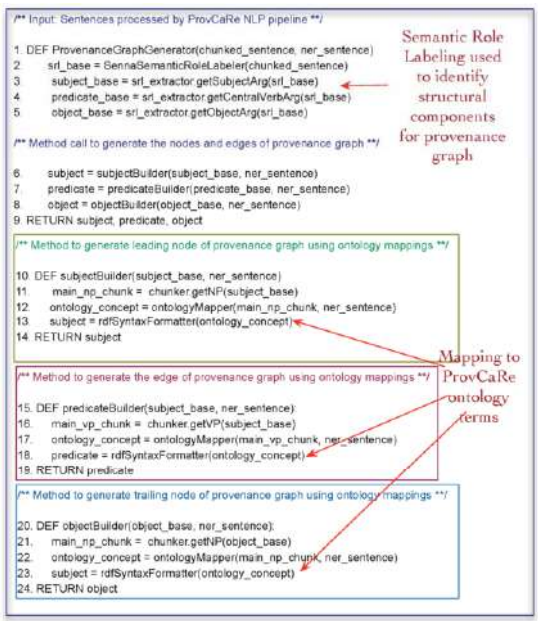

Figure 2: the algorithm used to generate a sematic provenance graph from terms stored in the ProvCaRe knowledgebase

components of the provenance graph. For example, the sentence from an article by O'Connor et al. describing a prospective cohort study on sleep disordered breathing and hypertension [20], "*The institutional review boards of all participating institutions approved the study, and participants signed a consent form*" describes provenance of ethical approval and participant consent for the research study. The graph generation algorithm following the steps described in Figure 2 generated a semantic provenance graph (Figure 3).

It is important to note the differences between the verbose structured provenance information generated by the ProvCaRe NLP pipeline and the concise graph representation generated by the new algorithm. For example, the provenance RDF graph supports querying by graph query languages, including SPARQL and the use of reasoning techniques based on RDF semantics [9]. An important feature of the semantic provenance graph generation algorithm is its ability to correctly identify different constituents of a sentence containing provenance terms and generate one or more provenance RDF triples that accurately represents the information content of a sentence. As shown in Figure 3, the algorithm correctly generates two provenance triples representing: (1) the formal approval for the study; and (2) the consent forms signed by the study participants.

These individual provenance triples can be linked or aggregated together to form the corresponding semantic provenance graph for analysis. This approach allows the ProvCaRe query feature to support graph traversal-based queries. For example, using the predicate "recruited" to link the two provenance RDF triples in Figure 3, a graph traversal query can identify that a research study used consent forms as part of the recruiting protocol.

Query and analysis of provenance graphs

As we discussed earlier, a key objective of the ProvCaRe

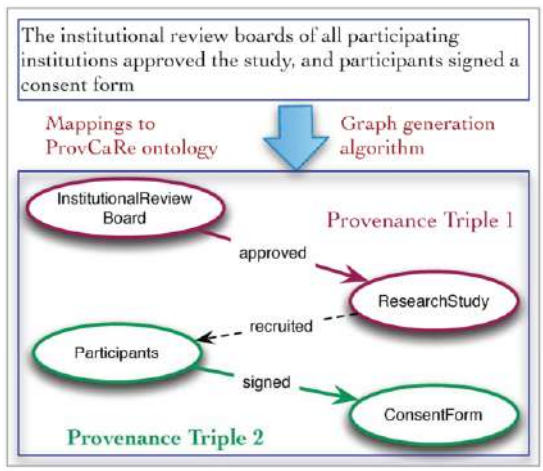

Figure 3: An example semantic provenance graph generated from provenance terms extracted from a sentence in an article describing a prospective cohort study by O'Connor et al.

project is to query and analyze these semantic provenance graphs to characterize the reproducibility of research studies. Therefore, the ProvCaRe project developed a Web-based user interface to support user queries that search for research studies associated with their research hypothesis. The query results include the provenance metadata extracted from the research studies associated with the user query. This provenance query and analysis interface is accessible at https://provcare.case.edu, which allows users to explore the ProvCaRe knowledge repository.

The current version of the ProvCaRe query module uses a "keyword-based search" together with ontology-driven "query expansion" approach to query the structured provenance information in the ProvCaRe knowledgebase. As part of our ongoing work, we are implementing a SPARQL query engine in ProvCaRe to query the semantic provenance graph generated by the new graph generation algorithm described in this paper. In the next section, we evaluate the results of the graph generation algorithm.

Results

We used a corpus of 75 articles describing sleep medicine research studies for evaluation of the graph generation algorithm. This corpus of articles was selected from sleep medicine reearch studies that made their data available as part of the National Sleep Research Resource (NSRR) [7]. However, we note that as part of the ProvCaRe project, we have processed more than 1.6 million full text articles available in the PubMed database. For example, Figure 4 illustrates the distribution of 35 million terms extracted from the 1.6 million articles categorized according to a select number of ProvCaRe

ontology classes (terms are organized by their frequency in the figure). Provenance terms describing the design of research studies, for example "comparative" research studies have the highest frequency, whereas provenance terms describing the statistical data analysis term "variance" has the lowest frequency.

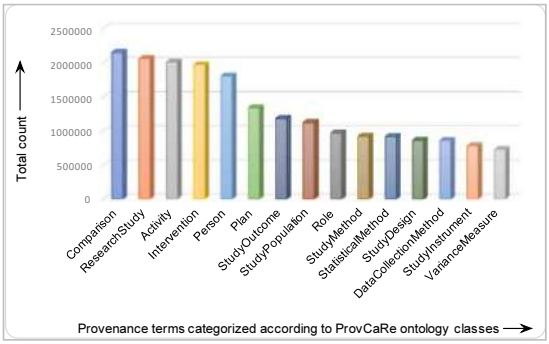

Figure 4: Distribution of provenance terms from 1.6 million full text articles corresponding to ProvCaRe ontology classes

Evaluation of the graph generation algorithm and properties of the semantic provenance graph

In Table 1, we describe the characteristics of the semantic provenance graph generated from the corpus of 75 papers with 10,875 provenance RDF triples generated from more than 30,000 sentences. The 33,783 nodes of the provenance RDF triples were mapped to various biomedical ontologies, for example the term *Population* was mapped to SNOMED CT and the term *Study* was mapped to the ProvCaRe ontology. It is interesting to note that more than 6900 sentences generated more than 1 provenance RDF triple, which is a key feature of the semantic provenance graph generation algorithm as it accurately reflects the information content of the sentence.

Table 1– Properties of semantic provenance graph generated from 75 full-text research articles

Type of characterization	Count
Number of provenance RDF triples	10,875
Provenance terms mapped to ontology classes	33,783
Total number of sentences processed from 75 papers	30,450 sentences
Total number of sentences with more than 1 provenance RDF triple generated	6917 sentences

An important feature of the semantic provenance graph generation algorithm is scalability in terms of time required to process large number of provenance terms. Figure 5 shows the performance of the algorithm for five sets of articles with increasing size. The results show that the algorithm scales almost linearly as the number of articles increases. As part of our ongoing work, we are further optimizing the performance of the algorithm as we aim to process all 35 million provenance terms extracted from the 1.6 million articles in ProvCaRe .

Qualitiative evaluation of the semantic provenance graph

In addition to the quantitative analysis of the provenance triples generated by the semantic provenance graph generation algorithm, we qualitatively evaluated the graph generated for the research study described by O'Connor et al. (this article was selected at random from the corpus of 75 articles). We used a set of eight queries to represent important contextual information about not only this specific research study reported by O'Connor et al., but also other biomedical research studies. The queries are listed below:

Q1. What were the inclusion and exclusion criteria?

Q2. How were subjects assigned to groups?

Q3. How was blood pressure measured?

Q4. What was the definition of hypertension?

Q5. What method was used to perform sleep studies?

Q6. How were apnea-hypopnea indices categorized?

Q7. When were repeat blood pressure measurements checked?

Q8. How was the data analyzed?

The objective of evaluating these queries over the semantic provenance graph was to evaluate the quality of the graph. The query results were manually reviewed and were found to closely correspond to the provenance information available in the original article by O'Connor et al. We propose to perform a systematic evaluation of the provenance graph query results using the sematic provenance graph generated from the 1.6 million articles in future.

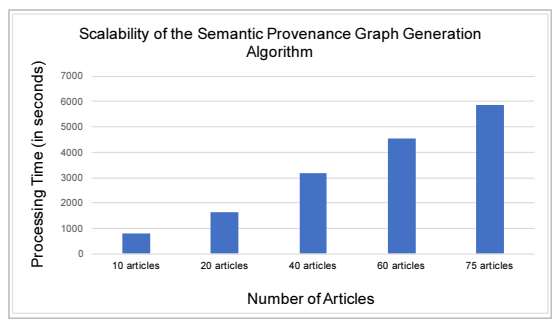

Figure 5: The performance of the semantic provenance graph generation algorithim over five different sets of articles

Discussion

The use of the semantic provenance graph structure to underpin the ProvCaRe knowledge repository is expected to significantly improve query and analysis features available to users. This will in turn enable the biomedical research community to query and analyze provenance metadata reported by various research studies in the context of scientific reproducibility. However, there are several practical challenges that need to be addressed before the ProvCaRe knowledge repository can play a greater role in characterizing the reproducibility of research studies. These challenges include the lack of detailed description of a research study in published articles, for example protocol related to data collection, data analysis, and validation of study hypothesis.

This challenge can be addressed by making available the provenance information associated with research studies in public metadata repositories. Together with existing data repositories, these provenance metadata repositories can support reproducibility of published studies. An important challenge in the ProvCaRe project is the scalability of graph query operations as we progressively convert all the provenance

information in the ProvCaRe knowledgebase into an RDF provenance graph. We note that the ProvCaRe query interface includes a novel provenance-based ranking feature that allows users to assign weight values to ProvCare ontology terms to rank query results. Together with the provenance-based ranking feature and time complexity of graph operations, the current performance of the ProvCaRe query interface requires significant optimization to support real-time user interactions. We are exploring the use of customized indexing techniques to address this challenge.

Conclusions

We demonstrated the practical use of provenance metadata extracted from full-text articles in the PubMed database to characterize the reproducibility of research studies. In particular, we described the development and application of a new graph generation algorithm to transform verbose provenance metadata extracted by the ProvCaRe NLP pipeline into semantic provenance graphs, which can support the query and analysis of provenance metadata. The ProvCaRe knowledgebase, which includes provenance data extracted from more than 1.6 million full-text PubMed articles, is a unique resource to characterize the scientific reproducibility of biomedical research studies and its representation as a semantic provenance graph will allow users to perform knowledge discovery tasks using ontology-driven reasoning techniques.

Abstract

Social media may serve as an important platform for the monitoring of population-level opioid abuse in near real-time. Our objectives for this study were to (i) manually characterize a sample of opioid-mentioning Twitter posts, (ii) compare the rates of abuse/misuse related posts between prescription and illicit opiods, and (iii) to implement and evaluate the performances ofsupervised machine learning algorithms for the characterization of opioid-related chatter, which can potentially automate social media based monitoring in the future.. We annotated a total of 9006 tweets into four categories, trained several machine learning algorithms and compared their performances. Deep convolutional neural networks marginally outperformed support vector machines and random forests, with an accuracy of 70.4%. Lack of context in tweets and data imbalance resulted in misclassification of many tweets to the majority class. The automatic classification experiments produced promising results, although there is room for improvement.

Keywords:
Social media, Opioids, Surveillance

Introduction

The problem of opioid (prescription and illicit) addiction and overdose is having lethal consequences all over the United States [1]. The 2015 National Survey on Drug Use and Health (NSDUH) estimated that 11.5 million adults misused/abused prescription opioids, and among adults with prescription opioid use, 12.5% reported misuse [2]. The number of opioid overdose deaths continue to rise alarmingly, with 174 people dying from drug overdoses daily [3], and the current rate of opioid prescriptions is three times higher than in the 90s. Between 2014 and 2015, opioid related death rates increased by 15.6%, continuing a trend from 1999, and this increase was driven by illicit opioids other than methadone [4]. Despite the significant acceleration of the crisis in recent years, surveillance measures are slow, and deriving estimates from surveys, such as the NSDUH, is belated. There is almost a two-year lag between the occurrence of overdose related deaths and the time by which the statistics are publicized.[†] Such a lag in the process of data collection and synthesis makes it impossible to determine the trajectory of the epidemic or identify geographic areas that are more greatly impacted by the crisis at a specific point of time. Whether its illicit or prescription opioids, the vast numbers of people affected means that a comprehensive public health approach is needed to curb the crisis, going beyond simply changing patterns of prescribing [5]. Kolodny and Frieden [1] recommended 10 steps that the federal government should take to reverse the opioid epidemic, and, as their first point, the authors outlined the need for real-time assessment of the numbers, patterns, or trends of opioid misuse/addiction.

In this paper, we explore the possibility of using social media, namely Twitter, as a resource for performing real time surveillance of opioid abuse, including both prescription and illicit opioids. Past studies have shown that users post information related to drug abuse on social media [6]–[8]. However, there is a lack of analysis of the differences in abuse-related chatter versus other types of chatter, such as consumption, although it is well known that not all drug-related chatter represents abuse [9]. There is also a lack of understanding regarding the differences between the chatter associated with prescription and illicit opioids (*e.g.*, what proportions of illicit *vs*. prescription opioid mentioning chatter represent abuse?). Unsupervised methods that primarily rely on the volume of data do not take into account the large amounts of noise that is present in social media data (*e.g.*, [10]). There are currently no prototype end-to-end, automated pipelines that can enable the real time surveillance of opioid abuse/misuse via social media. In this paper, we take the first steps in addressing these gaps. We present (i) data collection strategies from Twitter, including the use of automatically generated misspellings and geolocation metadata, (ii) an analysis of the contents of tweets mentioning prescription and illicit opioids, and (iii) a comparison of several supervised classification approaches. Our experiments show that opioid chatter on Twitter can vary significantly between prescription and illicit opioids, with some illicit opioid keywords being too ambiguous to be useful for data collection. We also show that using annotated data, we can train supervised learning algorithms to automatically characterize tweets. We suggest that such a supervised classification system, paired with geolocation metadata from Twitter, can be used to perform localized surveillance of opioid abuse/misuse. We present our pilot methods using the state of Pennsylvania as example.

Methods

Data Collection

We collected data from Twitter using names of prescription and illicit opioid keywords (*e.g.*, *Percocet*® and *heroin*), including street names (*e.g.*, *china white*, *tar*, *skag, percs*) and common misspellings (*e.g.*, *percoset*, *heorin*). We used the list of drug slang terms recently released by the Drug Enforcement Agency (DEA) of the United States to create an initial list of possible slang terms for different prescription and illicit opioids [11]. We manually reviewed the terms and removed those we were sure to be too ambiguous. For example, some of the slang terms associated with heroin, as per the document, are '*basketball*', '*coffee*', '*lemonade*' and '*whiskey*'. Through manual searches of the Twitter web interface, we could not find any instances where these terms were used to refer to opiods. Therefore, we removed these to reduce the retrieval of noise. This strategy led us to use a total of 56 unique names of opioids. Since drug names are often misspelled on social media, we automatically generated misspellings for these keywords using a misspelling generation system [12]. Table 1 presents some sample opioid-related keywords and their automatically generated misspellings. After collecting an initial set, we analyzed samples of retrieved tweets for each keyword. We discovered that despite our initial filtering of keywords, approximately 85% of the tweets were retrieved by 4 keywords—*tar* (~6.5%), *dope* (~54%), *smack* (~20.5%) and *skunk* (~4%)—and in these tweets, these keywords were almost invariably unrelated to opioids and represented something else. We, therefore, removed these keywords for our final data collection. In this manner, we collected tweets between the years 2012 to 2015, only including those geolocated from within Pennsylvania and excluding retweets.

Table 1– Sample of opioid-related keywords and their automatically-generated frequently occurring misspellings

Keyword	Generated Misspellings
Tramadol	trammadol tramadal tramdol tramadols tramado tramedol tramadoll tramadole tramidol tamadol tranadol tramodol tremadol
Heroin	herione herroine heroins heroine heroin heorin herion
Methadone	methadones methadose methodone mehtadone metadone methadon methdone
Oxycontin	oxicontin oxcotin oycotin oxycotins oycontin oxycontins oxycoton oxicotin ocycotin oxycodin oxycottin oxycotine ocycontin
Codeine	codiene coedine codine codene codein
Dilaudid	delaudid dialudid dilaudad diluadid diaudid dilaudin dilauded dilauid dillaudid

Annotation

Our intent was to compare the distributions of tweets for prescription and illicit opioids and to attempt to train supervised learning algorithms—both of which require manual annotation/labeling of a sample of tweets. Based on manual inspection of the collected data,. we decided to manually code the tweets into 4 broad categories—self-reported abuse, information sharing, non-English, and unrelated. Details about these categories are as follows.

Abuse-related (A)

Abuse-indicating or possible abuse by the poster or by someone the user knows or is communicating with. This category also includes admissions of abuse in the past. For illicit opioids, any consumption is considered to be abuse. For prescription opioids, consumption is considered to be abuse only when there is evidence that the user is taking the drug without a prescription, through a non-standard route (e.g., injecting, snorting) or in combination with other substances in order to experience certain sensations.

Information Sharing/Seeking/Providing (I)

Tweets in which the poster is asking for information or providing information about an opioid. This category also includes expressions of medical use (e.g., mentions of having a prescription or taking painkillers after surgery), and sharing of news articles or other media that contain information about opioids. General statements about the drug may are also put into this class.

Non-English (N)

Tweets that are not written in English belong to this category.

Unrelated (U)

This category includes tweets that are not about the drug or opioid, but about something else. This category also includes tweets that make metaphorical comparisons (e.g., I am addicted to X like heroin). Some examples of tweets belonging to this category: handle related (@codeine_CXXX), heroine (hero), cooking (brown sugar). This category also includes tweets about movies or lyrics of songs that mention opioids, but don't have any information value. Table 2 presents examples of tweets belonging to these four categories.

Table 2– Sample tweets and their categories; opioid keywords shown in bold

Tweet	Category
@username naa, i just popped a few **percs** at 2, i drink, sip lean. Wbu?	*A*
Sooooo **heroine** addicts robbed the house 3 houses away from me...makes me feel safe	*I*
Ok I thought that it was just a really funny **oxy** clean commercial but turns out it was just the Spanish channel	*U*
Te quieroo muchito mi hermana **negra**	*N*

We iteratively annotated a set of 100 tweets and discussed the disagreements between pairs of annotators. The disagreements on the initial set were resolved via discussion, and the same process was executed twice until an acceptable level of agreement was reached. In the final set, disagreements for overlapping tweets were resolved by a third annotator—the first author of this article.

Analysis and Supervised Learning

Prescription versus Illicit Opioids

Using the annotated dataset, we compared the volumes of prescription and illicit opioids in the sample to better understand which of these two broad classes of opioids were

more frequently discussed on Twitter. Since the sample for annotation was drawn randomly, we assumed that the distributions of prescription and illicit opiod mentions represented their natural distribution in publicly available Twiter chatter. We also assessed the differences in the distributions of the four tweet categories for these two types of opioids by comparing their proportions. The results of these comparisons are presented in the Results section.

Supervised Machine Learning

To train and evaluate several machine learning algorithms, we first split the annotated data into training (~80%) and test (~20%) sets. We used the training set for analysis, algorithm training and feature analyses, and held out the test set for evaluation. Our intent was primarily to assess the utility of the annotated corpus for supervised machine learning, with the assumption that if supervised classification produced adequate performance, they can be employed in the future for real time monitoring. We trained and optimized three different classification algorithms over the dataset—support vector machines (SVMs), random forests (RFs) and deep convolutional neural network (d-CNN), and compared their performances with a naïve bayes (NB) baseline classifier. SVMs and RFs have been shown in the past to perform well for text classification tasks, particularly because of their suitability for handling large feature spaces. Meanwhile, CNN based classifiers have become popular in the recent past, and they work particularly well in the presence of large annotated data sets. For the SVMs, RF and NB classifiers, we performed basic feature engineering based on our findings from past work on the topic of automatic prescription medication abuse detection from social media [13]. As features, we used preprocessed n-grams (n=1—3), word clusters or generalized representations of words, and the presence or absence of abuse-indicating terms. We used 10-fold cross validation over the training set for the RF and SVM classifiers to find optimal parameter values. For the SVMs, we optimized the kernel and the cost parameter. For the RF classifier, we optimized the number of trees. For the d-CNN classifier, we used dense word vectors, or word embeddings as input. We obtained pre-trained word embeddings from our past work [14]. We used a three-layer convolutional neural network, and for optimizing the various hyperparameters, we split the training set further into two sets and used the larger set for training and the smaller set for validation. For NB, SVM and RF classifiers, we used implementations provided by the python scikit-learn library [15], and for the d-CNN classifier, we used the TensorFlow library [16]. Figure 1 summarizes our entire processing workflow for this study—from spelling variant generation through to supervised classification of tweets.

Results

A total of 9006 tweets mentioning both prescription and illicit opioids were annotated by 4 annotators. Among 550 overlapping tweets, average inter-annotator agreement was 0.75 (Cohen's kappa [17]). The final data set consisted of 1748 abuse tweets, 2001 information tweets, 4830 unrelated tweets, and 427 non-English tweets. The majority of the tweets mentioned illicit opioids—7038 illicit and 2257 prescription.‡ Figure 2 shows the distributions of illicit and prescription opioid mentioning tweets in our annotated set, illustrating that although the relative volume of illicit opioid tweets is much higher, a significantly larger proportion of these tweets are unrelated to opioids. The significantly higher number of unrelated tweets for illicit opioid mentioning posts suggests that such tweets have higher amounts of noise associated with them, and may be more difficult to mine knowledge from despite the large volume.

Table 3 presents the performance of the three classifiers and the NB baseline over the test set. In total, we used 7204 tweets for trainining and 1802 tweets for evaluation. For the d-CNN classifier, the training set was further split into 6304 for training and 900 for validation. It can be seen that, in terms of overall accuracy, macro-averaged recall and precision, the d-CNN classifier marginally outperforms the two traditional benchmark classification approaches (SVMs and RF) despite the relatively small amount of annotated data that was used. All the three classifiers perform significantly better than the NB baseline. The high performance of the d-CNN classifier is encouraging because such deep neural network based classifiers have more room for improvement, compared to their traditional counterparts, as more data is annotated.

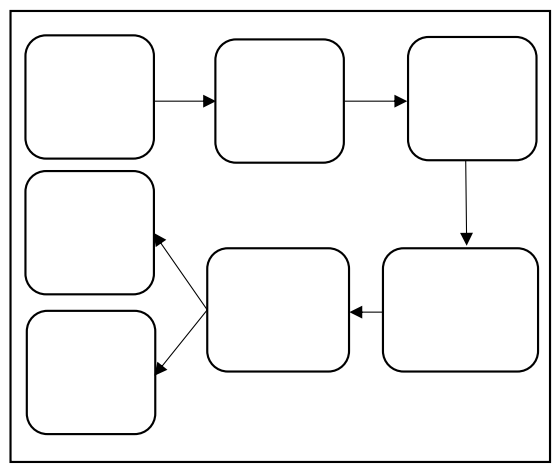

Figure 1 The Twitter data processing workflow for this study

Discussion

Our experiments produced very promising results and showed that automatic machine learning based approaches may in fact provide a possible mechanism for monitoring opioid abuse in near real time for targeted geographic locations (e.g., at the state leve). By combining geolocation information and manually annotated data, we were able to automatically characterize opioid-mentioning chatter from Pennsylvania with moderate accuracy. Table 4 shows three sample tweets, their automatic classifications, location by county and timestamp.

Our manual categorization efforts revealed the difficulty of annotating tweets with high inter annotator agreement. Creating a specific annotation guideline and several iterations of discussions over small sets of overlapping annotations helped improve agreement, although in many cases, due to the lack of context in the tweets, the assigned category depended on the subjective assessement of the annotator. This suggests that

‡ Note that the sum is of these two numbers is greater than the total number of tweets annotated (9006) since some tweets mention both prescription and illicit opioids.

thorough annotation guidelines and such an iterative approach to annotation are very important for achieving acceptable agreement levels for complex annotation tasks such as this.

We found that illicit opioid mentioning tweets were particularly highly noisy, with references to song lyrics or movie quotes, which led to a large proportion of them to be labeled as unrelated. The high proportions of unrelated tweets for both types of opioids, and particularly for illicit opioids, illustrate the importance of a supervised classification system for automatic surveillance. Keyword-based surveillance methods, which rely on the volume of data collected using specific keywords, are evidently not suitable for opioid toxicosurveillance since most of the data retrieved by the keywords will be unrelated noise. The amount of noise may increase or decrease based on events publicized over media outlets. In addition, as our initial analysis of the retrieved data showed, if ambiguous keywords are to be used, the vast majority of tweets collected via the ambiguous keywords (e.g., dabs) can be noise, and this noise may mask the real abuse related signals. Thus, when designing surveillance strategies for similar tasks via social media, care must be taken to identify noisy keywords that may invalidate the surveillance process by bringing in too much noise.

The automatic classification experiments produced acceptable performances, suggesting that automated, real-time opioid toxicosurveillance may be a possibility. In the future, we will explore additioal classification strategies for further improving performance. A brief error analysis revealed that lack of context in tweets caused our learning algorithms to often misclassify tweets to the majority class (U). To better understand the characteristics of the missclassified tweets, more analyses are required.

In the future, we will also apply supervised classifiers trained using our annotated data to automatically characterize unlabeled posts collected over a longer time period to better understand how opioid abuse related tweets are distributed over time and more fine-grained geolocations. Such an analysis may reveal specific time periods that are associated with higher rates of abuse. We will also explore how the opioid abuse rates reported on Twitter correlate, if at all, with real-world data regarding the opioid crisis, such as geolocation-centric opioid overdose death rates.

Conclusions

Our study suggests that Twitter is a promising platform to perform real-time surveillance of opioid abuse/misuse. Although we have only used geolocation data to identify the origins of tweets at the state level, it may be possible to further narrow down to the county or city level, particularly as the volume of data grows over time. Our manual categorization of the data and analyses shows that keyword based data collection from Twitter results in the retrieval of significant amounts of noise. Therefore, studies attempting to use streaming Twitter data for surveillance must be wary of the amount of noise retrieved per keyword and only use keywords that are unambiguous. The same protocol should be followed for research involving data from other social networks. Our annotation also showed that even when using keywords with high signal-to-noise ratios, the number of unrelated tweets is significantly higher for illicit opioids compared to prescription opioids. Thus, the total volume of opioid related chatter may not be indicative of the real abuse or misuse of opioids, but may be driven by other factors such as news articles or the release of movies/songs. To overcome this problem, we employed a supervised classification approach to automatically categorize the tweets, and we found a deep convolutional neural network to produce the best performance with an overall accuracy of 70.4%. In the future, we will try to improve on this classification performance by employing more advanced strategies, and also use the output of the classifiers to perform downstream geolocation-centric analyses.

Table 3– Classifier accuracies over the test set

Classifier	Recall	Precision	Accuracy (%)	95% CI
Naïve Bayes	0.61	0.58	53.9	51.6-56.3
Random Forest	0.66	0.70	70.1	67.9-72.2
Support Vector Machines	0.68	0.70	69.9	67.8-72.1
Deep Convolutional Neural Network	0.70	0.71	70.4	68.2-72.5

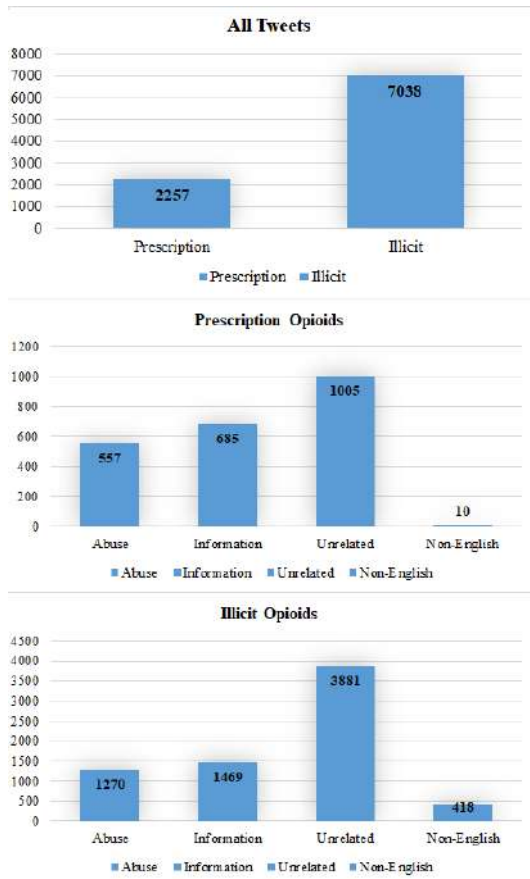

Figure 2– Distributions of tweets belonging to each category for illicit and prescription opioid mentioning tweets. The charts show that aabout 75% of the tweets in the sample mention illicit opioids, and that illicit opioid mentioning tweets have much higher proportions of unrelated information (including non-English tweets), while prescription opioid mentioning tweets have higher proportions of misuse/abuse and information oriented tweets.

Urban Disadvantage, Obesity, and Underweight in 31 Lower-Income Countries

Lincoln R. Sheets[a], Henok G. Woldu[a], Rina Swart[b], Eduardo Simoes[a]

[a] *Department of Health Management and Informatics, University of Missouri, Columbia, Missouri, United States*
[b] *Department of Community and Health Sciences, University of Western Cape, Cape Town, Western Cape, South Africa*

Abstract

Although some studies have shown that obesity and other non-communicable diseases are more common in more disadvantaged areas, no publications to date have examined the interaction of obesity with urban and rural disadvantage in lower-income countries. This study analyzed the rates of obesity and underweight in disadvantaged urban women and disadvantaged rural women in 31 lower-income countries, and calculated the age-adjusted odds ratios of urban vs. rural obesity and underweight. The odds of obesity were significantly ($p<0.05$) higher for urban populations in 16 of the 31 countries and in all aggregated regions; the evidence that underweight is also associated more with urban populations was mixed. Because obesity is a rapidly-growing threat to the public health and financial strength of lower-income countries, and urban disadvantage is associated with more obesity than rural disadvantage, policymakers should work to understand, predict, and prevent obesity in urban populations specifically.

Keywords:

Obesity Epidemiology, Healthcare Disparities, Geographic Factors

Introduction

An Inequitable Burden

Obesity is growing rapidly in low- and middle-income countries (LMIC), and is becoming a greater threat to global health than undernutrition and infectious diseases [1]. Obesity is a potentially preventable risk factor for many types of cancer and for heart disease [2], which are the leading causes of death around the world [3]. The global cost to treat excess morbidity due to obesity is already billions of dollars annually and the associated burdens of mortality, morbidity, economic costs, and social stigma are rising fastest in the countries least able to bear them [4].

What Is Known: Economic Disadvantage and Obesity

Some studies have shown that obesity and other non-communicable disease are more common in neighborhoods with more poverty, pollution, and crime, and less common in neighborhoods with access to healthy foods, exercise opportunities, and public transportation [5, 6]. These geographic associations can guide population-level interventions such as community-based preventive health programs and national health policy decisions [7]. While most of the published literature comes from the United States and Europe, there has been a recent increase in the number of high-quality global studies of obesity and geographic disadvantage [8, 9], including retrospective studies of the the rich, multi-national, multi-year data of the Demographic and Health Surveys (DHS) Program [10].

What Is Not Known: Urban and Rural Disadvantage

Although studies have shown urban-rural differences in the association of obesity with economic disadvantage in both high-income countries [11] and low-income countries [12], no publications to date have examined the interaction of obesity with urban and rural disadvantage in countries with diverse economic conditions. This study examined DHS data from multiple low-income and lower-middle-income countries to examine the association of obesity with urban disadvantage and rural disadvantage. Because many lower-income countries bear a double burden of underweight and obesity [13], the prevalences of both these conditions were analyzed.

Hypothesis

Both obesity and underweight are more strongly associated with urban disadvantage than with rural disadvantage among adults in lower-income countries.

Methods

Population

Thirty-one countries (shown in Table 1) met all four inclusion criteria: (a) DHS survey results were available within the last ten years (i.e. in 2008 or later) [10], (b) the survey results included body-mass index (BMI) values, (c) the survey results included responses from both urban and rural areas, and (d) the country was classified by the World Bank as a "Low Income" or "Lower-Middle Income" economy [14].

Data Sources

Results were included from the most recent DHS survey in each country [10]. DHS surveys only include weight-and-height measurements on women of child-bearing age, which DHS defines as 15 to 49 years old. Our study included those subjects but excluded subjects who were younger than 18 years old, and excluded women who were pregnant at the time of their BMI measurement Because independent studies [15, 16] have detected qualitative differences in health outcomes between adults in the lower three quantiles and the upper two quantiles of the DHS Wealth Index, the lower three quantiles were used to define economic disadvantage and only subjects in those quantiles were included in the analysis.

Data Elements

The independent variables collected for each included individual were country, urban/rural category [10], DHS Wealth Index [10], and age. Because the body-mass index or BMI classifications of the World Health Organization [17] have been shown to have predictive value in health outcomes including mortality [18], BMI categories were used as nominal dependent variables.

Statistical Methodology

The prevalences of obesity (BMI ≥ 30) and underweight (BMI < 18.5) were calculated for disadvantaged urban women and disadvantaged rural women in each region. The age-adjusted odds ratios of urban vs. rural obesity and urban vs. rural underweight were calculated for each region, using normal weight (18.5 ≤ BMI < 25) as the reference category. The 95% confidence interval was calculated for each odds ratio.

Results

Table 1 shows the survey characteristics and population characteristics of each region.

n = number of subjects; SD = standard deviation

As shown in Table 2, the odds of obesity were significantly ($p < 0.05$) higher for disadvantaged urban women than for disadvantaged rural women in 16 of the 31 countries and in all larger regions that were analyzed. The odds of obesity were not significantly different in the other regions.

The odds of underweight were significantly higher for disadvantaged urban women than for disadvantaged rural women in two of the 31 countries, but significantly lower in one country (India), in the aggregate of all lower-middle income countries, and in the aggregate of all 31 countries.

OR = odds ratio; CI = 95% confidence interval; * = 95% confidence interval which excludes the null hypothesis

Urban Disadvantage and Obesity

Figure 1 shows the geographic distribution of urban-rural disparities in the prevalence of obesity. Darker reds indicate a higher urban-rural odds ratio of obesity, ranging from 1.0 in countries with no significant urban-rural difference to an odds ratio of 4.4 in Cote d'Ivoire.

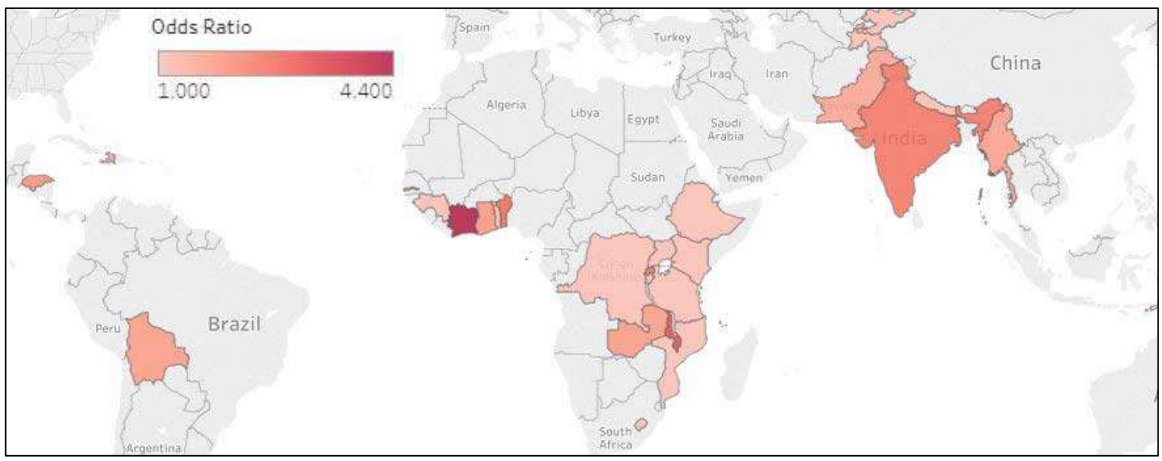

Figure 1– Odds Ratio of Urban vs. Rural Obesity by Country

Urban Disadvantage and Underweight

Figure 2 shows the geographic distribution of urban-rural disparities in the prevalence of underweight. Darker browns indicate a higher urban-rural odds ratio of underweight, ranging from 0.8 in India, through 1 in countries with no significant difference, to an odds ratio of 1.8 in Bolivia and Malawi.

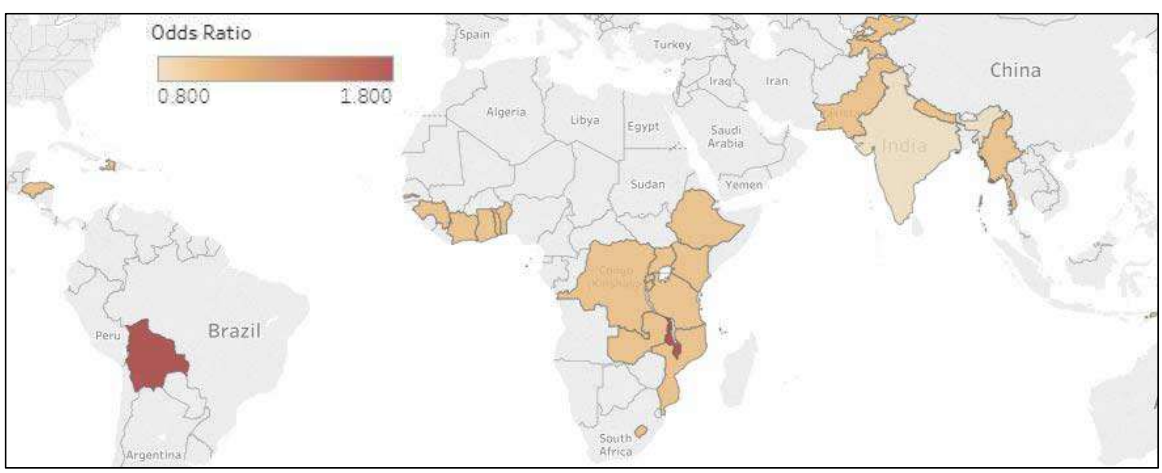

Figure 2– Odds Ratio of Urban vs. Rural Underweight by Country

Discussion

The hypothesis that obesity is associated more with urban disadvantage than with rural disadvantage was found to be true in about half of the lower-income countries for which data were available, in the aggregates of each continent, and in the worldwide aggregate of all 31 countries. However, the evidence that underweight is also associated more with urban disadvantage than with rural disadvantage was very weak, and was contradicted by the finding that underweight is actually associated less with urban disadvantage than with rural disadvantage in some regions and in the worldwide aggregate.

Limitations

The study was limited by the relatively few countries for which data was available, and by the restriction of BMI measurements to women in the survey data. The findings of this study cannot be generalized to higher-income countires, may or may not be generalizable to other lower-income countries, and cannot be be generlized to men in lower-income countries.

Further study

This preliminary study used a relatively simple statistical analysis on the more disadvantaged part of each country's population, as defined by quintiles of the Wealth Index. In order to better understand the interaction of disadvantage with urban residence in the rates of obesity and underweight, a multinomial regression against the Wealth Index of the entire population would provide further insights.

Broader impacts

Because obesity is a rapidly-growing threat to the public health and financial growth of lower-income countries, and urban disadvantage is associated with more obesity than rural disadvantage, policymakers should work to understand, predict, and prevent obesity in urban populations specifically.

Conclusions

The evidence that obesity is more strongly associated with urban disadvantage than with rural disadvantage is compelling, although no clear relationship could be established between underweight and urban or rural disadvantage. As obesity becomes more prevalent in lower-income countries, it is becoming more deadly and more expensive than underweight, as is already true in higher-income countries. More resources are needed for the scientific study and public-policy responses to this threat.

Abstract

Behavioral analysis for identifying changes in cognitive and physical functioning is expected to help detect dementia such as mild cognitive impairment (MCI) at an early stage. Speech and gait features have been especially recognized as behavioral biomarkers for dementia that possibly occur early in its course, including MCI. However, there are no studies investigating whether exploiting the combination of multimodal behavioral data could improve detection accuracy. In this study, we collected speech and gait behavioral data from Japanese seniors consisting of cognitively healthy adults and patients with MCI. Comparing the models using single modality behavioral data, we showed that the model using multimodal behavioral data could improve detection by up to 5.9%, achieving 82.4% accuracy (chance 55.9%). Our results suggest that the combination of multimodal behavioral features capturing different functional changes resulting from dementia might improve accuracy and help timely diagnosis at an early stage.

Keywords:

Alzheimer's disease, linguistic features, motion capture

Introduction

As the world's elderly population increases, the number of people living with dementia is rising rapidly, making dementia an increasingly serious health and social problem. According to a previous survey, around 47 million people globally were living with dementia as of 2015, corresponding to about 7.6% of the world's over-65-year-olds [1]. While dementia affects individuals within many domains, including cognition, neuropsychiatric symptoms, activities of daily living, and usually comorbid physical illnesses, it also affects their supporters, including relatives and even wider society because people with dementia require constant and costly care for years [2]. In fact, approximately 85% of the healthcare costs of dementia are related to family and society, and global annual costs reached over 818 billion USD in 2015 [2]. In contrast, there have been numerous attempts to develop an effective drug to combat dementia, but the results of trials have all been negative [2]. One of the remaining possible way to improve this situation is thought to intervene at earlier disease stages such as mild cognitive impairment (MCI) or preclinical Alzheimer's disease. Although there is no validated effective intervention, longitudinal studies suggested that early intervention at stage of MCI might reduce the progression to dementia [3]. An intervention that delays the onset of Alzheimer's disease (AD) dementia by 5 years is estimated to result in a 57% reduction in the number of AD patients and to reduce 45% of the projected Medicare costs [4]. Thus, early detection of dementia has been increasingly important. However, diagnostic coverage of dementia worldwide remains low, and even in high-income countries, only 40–50% of dementia sufferers have received a diagnosis [5,6]. Thus, detection at earlier disease stages should be a more challenging issue.

One of the most promising ways to detect dementia at early disease stages is identifying the evolution of behavioral change over the course of dementia's progression. Instead of medical examinations including brain imaging as well as in-clinic neuropsychological assessment, being capable of inferring dementia and MCI from behavioral features that can be measured in various everyday situations holds promise for increasing the opportunity for timely detection.

Among the behaviors, the most investigated might be speech and gait [7]. Speech has been used for characterizing language dysfunction resulting from cognitive changes [8-12]. For example, memory impairment causes difficulties with word-finding and word-retrieving, which has been measured by speech features such as fillers, including non-words and short phrases (e.g., "umm" or "uh") [9]. The reduction in speech expressiveness is another language dysfunction typically observed in both MCI and AD. This reduction is measured by the decrease in adjectives and indicators related to vocabulary richness (such as type-token ratio and Brunet's index) [10]. Gait disturbances are also common across the dementia spectrum, although the main clinical hallmark of dementia is cognitive impairment especially related to memory impairment [13]. Over the past decade, large cohort studies on dementia have shown the relationship between the severity of cognitive impairment and increased gait abnormalities [13-16]. For example, dementia is associated with a decrease in gait velocity and an increase in stride variability [17]. While there are limited studies evaluating gait in MCI, some but not all studies have suggested that gait dysfunction can be observed in patients with MCI even under normal walking conditions [13]. Although speech and gait features have been suggested as behavioral biomarkers for AD and possibly early in the course of dementia, including MCI, no studies have investigated whether combining both behavioral features could improve detection accuracy for MCI and AD. If speech and gait each could capture different aspects of subtle changes related to physical and cognitive functioning, the multimodal behavioral approach seems to be promising for building a model enabling detection at an earlier disease stage.

In this study, we investigate whether combining behavioral features of speech and gait could improve detection accuracy for patients with MCI. We collected speech and gait behavioral data from Japanese seniors consisting of cognitively healthy

adults and patients with MCI. Specifically, speech data were collected while performing an picture description task by microphones, while gait performance was assessed during a 5-meter walk at normal speed by a marker-based motion capture system. Through the analyses, we demonstrate that exploiting the combination of multimodal behavioral data to identify MCI outperforms that based on each set of single-modality data alone by up to 5.9%, achieving 82.4% accuracy (chance 55.9%). The results demonstrate how our multimodal behavioral analysis could identify the early stages of dementia by exploiting the combination of subtle changes.

Methods

Participants

We collected data from 34 elderly individuals (20 females and 14 males, between 64 and 82 years, i.e., 73.06 ± 4.76). Nineteen participants were grouped as healthy controls (HCs) and fifteen as having MCI. There was no significant difference in age among the groups. Table 1 shows the number of participants (number of female participants), mean age, and mean Mini-Mental State Examination (MMSE) score for the HC and MCI groups. None of the participants in the HC group were diagnosed as having MCI or dementia before the experiment. The definitions of the MCI groups were based on diagnosis by psychiatrists through medical examinations including structural magnetic resonance imaging, blood tests, and neuropsychological tests. More specifically, the doctors followed the guidelines and criteria of the study by Petersen et al [18]. This study was conducted under the approval of the Ethics Committee, University of Tsukuba Hospital.

Speech data collection and feature extraction

We collected speech data from the participants while they performed the Cookie Theft picture description task. The Cookie Theft picture description task, adapted from the Boston Diagnostic Aphasia Examination, is a task used to test the production of free speech in a structured context [19]. A picture is provided to the participants, showing a mother and two children (a boy and girl). Participants are asked to tell everything they see in the picture. This task is used to test the ability of the participants to describe the characters and events in the scene.

The task was administered using a 2nd generation iPad Air through a web-based application using a Wizard of Oz experiment method. This method is efficient for examining user interaction with computers and facilitating rapid iterative development of dialog wording and logic. The method requires two machines linked together, one for the subject and one for the experimenter. In this implementation, the experimenter (the "Wizard"), pretending to be a computer, "operates" using complete replies to user queries or presses function keys to which common messages have been assigned. The software automatically records the dialog and its timing. This was done as a step towards a fully automated system to first assess the ability to achieve similar results using tablet devices as in traditional assessment styles.

Table 1 – Demographics of participants

Status	No. of Participants (Female)	Mean Age (SD)	Mean MMSE (SD)
Control	19 (12)	71.63 (4.39)	28.42 (1.47)
MCI	15 (8)	74.87 (4.73)	25.53 (3.89)

Voice recordings were collected using three microphones: a throat microphone (NANZU SH-12iK), a lavalier microphone (SONY ECM-CS3), and the iPad's internal microphone. The throat and lavalier microphones were fitted onto the participants' necks and connected to a USB recording device (ZOOM H1/MB) for voice recording (wav format, 44.1 k/stereo) (Figure 1A). Analysis was done on voice recordings gathered from the lavalier microphone, which were selected after synchronization with the throat microphone showing which portions of the recordings contained actual speech from participants. The throat microphone does not record the sound of open-air, so participants' speech area can be detected by extracting the sections above a certain volume level in the recorded audio. Recordings from the iPad's internal microphone were collected but not analyzed in this study. These recordings will be used in later analysis after the proper features have been selected and a model is developed from higher quality audio. After assessment, voice recordings from the lavalier microphone were used for preprocessing. The recorded audio was preprocessed by automatic speech recognition (ASR), which automatically transcribes audio data into text format. Then the experimenter manually corrected the errors of the ASR by listening to the recorded audio. The experimenter also annotated fillers and false starts during the transcribing procedure. For the preprocessing, we used the Japanese morphological analyzer MeCab [20].

Once all the transcribing and annotatince were completed, we collected speech features on the basis of the previous studies.

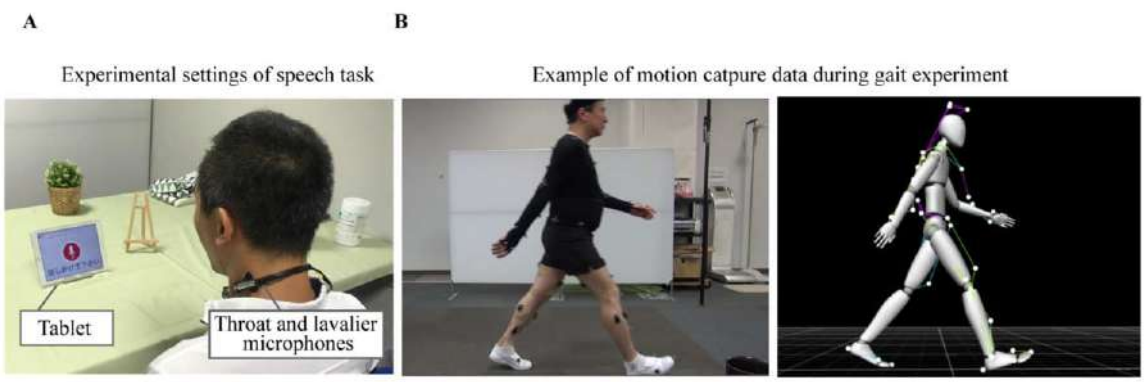

Figure 1 – Overview of speech and gait experiments. (A) Example of the speech experimental setup. (B) Example of motion capture data during gait experiment.

Previous study reported that syntactic complexity is closely associated with the incidence of dementia [21]. Syntactic complexity was measured in various ways, such as the mean length of sentences, number of sentences, ”part-of-speech” frequency, and dependency distance [10,22]. Dependency distance infers the number of intervening words between two syntactically related words in a sentence [23]. Another feature that must be considered is vocabulary richness. This measures lexical diversity, which tends to reduce in dementia cases [9]. Repetitiveness is also reported as an important factor of capturing the linguistic dysfunctions of the patients with dementia [24]. Some matrixes measure the frequency of repeated words and phrases, and others estimate sentence similarities by calculating the cosine distance between two sentences [10]. The feature which widely used in image description tasks is semantic density. It was calculated on the basis of ”informational units” that are predefined objects or text segments that might refer to important information. For example, in the Boston Cookie Theft picture description task, information units consist of objects such as ”Woman”, ”Cookies”, and ”Boy taking the cookie”. With the information units, semantic density can be defined as the number of information units divided by the total number of words [10,22]. A number of previous studies have found that individuals with dementia tend to produce speech with lower information, defined as semantic density, than with healthy controls [22, 25].

In this study, we collected 49 speech features from the transcribed and annoteated text of picture descrtion task. It includes twenty-seven features related to parts-of-speech (POS), four features related to information units (e.g. frequency, ratio), six features for syncatcic complexity (e.g. maximum dependency level), six different measures of sentence similarities (e.g. cosine-disntance), and three measures of vocabulary richness (e.g. type-token-ratio). Number of false starts and number of fillers are extracted from the annotation in the transcribed text. Addition to the text features, the speech rate (audio length/syllables) was also caluclated.

Gait data collection and feature extraction

The gait experiment was conducted on the same day as the speech experiment. The participants took enough rest between experiments. We collected motion data of the participants walking five meters in a lab area at their usual speed. To ensure that gait features were collected during steady-state walking, participants started walking at least two meters before the target zone and completed their walk at least two meters beyond it, which makes nine meters walk in total. Start and end points were marked on the floor with tape. Before each experiment, a trained experimenter gave verbal task instructions to the participants as “Please walk up to the tape at your usual speed”.

Participants’ body positions during their walk were captured by the motion capture system, OptiTrack Flex 13, with eight cameras allocated in a 6 meters × 12 meters walking area (Figure 1B). Three-dimensional kinematic data were measured at 120 Hz using a full body skeleton model of 50 markers. 50 markers includes head (4 markers), torso (6 markers), waist (4 markers), shoulder (4 markers), arm (6 markers), hand (8 markers), leg (8 markers), foot (6 markers), and toe (4 markers). Skeleton is calibrated for each participant before the gait experiment.

In a previous study, a broad range of characteristics is used to describe gait performance. Gait speed is applied widely as an evaluative and a predictive measure of various diseases [13,14,26]. Other measures such as gait velocity and stride variability has also been suggested as a sign of dementia [17]. Step width and step width variability reflect the postural control of gait [27].

In this study, we collected 13 gait features from the positional data obtained from each markers during a gait task. We calculated the gait cycle from four markers on each foot (toe in, toe out, toe tip, and heel). Once all the data preprocessing was completed, gait speed (walk length/time), step length (mean and standard deviation), stride (mean and standard deviation), left-right stride variability, toe angle (mean and standard deviation), left-right toe angle variability and step width (mean and standard deviation) were extracted from gait cycle. We also

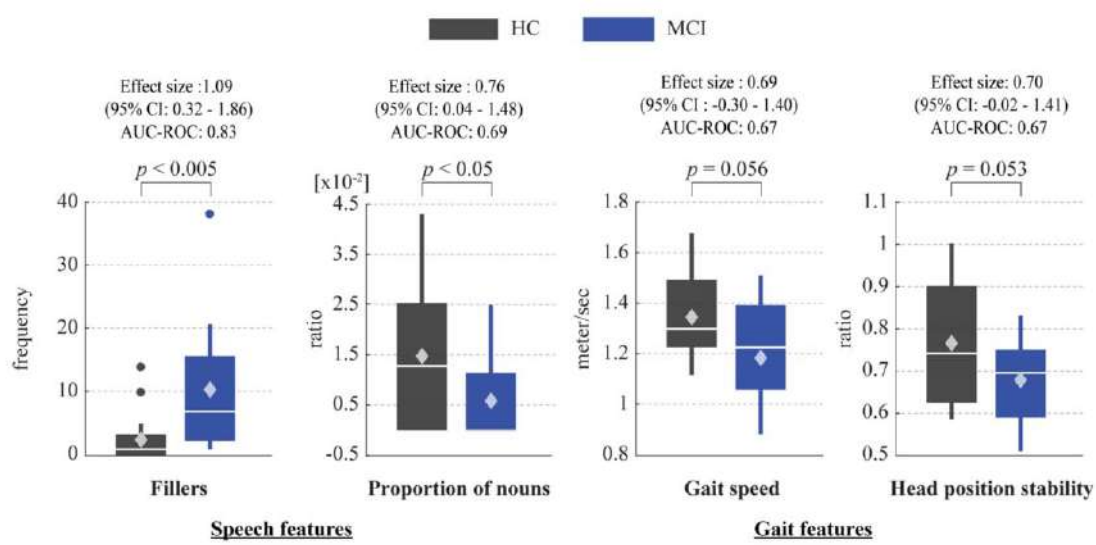

Figure 2 – *Distributions for speech and gait features which may have tendancy between HC and MCI groups. Boxes denote 25th (Q1) and 75th (Q3) percentiles. Line within box denotes 50th percentile, while whiskers denote upper and lower adjacent values that are most extreme within Q3+1.5(Q3-Q1) and Q1-1.5(Q3- Q1), respectively. Filled circles show outliers, and squares represent mean values.*

extracted the position of head top marker and calculated the variablity of the distance from the direction of travel to see the stability of the head position.

Feature anaysis & classification models

After linguistic features and gait features were extracted, we investigated if each feature differed significantly between the HC and MCI groups. We performed Student t-test for statistical examination, and considered to be significantly different when the p value was less than 0.05.

Classification was then done using support vector machine (SVM) models with a linear kernel function with a two-class classification model for testing the strength of features for differentiating patients with MCI from HCs in an automated fashion [28]. We used the algorithm for the SVM models implemented in MATLAB (MathWorks Inc., Natick, MA). Features were selected on the basis of the receiver operating characteristic (ROC) score for each feature.

We evaluated the model's accuracy by leave-one-out cross-validation, where classifers were trained using data collected from all participants expect one and then were tested on data of the one participant left out of the training data set. After obtaining loss estimate using cross-validation, accuracy, sensitivity, specificity and F-measure were calaulated for the model.

Results

We investigated if these features differed significantly between the HC and MCI groups for each task. Through the analysis, two features in speech, fillers and proportion of nouns showed siginificant difference between HC and MCI groups ($p < 0.005$ and $p < 0.05$, respectively; Figure 2). We calculated the effect size (Cohen's d) of each feature as discriminative power [29]. For Cohen's d, the 0.8 effect size is thought to be large, while the 0.5 effect is medium, and the 0.2 effect size is small [29]. We found large and medium effect size with fillers (effect size of 1.09, 95% CI: 0.32-1.86; Figure 2) and medium effect size with proportion of noun (effect size of 0.76, 95% CI: 0.04-1.48; Figure 2). For the gait features, gait speed and head postition stability were higher with HC than MCI, although this differences were not statistically significant (p=0.056 and p=0.053, respectively; Figure 2). These changes in the speech and gait features consistent with the results of previous studies that investigated the differnces in these measures with HC and dementia [10,13,22].

Next, we evaluated classification models for each speech and gait task between HC and MCI groups. As a result, for the speech features, three features were selected to be used for the classification model, which achieved 76.5% accuracy (sensitivity: 73.3%, specificity: 78.9%, F-measure: 0.733). As for gait features, three features were also selected for the classification model, which achieved 76.5% accuracy (sensitivity: 88.9%, specificity: 72.0%, F-measure: 0.667).

Finally, we analyzed the classification model by combining speech and gait features. We combined speech and gait features that were selected in each classification model. The accuracy was 82.4% (sensitivity: 76.5%, specificity: 88.2%, F-measure: 0.813) which improved by 5.9% from that of the classification models using the features of individual tasks.

Table 2 – Classification model performance for HC vs. MCI. Performance is measured after leave-one-out cross-validation (Acc: accuracy, Spe: specificity, Sen: sensitivity).

Features	Acc (%)	Spe (%)	Sen (%)	F-measure
MMSE (baseline)	76.5	72.0	88.9	0.667
Speech	76.5	78.9	73.3	0.733
Gait	76.5	72.0	88.9	0.667
Speech & Gait	82.4	88.2	76.5	0.813

Discussion

In contrast to previous studies focusing on detecting MCI and AD from a single modality of behavioral data, we aimed to argue the effectiveness of multimodal behavioral analysis. To this end, we collected and investigated speech data during the image description task and gait data during the 5-meter gait test with normal speed from cognitively healthy controls and MCIs.

We first investigated the significant differences of each feature and found significance only in speech features with a medium to large effect size. We did not find differences in gait features when comparing people with MCI to controls. Gait disturbance in MCI is still controversial [30], but a reason for the absence of significant differences can be explained by the following: gait patterns differ between MCI subtypes, and then the use of a heterogeneous MCI group, including people with single-domain and multi-domain MCI, increases the intra-group variability of gait features in MCI groups [31,32]. In our experiment, such a heterogeneous MCI group in addition to the small number of participants might be a possible reason. Therefore, we could not find features that differed significantly between the MCI and controls with a larger effect size in both sets of behavioral data.

We then built a classification model by combining these features. When we built models by using speech and gait data separately, the models each showed the same accuracy of 76.5%, which was the same accuracy of the baseline model by using MMSE scores. In comparison with these models, we showed that the model using multimodal behavioral data could improve detection by up to 5.9%, achieving 82.4% accuracy. The results indicate that exploiting the combination of multimodal behavioral data could improve the detection accuracy of MCI. Though no gait features differed significantly between the MCI and controls, these gait features could contribute to improving detection performance by combining speech features. These results might be made possible by exploiting the combination of multimodal behavioral features capturing different functional subtle changes resulting from MCI. If this hypothesis is true, our approach focusing on the multimodal behavioral analysis might be important especially (i) in targeting at earlier stages such as MCI or preclinical AD stages and (ii) in using data collected in non-controlled environments such as free living situations with a lot of noise.

One of the limitation in this study is the relatively small number of participants.. For future work, we will need to confirm our results on a larger number of participants. Another limitation is the limited number of task trials. The speech and gait data we analyzed were collected from a single trial from a single task. We need to conduct further research with data from multiple trials to verify our results.

To the best of our knowledge, this is the first empirical study to demonstrate that multimodal behavioral analysis on speech and gait data could improve detection accuracy for patients with MCI and might be useful for early detection of AD. We hope the results of our study will help promote future efforts towards timely diagnosis at an early stage such as MCI.

Abstract

Computer-assisted text coding can facilitate the analysis of large text collections. To evaluate the functionality of providing an analyst with a ranked list of suggestions for suitable text codes, we used a data set of discussion posts, which had been manually coded for reasons given for taking a stance on the topic of vaccination. We trained a logistic regression classifier to rank these reasons according to the probability that they would be present in the post. The approach was evaluated for its ability to include the expected reasons among the n top-ranked reasons, using an n between 1 and 6. The logistic regression-based ranking was more effective than the baseline, which ranked reasons according to their frequency in the training data. Providing such a list of possible codes, ranked by logistic regression, could therefore be a useful feature in a tool for text coding.

Vaccination Refusal, Text Mining, Supervised Machine Learning

Introduction

Vaccination hesitancy has led to outbreaks of vaccine-preventable diseases in several parts of the world [1]. To study reasons that are given for vaccination refusal and vaccination hesitancy in different types of user-generated text resources, e.g., Internet discussion forums, might be one method for increasing our knowledge about this phenomenon.

There are previous studies in which these types of texts have been manually analysed for reasons for vaccination hesitancy [2, 3]. There are also studies which have applied topic modelling for automatically extracting vaccination-related information from text collections too large for a fully manual analysis [4, 5]. Previous research has shown topic modelling to be an efficient text-mining method for selecting and topically sorting texts, but a manual coding of the selected texts is also recommended for a deeper understanding of their content [6].

We have, in a previous study, performed such a manual coding of texts selected through topic modelling. We had applied topic modelling on Internet discussions of the subject of vaccination, and the topic modelling algorithm automatically extracted six topics present in the collection. We then manually coded 50 texts associated with each one of these topics, through identifying the reasons that the authors had given for taking a stance *for* or *against* vaccination. We detected 242 different unique reasons in total, some only occurring once and some reoccurring [7]. Although the text selection and sorting that was provided by the topic modelling facilitated the coding, it was still a demanding task. It was particularly difficult to determine whether a reason identified in the text was a new one, not yet included in the analysis, or whether this reason had occurred in any of the previously analysed texts.

The coding procedure might, therefore, be simplified if the user is assisted in the task of locating suitable text codes among the codes previously identified. That is, when an analyst selects a text for a manual coding of reasons, a system could automatically suggest which previously identified reasons that might be found in the text that is being coded. The system could, for instance, rank previously identified reasons according to how likely it is that they are present in the text. Such a ranked list could support the analyst in the task of determining whether a reason identified in the text that is being coded has occurred in any of the previously analysed texts.

The aim of the study described in this paper is to design and evaluate a method for providing such a ranked list of previously identified reasons.

Previous Studies on Reason Classification and Identification

Among the large body of recent research on stance detection and argumentation mining, the ones most relevant for the present study investigate a task that is referred to as argument identification or recognition [8, 9] or as reason identification and classification [10]. These studies have either (i) analysed a text collection for all reasons occurring in the collection, and then not included the infrequently occurring ones in the automatic classification experiments [10], or (ii) used external resources for finding a few important reasons that are likely to occur in the text collection, and then labelled the texts with these reason categories [8, 11]. When training classifiers on four different text collections to recognise 11, 12, 15, and 18 reason categories, respectively, F-scores in the low 50s were achieved [10]. When instead training classifiers on two different text collections to recognise six and seven reason categories, respectively, micro-average F-scores between 0.7-0.8 were achieved [8]. Topic-independent classifiers were created by using training data that was constructed through measuring the similarity between the opinionated text and the text describing the reason. Finally, an F-score of 0.49 was achieved for the task of classifying texts into 16 reason categories, by using the method of clustering texts according to 16 topics derived from topic modelling based on Non-negative Matrix Factorization (NMF) [11]. The automatically

extracted topics were manually mapped to 16 pre-defined, prominent reasons. There were also previous attempts to identify prominent reasons in texts in a fully unsupervised fashion, which however have yielded low results [9].

In contrast, for the use case studied here, also the less frequently used reasons must be included. A final report of the outcome of the text coding might only include frequently occurring reasons; however, during the process in which the analyst carries out the text coding through identifying reasons in the texts, it is still unknown which reasons that occur frequently in the text collection. Both the prominent and non-prominent ones among previously identified reasons are therefore relevant to identify in the text that is in the process of analysis. Consequently, both prominent and non-prominent reasons should be provided as coding suggestions to the user, and should therefore also be included in the experiment.

Methods

The experiments consisted of training a classifier to rank the reasons that had previously been identified in the coding, according to the likelihood that they are present in the text that is currently coded.

The Previously Constructed Data Set

Our previous study consisted of applying the NMF topic modelling algorithm on posts from vaccine-related Internet discussions from the British parental website Mumsnet [7]. We chose the data based on the fact that the discussions were taking place on a general discussion forum for parents. Although views expressed in the Mumsnet forum by no means could be claimed to be representative for a population other than its actively participating users, the opinions expressed on Mumsnet are likely to be more general than, e.g., opinions expressed on an anti-vaccination website. In addition, Mumsnet informs their users of the fact that the site's discussion threads are published as publicly available posts, for which no login is required. Debaters are also asked to anonymise their postings, e.g., by using a chat nickname. Therefore, according to the data classifications provided by Eysenbach and Till [12], the content of the forum belongs to a public sphere rather than a private one.

Before applying topic modelling, we pre-processed the texts by removing stop words and performing a concept cluster-detection. That is, we concatenated into one term word collocations that occurred frequently in the text collection, and we replaced different term instantiations of the same concept,

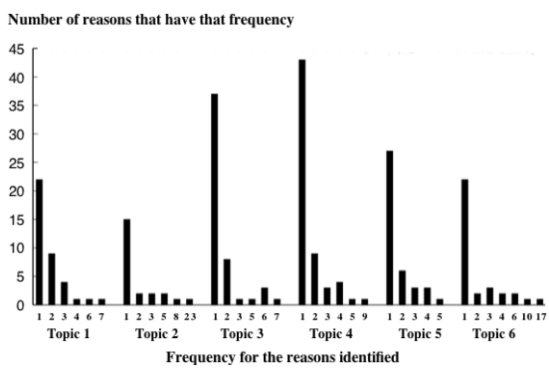

Figure 1 – The distribution of the frequency of the unique reasons identified for the six topics.

e.g., synonyms and different inflections of a word, with a common string representing this concept. The term-replacement was achieved by the use of word embedding vectors associated with the terms in the corpus. These vectors were clustered using DBSCAN clustering [13], and terms whose vectors were assigned to the same cluster were considered as belonging to the same concept. We chose DBSCAN, since it uses the properties of the data set that is to be clustered to determine how many clusters to create, and the user thereby does not have to provide an a priori specification of the number of appropriate clusters. A clustering algorithm with this property is a requirement for this clustering task, as the number of clusters of inflections and synonyms that occur in the text collection is unknown beforehand. We used a final cluster set of 402 clusters, which we obtained by a manual quality control of the automatically constructed clusters. Through the quality control, 165 terms were added to a list of terms to exclude in the cluster construction process.[1]

The topic modelling algorithm automatically extracted six topics from the text collection. The subject of Topic 1 and 4 was Measles, Mumps, and Rubella (MMR) vaccination; for Topic 1, it was in the form of reasons related to fear of and research on adverse vaccine reactions, and for Topic 4, it related to vaccine immunity duration, disease severity, and single vaccines. Topic 2 was about the vaccinology professor Paul Offit, Topic 3 was about eradication of diseases through vaccinations, and Topic 5 contained reasons related to trust/distrust in the medical profession and industry, as well as reasons related to attitudes towards vaccination among medical professionals. Finally, texts for Topic 6 discussed risk assessments for vaccination, for diseases, and for infecting others.

For each one of the topics extracted by the topic modelling algorithm, we manually coded 50 texts for reasons that were given *for* and *against* vaccination. This analysis consisted of reading the selected texts and identifying reasons mentioned in the text. A reason identified could either be (i) a reason that had not previously occurred in the text collection, or (ii) a reason previously identified in the text collection. In the first case, we wrote a new description of this reason in the coding sheet, and in the second case, we noted the exact same description as previously used in the coding sheet. We performed the analysis in Microsoft Excel, with one column for the texts and additional columns for the descriptions of the reasons identified in the texts.

Most of the coded descriptions of reasons were formulated as an argumentative statement, e.g., "*There is no proven link between MMR and autism, despite many studies*", "*That small pox vaccination has been successful does not mean that there are no problems with other vaccines*", "*Not only the MMR combination should be offered, but also single vaccinations*", and "*The risk of catching the vaccine-preventable disease or that the disease will result in complications is higher than the risk of the vaccination*". Some were, however, formulated as a meta-description of reasons, e.g., "*Expression of distrust in government/pharmaceutical industry*". The original study reported on the detailed results of the coding [7].

The number of reasons identified varied between the different topics, as did the frequency of occurrence for the reasons (Figure 1). For a few texts, no reasons were detected, and these were removed from the data set used in the experiments for the present study. This resulted in a final data set for the six topics that contained 42, 47, 50, 49, 49 and 50 texts,

[1] Examples of word pairs clustered together are: worry/concern, problem/difficulty and autism/autistic

respectively, and where each one of them had one or several associated reasons.

Classifier Training

We carried out six separate experiments for each one of the extracted topics. That is, classifiers were trained and evaluated on texts and reasons that belonged to one topic at a time. In addition, we also performed an experiment on a data set in which the six topic-divided data sets were combined into one set. This evaluation used leave-one-out cross-fold validation.

The type of machine learning classifier chosen for the experiment was a logistic regression classifier. This choice was based on the inherent data scarcity of the task evaluated. That is, the task of assisting a text coder in locating the appropriate reason category among a set of previously identified reasons required a classifier suitable for small training data sets. This inherent data scarcity is due to that, in the typical use case, most of these previously indentified reasons will have a limited number of associated texts that can be used for forming the training data set.

Moreover, the logistic regression classifier returns a probability estimate for each one of the possible classification categories in the data set. This probability estimate is not only suitable to use for ranking the previously created reasons that the coding process suggests to the user, but it also forms an output that is human interpretable. The probability estimate of a logistic regression classifier could therefore be shown to the user as an indication of the likelihood that a previously identified reason is present in the text that is currently being coded. This would not be the case for classification outputs such as the distance to the separating hyperplane of a support vector machine, which would make little sense to a human text coder.

The situation simulated in the experiments was that all texts associated with a topic would have been coded for reasons, except one of them. That is, a situation in which the left out data point in the leave-one-out scheme would not yet have been coded. We used the rest of the data, i.e., all data points except the one left out, for training a logistic regression classifier. Features were extracted from the texts, and their associated reasons were used as classification categories. Texts with several associated reasons were added multiple times to the training data set, once for each of its associated reasons, with that reason as the classification category. The describing text for each one of the coded reasons was also added to the training data, to form one additional training data point for each one of the classification categories.

Tokens that occurred at least twice in the data set were used as features, and the same stop word list as had been used for constructing the topic models was applied to remove stop words. Due to the scarcity of data, no n-grams were used. The probability estimate for each classification category that is returned by the logistic regression classifier was used for producing a ranked list of reasons, which thus formed the output of the classification. That is, the larger the probability that a text would be classified as containing a certain reason, the higher ranking did this reason achieve in the ranked list produced for this text.

Apart from the standard method of using tokens as features, we also performed an experiment with the same term-cluster replacement as used for the topic modelling. That is, different terms that belong to the same concept were replaced with a unique string representing this concept. This concept-string was then treated as a normal token by the feature extraction procedure.

The logistic regression classifier available in scikit-learn was used with default parameters [14], as we considered the data available too small for parameter tuning. However, we ran all experiments with the default inverse L2 regularisation strength of 1 as well as with a strength of 10. We used the Gensim library [15] for accessing embedding vectors and used an out-of-the-box word2vec model,[2] trained on Google news.

Evaluation

Results for the logistic regression classifier with standard features, as well as for the same classifier with cluster features, were recorded for both L2 settings. We applied leave-one-out cross-fold validation on all evaluations.

The situation that the analyst needs to find a reason among previously identified reasons only arises when a reason contained in the text already has been identified in at least one of the previously analysed texts, i.e., not when a text is going to be assigned to a *new* reason. For reasons that have exactly one text association in the data set, the only situation that arises is this one where a new reason is created. A ranking of existing reasons thereby does not make any sense for this situation. Therefore, this evaluation of the reason ranking did not include these text-reason associations as left out data points. The associations were however included in the training data, and thereby as possible classification categories. This is in accordance with the authentic situation, in which it would be unknown to the classifier that the reasons that only occur once in the data are not to be associated with the held-out data point. When performing the classification for the left out data point, these reasons are therefore just as valid as any of the other reasons to include in the ranking. The inclusion of these data points makes the evaluation more realistic, as the task would have been simplified if these reasons had been removed altogether from the experiment.

The ranking was evaluated on the criterion of the proportion of cross-validation folds for which the expected reasons were among the *n* top-ranked reasons. An *n* ranging from 1 to 6 was used, as up to around six reasons would be a reasonable number of coding suggestions to scan through when coding a text.[3]

Baseline and Ceiling

The aim of the study was to find out whether the use of machine learning would be an appropriate approach for solving the task of providing the user with coding suggestions. We therefore focused the study on evaluating the performance of the machine learning classifier we deemed most suitable for this task, rather than on comparing different machine learning algorithms. We compared this classifier, i.e., a logistic regression classifier, to a baseline strategy that did not employ machine learning. This baseline strategy instead ranked the reasons according to their frequency, i.e., according to the number of texts they were assigned to in the training data.

Note that the baseline strategy ranked the texts according to the reason frequency in the training data set, not the entire data set. This means that the reason frequencies that the held-out data point contributed to were not a part of the frequency count, as these would not be known in a realistic setting. This, in turn, results in that the baseline rankings sometimes differ depending on which data point is used as held-out data. It is

[2] code.google.com/archive/p/word2vec/ (March 27 2019)

[3] The experiments can be replicated by running the Python script *run_classifier.py*, found at https://github.com/mariask2/topics2themes (March 27 2019).

therefore possible for the baseline to, for each evaluation fold, fail to produce a correct ranking.

Since the same text often is associated with several reasons, it is not possible to achieve a score of 100 percent correct inclusion of reasons when the evaluation criterion only takes the most top-ranked elements into account. That is, not all *a* reasons that are associated with a held-out text can be included among the *n* top-ranked elements for the cases when $a > n$. For each of the six topics and each of the top *n* rankings for which results were evaluated, we therefore calculated an upper ceiling. If *n=1*, and there is only one associated reason (*a*) that belongs to the text (*a=1*), an optimal ranking will give that reason the highest-ranking position and contribute to one correct classification. However, if there, e.g., are three reasons associated with a text (*a=3*), two of these reasons can *not* be ranked highest, and an optimal ranking of reasons for that text will therefore contribute with one correct classification and two incorrect ones, or generally: for each text, if $a > n$, the number of incorrect classifications of an optimal ranking are equal to $a - n$.

Results

Table 1 below shows results for each one of the six topics as well as for the combined data set. The results show the proportion of times that the expected reason was included among the *n* top-ranked reasons (where *n* ranges from 1 to 6). Four numbers are presented, which includes the standard and cluster features for logistic regression (for an inverse L2 of 10) and the frequency-based baseline ranking and ceiling results, for each one of the points of measure. The boldfaced font indicates the best result among the three ranking methods.

Both of the logistic regression-based methods performed better than the baseline method, except for three points of measure (shown by underscore in Table 1). For one of these points of measure, the lower-performing of the two logistic regression-based methods performed equally to the baseline method, and for the other two points of measure, the lower-performing of the two logistic regression-based methods achieved a result that was two percentage points lower than the result achieved by the baseline. Despite these few exceptions, the logistic regression-based methods clearly outperformed the baseline method with general and large performance differences.

The difference was less evident between standard logistic regression and logistic regression with concept clusters. Which of the two methods performed best varied between different topics and between different values of *n*. Also the regularisation strength had a very limited effect on the overall results. For half of the topics, the results decreased a few percentage points with a stronger regularisation, while it led to a minor increase in results for the other half of the topics.

Discussion

There is a large variation among the six topics in the data set. That is, a variation (i) in terms of the number of identified reasons (from 23 to 61), (ii) in the frequency distribution of these reasons (see Figure 1), (iii) to what extent several reasons were associated with the same text (as indicated by the ceiling calculations), and (iv) in terms of what classification results were achieved. That the logistic regression methods generally performed better than the frequency-based ranking for this diverse data set indicates some level of generalisability of the results, despite the limitation that the experiment was performed on one single data set. Although the actual efficiency of the ranking might differ between different text collections and different manual coding strategies, the results achieved encourage us to implement text coding support by using logistic regression-based ranking of previously identified reasons.

In contrast, since the use of concept-cluster features does not yield any obvious advantage, there is no point in carrying out the more complex feature extraction process that the use of these features entail.

It should be noted that the situation evaluated here is when all but one of the texts already have been assigned reasons, and that other results might have been achieved if an earlier point in the analysis process had been simulated. To perform such a simulation is a task to include in future work. It might also be interesting to, similar to previous work [8], evaluate the performance of a ranking that relies entirely on the analyst's description of the identified reason; however, such an approach might be less suitable for detecting reasons that are formulated in the form of meta-descriptions.

We have previously constructed an interactive visualisation tool whose graphical user interface displays the output of topic modelling applied to a text collection [16]. The tool displays the texts selected by the topic modelling algorithm, and includes methods for searching and sorting among these texts. The tool also provides the functionality of attaching user-defined *themes* to the texts. That is, for the application described here, these themes would correspond to reasons identified when analysing texts. The interactive tool does, however, not yet include any functionality for suggesting which themes to associate to a text that is being analysed. Instead, the tool shows themes in a list previously identified by the user, which is simply sorted according to the creation time of the themes. The next step in developing the tool will therefore be to add the text analysis support investigated here.

n=6	**57**	**57**	36/100	**88**	**88**	80/100	**82**	76	61/99	**79**	**79**	44/100	**74**	68	26/100	**83**	82	72/100	**68**	66	20/100

That is, to use a logistic regression classifier to rank the previously identified themes in the list according to the likelihood that they are present in the text that is currently being analysed. Such a classifier could be re-trained, whenever the user creates a new text-theme association, and thereby be able to continuously adapt and improve the theme ranking when the user extends and refines the manual analysis.

We hope that such a tool, with the extended coding support investigated here, could be useful for assisting coding of recurring content in large text collections. For instance, for coding discussion forums for recurring arguments used in vaccination debates. The semi-automatic approach of such a tool, i.e., to extract texts typical to frequently occurring topics and then assist the user in the task of manually coding the extracted texts, does not guarantee that all important subjects discussed in the text collection are detected. However, the approach offers the possibility of accessing important content in text collections that are too large to make a fully manual coding feasible. The output of the semi-automatic coding could, for instance, be used for forming hypotheses on reasons why different types of health decisions are made, e.g., health decisions related to vaccination.

Conclusions

We have investigated the efficiency of ranking previously identified reasons according to the likelihood that they are present in a text that is being manually coded. The performance of a logistic regression classifier that ranked reasons according to the probability that they would be present in the text that is being coded was compared to a ranking based on the frequency of the reasons in the data set. When evaluating the approaches for their ability to include the expected reason among *n* top-ranked reasons, using an *n* between 1 and 6, we could conclude that the logistic regression-based ranking outperformed the frequency-based one. These results therefore encourage us to construct a system that provides the human text coder with a ranked list of suggestions for possible reasons that might be present in a text, and to implement this ranking by the means of a logistic regression-based classifier.

Acknowledgements

We would like to thank the Swedish Research Council (Vetenskapsrådet) that funded this study through the project "Navigating in streams of opinions: Extracting and visualising arguments in opinionated texts" (No. 2016-06681). We are also very grateful for the useful input provided by the reviewers.

Abstract

To provide the best treatment, a physician needs information about both the patient and the medicines matching the patient status and improving it. In this article, we present three methods for structuring the sections of medical prospectuses using neural networks. To structure the information from a medical prospectus we use 3 web sources with structured data from sections (with names sections from prospectuses and with uniformized names of sections) to train as input for neural networks. The tests were conducted on Romanian prospectuses. After running the three algorithms, the prospectuses were compared in terms of accuracy and execution time for each source. It was concluded that the accuracy is higher in convolutional networks and in the case of uniform name sections. The output data is used in applications with decision support for the treatment, matching best treatment with the patient's status.

Keywords:

Prescriptions, neural networks (computer), drug information services

Introduction

Prescribing medicines for certain illnesses in as correct manner as possible is a challenge for all doctors and healthcare providers worldwide. The number of illnesses and medicines is higher and higher, and new treatments for new diseases are rare. The lack of sufficient information on treatments and the lack of uniformity of existing data on medication, as well as the lack of tools to compare and verify interactions between patient medication, creates a vulnerable situation. Prior to providing a specific treatment, a physician needs data such as: medical history, diagnosis, and complete information about the appropriate medication for the diagnosis.

The drug prospectus contain very important information for the doctor. For example, in a Nurofen 200 mg prospect, there are several sections, such as "What is Nurofen 200 mg and What is used for," "Warnings and precautions," "What should you avoid when you are taking this medicine?", "Nurofen 200 mg with other medicines", "Pregnancy, breast-feeding and fertility", "How to take Nurofen 200 mg", "Possible side effects", "Containing 200 mg nurofen". These data are useful for the physician to not prescribe wrong medication that may interact with another drug / disease / allergy / condition of the patient. For example, in the prospectus of Nurofen 200 mg, it is emphasized that a patient with gastro-duodenal ulcer cannot take this medicine. The same data is found in any medical prospect, but each manufacturer names the sections differently or locates them in different order. Any doctor has access to online prospectuses, but they need extended knowledge about the medication and for this knowledge they have to read the full prospectus for the right information each time they consult the information about the drug, especially for new ones. This means a lot of invested time for this process.

Information and medical data are both structured and unstructured. Most structured information is available in English. Various databases with structured information have been created and are easily included in medical applications or used by physicians to provide effective treatment for patients. Many researchers have begun to develop algorithms or to use new technologies to create the largest possible structured information. Structured information is easier to read and requires less time to be found. The researchers also seek to extract important data from various documents to use them in specific areas or to build for physicians structured databases with the extracted information. .

In this age of technology, we are confronted with a great deal of medical information coming from different sources. For physicians to have access to this ocean of information, structuring and compaction of data is needed. Important data can come from our daily activities, from the internet or even from clinical staff. Figure 1 shows the diversity of sources from which important clinical information can be obtained to be used later to treat and improve the medical condition of a patient. The goal is to integrate and structure information from these sources as to make it more easily available to medical units [1].

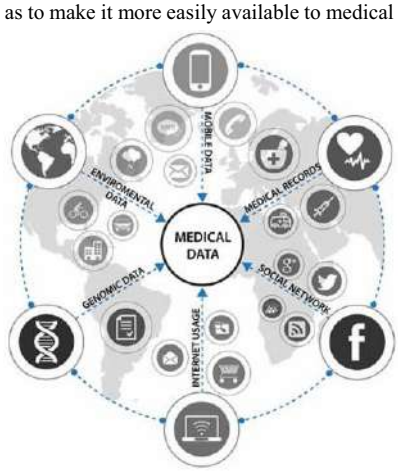

Figure 1– Sources of Medical Data [1]

A lot of work has been done on natural language processing (NLP) in English. This also applies to the processing of medical texts where the most robust data structuring and processing is for English texts. Deléger, Grouin, and Zweigenbaum [2] describe the implementation of a system for extracting

medicines and adjacent information from French texts based on an originally algorithm used for English medical text. The system is based on special dictionaries of medical terms and extraction rules. The texts resulted from 17,412 French electronic health records (EHRs) from the Cardiology Unit of the French University Hospital registered between 2004 and 2006. This dataset was divided into two data bodies: a corpus of development of 17,362 documents used to implement the system and a test body of 50 documents. The test body contains 253 drugs plus associated information items. The extraction rules were designed using English rules and examples of the development corpus. The dosing, form, frequency, duration and reason for which the drug was administered were extracted from the documents. The evaluation of the algorithm on the 50 documents obtained an F-measure score of 86.7%.

In Xu and Wang [3], a simple and accurate learning algorithm was developed to extract drug-disease pairs from 20 million biomedical summaries available on MEDLINE. The authors' process for extracting these data consists of the following steps:

1. Obtaining and analyzing the MEDLINE corpus
2. Creating lexicons for diseases and medicines
3. Correlation of MEDLINE sentences with disease and drug entities
4. Find patterns of treatments
5. Extract extra pairs from MEDLINE using selected patterns
6. Perform a semantic analysis of extracted drug-disease pairs.

The authors have used around 100 million sentences extracted from MEDLINE abstracts published between 1965 and 2010. A total of 34,305 pairs of single-disease treatments were extracted, most of which were not included in the existing structured databases. The algorithm of the authors reached a precision of 0.904 in extracting all pairs.

Extracting information about medicinal products from clinical texts is very important for EHR research. Jiang *et al.* [4] present the implementation of Java MedEX, an existing Unstructured Information Management Architecture (UIMA) data extraction system. In addition to showing earlier developments, the authors included new coding modules in the MedEx-UIMA system that map the data of drugs extracted with the RxNorm concepts. The MedEx-UIMA system consists of two main components: the clinical text extraction module and a standardization module encoding RxNorm (RxNorm concept unique identifiers) and normalizes TIMEX3 [5] frequency information. The information extraction module is a Java implementation of an older MedEx version then implemented in Python. The authors processed 826 documents with both systems (MedEx-UIMA and MedEx-Python) reaching similar results with both systems. Using the 300 annotated drug entries manually, the MedEx-UIMA system obtained the F-measure score for accuracy of 98.5%.

Casillas *et al.* [6] present a model for extracting allergic drug reactions from medical electronic records. The purpose of the paper is to extract this data from medical texts into Spanish. The authors developed two methods: a rule-based and a machine-based method. Both methods include semantic knowledge derived from FreeLing-Med, a software explicitly developed for medical text analysis. The corpus of text used in this research is composed of EHR documents written by doctors from Galdakao-Usansolo Hospital. First, a simple approach has been attempted to co-ordinate the terms of the EHR with SNOMED CT terms for allergy detection. This approach is effective but has not proven appropriate for medical texts written by physicians in which the type of allergy writing is different from the standard. Follow a rule-based algorithm has better results (70% accuracy) than the first simple approach (30% accuracy). The best approach with great results was the machine learning-Inferred Classifier method that gave a precision score of 88%.

Despotou *et al.* [7] uses NLP techniques to interpret UK NICE BNF drug recommendations that are provided as free text. The NLP component, MetaMap, identifies and interprets the semantic meaning of concepts in medical texts. NICE BNF provides structured definitions for drug-related issues but uses raw text for instructions on indications for drugs such as "500 mg three times a day" or "300-900 mg every 4-6 hours; maximum 4g per day." The authors analyze the dosing instructions and using NLP techniques identify types of semantic expressions and investigate how they can be generalized and used in specific rules to be applied in medical IT systems that contribute to e-prescribing.

Over the last few years, as presented in this section, a lot of applications were developed to support structuring and embedding information in medical applications. Databases have been created with a wealth of drug-related information, but most research has been made in and for English-speaking countries.

In this study, we use neural networks and the associated algorithms to structure Romanian medical prospectuses in order to extract the information from each section for further use in medical applications. We use the algorithms to train the neural networks since there are no other alternatives that we can use for Romanian text to extract certain sections from the prospectuses. This kind of processing works in cases where translate coding or databases is missing. In the following we present the methods, the results, and conclusions of the study.

Methods

Deep learning methods or neural networks have recently influenced many areas, including the processing of natural language. These methods are constantly improved with algorithms and increased performance compared to what exists in each field. A number of tools have been developed to enable the implementation of deep learning such as: Caffe, DeepLeaning4J, Eblearn, Keras, Neon, Scikit-learn, TensorFlow, Theano, etc. These tools attempt to optimize different aspects in learning or developing deep learning algorithms. These deep learning software tools have begun to receive a great deal of attention from the research community and are being increasingly developed to allow the formation of deep networks with thousands of parameters. Developers are trying to continually improve these tools to attract as many users as possible and to promote research [8].

In the current study we use medical prospectuses in Romanian language extracted from three online sources and structured on sections by extraction algorithms that we propose for this action [9].

In this study we use a method of training the neuronal networks with the names of selected already structured sections through various neural network algorithms and test them by providing other texts to which the trained network predicts the correct section name. The purpose of categorizing the text is to categorize the texts into categories that are easier to access. Each text can be categorized into one or more categories. We use neural networks to learn the classifiers in the examples and automatically categorize other documents in the same categories. In order to obtain this structure, we use three neural network models: Vector Support Machine Classifier from Scikit-learn library, Naïve Bayes Classifier from Scikit-learn

library, and 1D Sequence-Model Convolution Networks with sequential model from the Keras library. Figure 2 presents the workflow obtaining this structure.

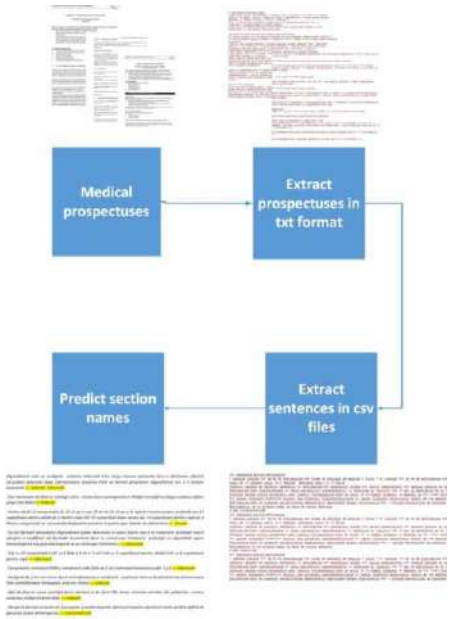

Figure 2 – Workflow for Structuring Prospectuses

Support Vector Machine (SVM) is a supervised classification algorithm that is extensively and successfully used for text classification task. An SVM represents the examples as points mapped in space so that the examples of the separated categories are divided by a clear gap that is as broad as possible [10].

Naive Bayesian is a simple and efficient classifier to implement NLP because it supposes that all the words of the documents are independent one of each other. The Naïve Bayes Classifier is the simplest probabilistic classifier used to classify text documents. The Naïve Bayes method is a module classifier based on probability and the probability of known conditionality. The basic idea is to use common words and category probabilities to estimate the class of a particular document [11].

Convolutional Neural Network (CNN) is a class of artificial neural networks that use convolutive layers to filter inputs for useful information. Convolution involves combining input data (a feature map) with a convolution kernel (filter) to form a map of the transformed features. Convolutional filters are modified based on the learned parameters to extract the most useful information. Text convolution is used for convolutional 1D networks [12].

To learn these three types of neural network models we use the structured data from the three medical prospecting websites: HelpNet, Pharmacists' Page and CSID. Table 1 presents the figures found in each data file.

After creating the files for each source as well as for mixed sources, we ran the three previously specified algorithms one by one to train the network section names for each text and then predict the section names for other text files. For training and testing, we use combinations between the above-mentioned sources. In order to run the algorithms, we use a computer with Intel Core i5-6400 processor of 2.70 GHz and 8 GB RAM and the processing time was quite good. Each run calculates the accuracy of the results and the running time. The outcomes of the process are presented in the Results section.

Table 1 – Number of Data Used in Neural Network Structuring

Name of the source	Number of prospectuses	Number of sections
CSID	3814	44834
Help Net	2820	18336
Pharmacists' Page	1513	22851

For all the algorithms, the first step consists of creating the learning and testing files containing the information of interest, specifically the label and the text associated with that tag. The learning files contain 70% of this information, and the test files 30%. For each solution we use specific items, as follows. The SVM (Support Vector Machine) algorithm uses the LinearSVC (Linear Support Vector Classification) classifier to train the network, and the prediction function is called on the test file. CNN uses the Sequential model in the Keras library to train the network, using the 'Dense layer' and calling the 'relu' activation function. We use 3 iterations (epochs) per learning file. Since we use textual classification, we only need a layer of convolution, so we use 1D Convolution. In the Naive Bayes algorithm, the text is transformed firstly as an array of elements, followed by a normalized expression of frequent terms and calling the NB multinomial classifier for the data previously obtained.

Each classifier is evaluated by calculating the accuracy and F1 score.

One of the main issues we had to deal with was the unevenness of the section names for the same type of section, different names for each drug may appear. For example, in the warning section, the following names may be found: caution, special warnings, warnings, warnings and precautions, precautions for use, warnings and special precautions, precautions, warning. To overcome this problem, we began aligning these sections creating files with similar section names and reference names. In [13] we propose a method of refining prospectuses sections to make them uniform.

To refine section names, we identified the most important section names: 'Indications', 'Contraindications', 'Dosage', 'Pregnancy and Breastfeeding', 'Active Substance', 'Composition', and any other section in the 'Information' section. We restored prospectus sources using just these section names and we ran the three algorithms again for all sources and their combinations. The outcomes of the process will be presented in the Results section.

Following the SVM algorithm running on data from the three sources, accuracy scores range from 1.99% in different training and testing sources and up to 56.78% on the same data source both for training and for testing. Execution time depends on the size of the text and the number of section names in the training source so that in the sources where the data from the CSID site is used, the running time is longer, the section names being varied and the prospectuses being more.

When running the Naive Bayes algorithm on the same data, the running time has dropped a lot, and accuracy is higher for all tests. For the algorithm, when referring to data with many different section names (CSID), we train the network only for fewer sections, choosing the most common ones. In this case, the results were more accurate, between 45.41% and 68.44%.

When running the convolutional network, the accuracy increased even more, but running time increased significantly as compared with the previous methods. The best accuracy was

recorded for training and test data for the CSID source (77.47%). With this method we had to lower more the number of training sections for an optimal algorithm operation. When we use CSID source to train the neural network we select only the most common 350 names from sections since the array that is created in the algorithm is very large and the algorithm cannot be run on a usual computer.

The percentage of accuracy is lower when providing new sources of information different from those with which the network was trained. Section names are very different from one source to another. Thus, in the CSIDs there are approximately 11,300 unique names for different sections, in the Pharmacists page there are around 450 unique names of sections, and in Help Net there are around 350 unique names of sections.

After the sections were reduced and uniformized, the accuracy increased greatly after running the SVM algorithm. The algorithm run times have also decreased, obtaining an accuracy of 38.26% for two different sources and an accuracy of up to 93.08% for training and testing data from the same source.

After running the Naive Bayes algorithm for data sources with uniform sections the accuracy increased significantly, and the running time of the algorithm decreased. The accuracy in this case ranges between 71.86% and 85.05%, both of which are this time for sections of the same data source.

Following the run of the convolution algorithm, the accuracy is highest, but the times stay high. Accuracy ranges between 77.62% and 91.31%. As can be seen, the accuracy of all source combinations is over 77%, which means that the correct prediction rate of the sections is the best.

As can be seen in the results presented with data uniformity, the accuracy result increased. Training the algorithms with the most complex and complete databases, the accuracy will increase. For what we need in medical applications, namely as accurate as possible, the best algorithm tested in this paper for accuracy in both non-uniform and uniform sections is the convoluted neural network. Due to the fact that it is working with multiple layers to drive information, the accuracy is the highest.

Discussion

The first algorithm that was run was the Support Vector Machine on the three sources and their combinations. The first run was on data with non-homogeneous sections, and the second run was on data with homogeneous sections. Figure 3 shows a comparative diagram of the two results in terms of accuracy.

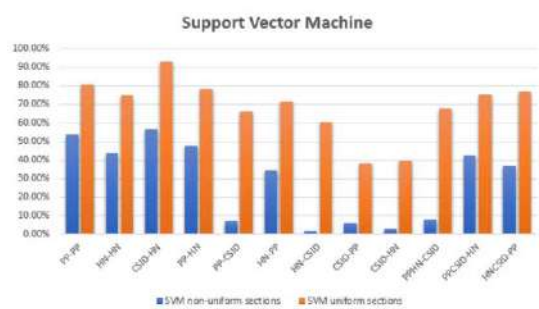

Figure 3 – SVM Accuracy

The first comparison is between the type of source used for the SVM algorithm, non-uniform sources in the blue version on the graphs, and sources with uniformized sections in the orange version on the graphs. As can be seen, the accuracy in the second case has increased significantly, especially if different data sources were used for training and testing and the running time decreased due to the number of low sections. For this algorithm, a relatively higher accuracy was obtained only for uniform sections.

The average accuracy for SVM on non-uniform sections is 28.52%, and for SVM on uniform sections the average increased to 68.58%, with an increase of 40.06%.

The median of accuracy for SVM on non-uniform sections is 35.65%, and for SVM on median uniform sections is 73.20%.

The second comparison was made between data used, with a different number of sections for the Naive Bayes algorithm. Figure 4 shows a comparative diagram of the two results in terms of accuracy.

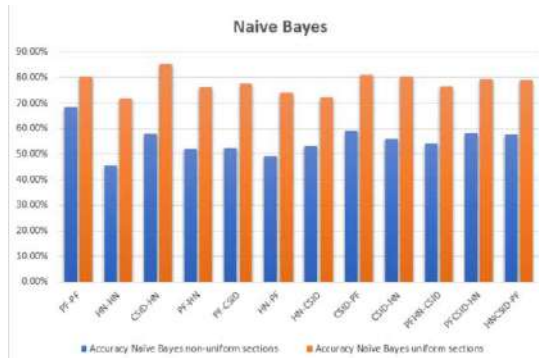

Figure 4 – Naïve Bayes Accuracy

In this case, the accuracy between the two types of sources used differed less. And in this case, the accuracy was bigger and more constant, as can be seen in the graph for the uniform sections. The average accuracy for Naive Bayes on non-uniform sections is 55.28%, and for Naive Bayes average uniform sections increased to 77.76%, with an increase of 22.48%.

The median of accuracy for Naive Bayes on non-uniform sections is 54.93%, and for Naive Bayes on uniform sections is 78.17%.

The last comparison between the accuracy of the different three algorithms on data sources was done for the convolutional network algorithm. Figure 5 presents a comparative diagram of the two results in terms of accuracy.

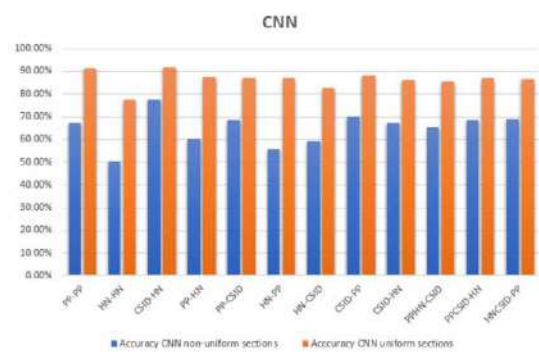

Figure 5 – CNN Accuracy

In this case, the accuracy was also good for non-uniform sections, but increased over 85% in most cases to uniform sections. The average of CNN accuracy for non-uniform

sections is 64.87%, and for CNN on uniform sections the average grew to 86.55%, with an increase of 21.68%.

The median of accuracy for CNN on non-uniform sections is 67.10%, and for CNN on uniform sections is 86.97%.

As can be seen, the best accuracy was in the case of convolutional neural networks and on uniformized sections. In Figure 6, we can see comparatively the accuracy of the algorithms on the non-uniform databases, and in Figure 7 we can see comparatively the accuracy of the algorithms on the uniform databases.

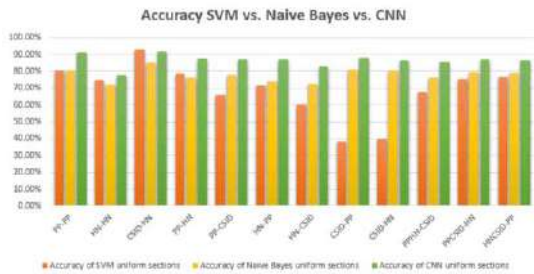

Figure 6 – Comparative Accuracy on Non-Uniform Sections

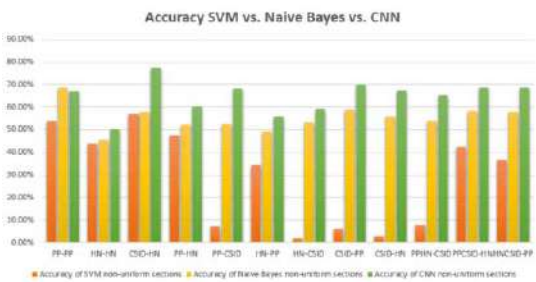

Figure 7 – Comparative Accuracy on Uniform Sections

Conclusions

Structuring medical information is very important to help doctors find the best treatments for patients and to create systems with alerts when drugs can interact with certain diseases / allergies or other medicines that the patient already has. In this study, we have chosen to structure the medical prospectuses in Romanian because in this language there are no databases with full structured information about the drugs. The extracted information can then be used to create databases that are added to the prescription modules. In the future, we will test algorithms on medical prospectuses from other languages in order to create a general model for structuring medical prospectuses. Future work also focuses on more solutions to be multilingual and adapt easy to situations in which there are no structured databases or translated codes with drug information.

The results are encouraging and the solution is easy to implement as a module in healthcare information systems.

Modeling Multi-View Dependence in Bayesian Networks for Alzheimer's Disease Detection

Parvathy Sudhir Pillai[a], Tze-Yun Leong[a], the Alzheimer's Disease Neuroimaging Initiative

[a] School of Computing, National University of Singapore, Singapore

Abstract

Early detection of Alzheimer's disease is important for deploying interventions to prevent or slow disease progression. We propose a multi-view dependence modeling framework that integrates multiple data sources to distinguish patients at different stages of the disease. We design interpretable models that can handle heterogeneous data types including neuro-images, bio- and clinical markers, and historical and genotypical characteristics of the subjects. We learn the dependence structure from data with guidance from domain knowledge in Bayesian Networks, visualizing and quantifying the conditional probabilistic dependence among the variables. Our results indicate that the hybrid dependence models also improve prediction performance.

Keywords:

Alzheimer Disease, Bayesian networks, Classification

Introduction

Alzheimer's Disease (AD) is a neurodegenerative disorder that leads to cognitive decline of the elderly and renders them incapable of performing routine activities of daily living. The neuronal degeneration is often irreversible [1]; common clinical symptoms such as memory loss or speech impairment may only appear at a later stage. It is important to identify the relevant factors that may individually or collectively impact the cognitive condition or state to assist in accurate and early diagnosis. Such factors may be categorized based on demographics, physical examinations, clinical tests, cognitive assessments, etc. Each category presenting information about an individual froms a distinct *view* or perspective. We propose a framework for detecting AD at different stages by fusing multiple views of patient-related data and explicating the dependence among the factors or variables.

In practice, AD severity is usually assessed by psychometric tests such as Mini Mental State Examination (MMSE) and Alzheimer's Disease Assessment Scale-Cognitive (ADAS-Cog). Disease markers acquired from neuroimaging and protein studies are considered better indicators of AD in the early stages of Mild Cognitive Impairment (MCI) [1]. Genotype and non-behavioral background factors from demographics, family and medical history have been associated with cognitive decline. Linking potential diagnoses to background factors helps to identify the individuals at risk of developing AD and indicates ways to plan for its prevention and intervention.

We aim to build a disease model that accommodates the *correlational*, *causal* and *complementary* semantics of dependence and uncertainty from heterogeneous, multi-view data, possibly from different modalities. Clinical data is heterogeneous and variables relevant to AD coud be discrete (e.g., medical history of diabetes is binary) or continuous (e.g., individual's age). Knowledge discovery from medical data can be broadly categorized into correlation-based and causality-based. Correlation identifies how close two variables are to having a linear relationship with each other and indicates a predictive relationship. Most multi-view disease models identify correlations of bio- and clinical markers for predicting the clinical status. On the other hand, a variable A causally influences variable B if we manipulate A to different values, measure the effects on B, and observe changes in the probability distribution of B under different values of A. Incorporating the causal contributions from background factors in the model helps us understand their interactions that manifest as the individual's cognitive state. The cognitive state cannot be causally established from the background factors in a fully data-driven approach using only observational data [4]. Knowledge about disease epidemiology can help identify beneficial or risky causal factors. Complementarity separates the unique knowledge in a view, leading to better predictions through combining different views [2].

We propose a hierarchical probabilistic graphical model that incorporates two types of views: *markers* including MMSE, neuro-images that measure the cognitive state, etc., and *background* including genotypic, demographic variables that could possibly impact the cognitive state. The variables in each high-dimensional view are linear transformations of the underlying continuous, low-dimensional latent traits. The dependence between the predictor variables and the cognitive state is depicted in Bayesian Networks (BNs). We learn relevant evidence-based relations among the variables using prior knowledge of domain rules elicited from experts. We examine the key classification metrics: accuracy, precision and recall to determine the disease stage of a set of individuals from the Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset [5].

Related Work

Multiple linear/logistic regressions are the most popular correlation-based approaches used by clinicians and epidemiologists. Classifiers such as naive Bayes (NB), decision tree, back-propagation neural network (NN), and support vector machine (SVM) [6] have also been used for disease prediction from clinical data. With the recent progress in multi-view machine learning, combinations of markers distinguish AD patients from cognitively normal (CN) controls with high accuracy. Multiple kernel learning [2], canonical correlation [15] and shared subspace learning [3] are applications of multi-view learning that target the correlations between views of bio-

or clinical markers. These methods treat all views uniformly as results of the clinical state.

To identify risky/beneficial factors from background views, it is necessary to understand how changes in the variables affect the clinical state. Previous studies that explore associations between background factors and diseases are mostly hypothesis-driven; the validity of a hypothesis is tested with the available data. Structural equation models and dynamic causal networks [8] operate on causal assumptions given by domain experts about the disease. However, since the data may be from different sources, it is hard to include all the assumptions that may be valid in one source but not in another. Also, those relationships that are not included a priori are possibly missed.

Jin et al. [9] analyzed 16 multimodal features from ADNI, including age, sex, education, hippocampal volume, 2 average Positron Emission Tomography intensity measures, 7 Single Nucleotide Polymorphisms (SNP), MMSE and ADAS-Cog for cognitive score prediction in a BN. They included the notion of causality in determining the conditional probabilsitic dependence. However, feature or variable selection was done manually and solely based on domain knowledge, without considering other potentially important markers from the corresponding modalities. Hence, they do not address correlations among the variables within a modality.

Methods

A Bayesian Network (BN) is a probabilistic model that consists of two parts: a graphical model visualizing the dependencies among the variables and a probability model quantifying the dependencies. Learning the structure of a BN is done either purely from domain knowledge or the dependencies learnt from the data or a combination of both.

We learn probabilistic dependence models from multi-view clinical data using a hybrid approach i.e., score-based BN structure learning [9] guided by inputs from experts about the direction of dependencies. We adopt the prior knowledge of a causal approach in which genetic variables like SNPs and demographic variables such as age and sex are fixed before other variables and are not influenced by them. We assume that i) the markers assume certain values as manifestations of the clinical status and ii) non-behavioral background variables may influence the occurrence of AD and not vice-versa. We use a multi-level BN [10] to simulate this hypothetical data generation hierarchy: background traits ⇒ cognitive state ⇒ marker measures. We summarize the procedure to learn the dependency model, i.e., the BN of multi-view data in Figure 1.

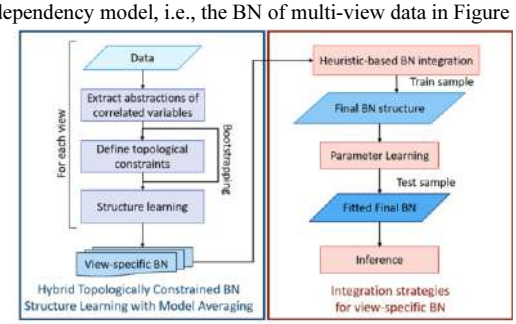

Figure 1. Modeling multi-view dependence via BN integration

We consider a supervised setting, where $\mathbf{X}^{(1)}, \ldots, \mathbf{X}^{(M_{mark})}$ represent the multi-view markers, $\mathbf{B}^{(1)} \ldots \mathbf{B}^{(M_{bg})}$, the background views and $\mathbf{Y}$ the response variable, i.e., clinical status of AD, the intermediate stage of Mild Cognitive Impairment (MCI) or normal controls (NC). $\boldsymbol{M_{mark}}$ is the number of marker views, while $\boldsymbol{M_{bg}}$ is the number of background views and $\boldsymbol{N}$ the number of subjects. We divide the variables in the dataset into mutually exclusive views based on their modality and the features they describe. The target variable, i.e., the clinical status of the subject is included in each view; it connects the background variables and the disease markers during view integration.

Extracting abstractions of correlated variables

In using multi-view patient data, we face the 'curse of dimensionality', which results in complex models that overfit and are not very "interpretable". There is also the issue of multi-collinearity among the variables within a view. We overcome these by abstracting out latent factors/traits from the variables which simultaneously explain their correlations and achieve dimensionality reduction. The latent factors are continuous-valued, follow a normal distribution with zero mean and unit covariance and, emulate a continuum: low to high, sick to healthy, etc. We use Bayesian matrix factorization (BMF) [14] to extract latent factors from continuous-valued views. We represent markers, $\mathbf{X}^{(j)}$, and background variables, $\mathbf{B}^{(k)}$ as linear transformations of uncorrelated low-dimensional latent factors, $\mathbf{Z}^{(j)}$ and $\mathbf{U}^{(k)}$ with $\boldsymbol{l}^{(j)}$ and $\boldsymbol{l}^{(k)}$ numbers of latent factors respectively, as depicted in Equation 1.

$$\boldsymbol{X}_{pq}{}^{(j)} = \sum_{r=1}^{l^{(j)}} \boldsymbol{Z}_{pr}^{(j)} \boldsymbol{V}_{rq}{}^{(j)} + \boldsymbol{\varepsilon}^{(j)} \qquad (1)$$

$$\mathbf{Z}_{\boldsymbol{p}}^{(\mathrm{j})} \sim \boldsymbol{\mathcal{N}}_{\boldsymbol{l}^{(j)}}(\mathbf{0}, \mathbf{I}_{\mathbf{l}^{(\mathrm{j})}}), \mathbf{V}_{\boldsymbol{q}}^{(j)} \sim \boldsymbol{\mathcal{N}}(\mathbf{0}, \boldsymbol{\lambda}_{\mathbf{q}}^{(\mathrm{j})^2}), \boldsymbol{\varepsilon}^{(j)} \sim \boldsymbol{\mathcal{N}}(\mathbf{0}, \boldsymbol{\sigma}_{\mathbf{q}}^{(\mathrm{j})^2})$$

where $\mathbf{V}^{(\mathrm{j})}$ is the weight matrix and $\boldsymbol{\varepsilon}^{(j)}$ is the noise. Further, we specify a Gamma prior for the inverse variances, $\boldsymbol{\sigma}_{\mathbf{q}}^{(\mathrm{j})^{-2}}$ of the noise term, $\boldsymbol{\varepsilon}^{(j)}$ i.e., $\boldsymbol{\sigma}_{\mathbf{q}}^{(\mathrm{j})^{-2}} \sim$ Gamma $(\boldsymbol{a_\sigma}, \boldsymbol{b_\sigma})$, where $\boldsymbol{a_\sigma}$, $\boldsymbol{b_\sigma}$ are hyperparameters. The impact of each factor in $\mathbf{Z}^{(j)}$ on the actual variables in $\mathbf{X}^{(j)}$ can be derived by inspecting $\mathbf{V}^{(j)}$. The higher a variable weighs, higher is the corresponding factor's ability in capturing its correlations with other variables. Specifically, the variables with higher weights in a factor are interpreted as a cluster because they are similar due to their high correlations. To make the clusters interpretable, we need to reduce the number of variables with higher weights on many factors. Thus we apply sparsity constraints on the weights to have fewer non-zero weights and seggregate the strongest signals. We apply the constraint as a prior probability to the weight matrix. However, with the multiple heterogenenous views of data, our model needs to handle outliers and unknown sparsity structures of variables. For this we apply the horseshoe prior on the weight matrix, $\mathbf{V}^{(\mathrm{j})}$, with a shrinkage parameter, $\boldsymbol{\lambda}_{\mathbf{q}}^{(\mathrm{j})} \sim$ Half- Cauchy (0,1), that is robust at handling unknown sparsity and leaves out large outliers [12].

For categorical-valued views, we use multi-dimensional Item-Response Theory (IRT) models [16] to express the observed variables as resulting from continuous latent traits. For example, the probability of a person achieving a certain score in a test is a consequence of their ability, the test's difficulty and the discrimination power of a question. It is then possible to assume that individuals with the same ability answer a question correctly with a certain probability. Cognitive capability is an interpretation of this ability with respect to MMSE. IRT relates the latent ability, $\boldsymbol{\theta_i}$, to the probability of getting the correct answer to a question through the Item Characteristic Curve (ICC). Difficulty, $\boldsymbol{\delta_j}$, is practically the point on the ICC where the probability for answering correct is 50%, whereas, discrimination, $\boldsymbol{\alpha_j}$, is the slope of the ICC. An

ICC with a steep slope imparts sudden value jumps even for a small change in ability. This in turn implies that the particular question's discrimination power is very high. Meanwhile, if the item achieves a median (50%) probability at higher values of cognitive ability, the item is difficult. Equation 2 shows the probability of choosing the right option, $\boldsymbol{j}$, for a question, $\boldsymbol{i}$.

$$\boldsymbol{P(X_{ij} = 1|\theta_i,\ \alpha_j,\ \delta_j) = \frac{exp(\alpha_j(\theta_i - \delta_j))}{1+exp(\alpha_j(\theta_i - \delta_j))}} \quad (2)$$

where $\boldsymbol{\theta_i \sim \mathcal{N}(0, 1)}$. For ordinal-valued views, where there are more than two possible values of responses, we use the Partial Credit Model (PCM). The above equations apply for both marker and background views.

Learning the structure of dependence in a view

Directed edges in a BN represent the probabilistic dependence between variables, with the child node being conditionally dependent on the parent. Therefore, learning the structure of dependence among the latent factors from a view translates to learning the edges of the BN. However, as the number of variables in a view increases, an exhaustive search in the space of possible graph structures becomes infeasible. In clinical data, there my be many variables of interest in each view of different data types. We use the Conditional Gaussian BN (CGBN) framework [9] with multinomial and Gaussian distributions to model discrete and continuous nodes respectively. The discrete nodes are parameterized by conditional probability tables, with their values depending on their discrete parents. The mean of a continuous node is deduced as a linear regression of the continuous parents on each configuration of its discrete parents. Variance, however, depends only on the discrete parents. CGBN disallows discrete nodes with continuous parents. We incorporate the following techniques in the CGBN structure learning procedure to reduce the search space.

Incorporating topological constraints

Certain constraints which represent either scientific laws, common sense, expert opinions, accumulated personal experiences, etc., help to build better structures. These are usually qualitative constraints and do not signify the strength of dependence between variables. Following the convention in Li and Leong [3], we define the domain constraints in Table 1. The values of demographic (e.g., "Age", "Sex") and genetic variables (e.g., SNPs) are fixed before other variables and are not influenced by them; these should be roots in the BN. On the contrary, the values of bio- or clinical markers are dependent on other variables and do not affect other variables; these should be leaves in the network. Older age is known to be linked to AD and hence there is a directed edge from "Age" to the clinical status. We also restrict edges from clinical status and latent markers to latent background and, latent markers to status.

Table 1. Types of topological constraints in a BN

Constraints	Description
Roots	Cannot be children of other nodes
Leaves	Cannot be parents of other nodes
Known links	Links that domain experts know exist
Forbidden links	Links that domain experts know don't exist
Ordering	Chronological or logical ordering of variables

BN structure learning with search space reduction

We achieve further search space reduction by trying to build edges only between variables that are correlated. For each node the candidate neighbors with a definitive correlation, we create the dependency structure of a view using a search and score algorithm. We use a greedy hill climbing strategy that searches for a possible distribution of edges, while trying to maximize the Bayesian information criterion (BIC) score [10]. BIC measures the goodness of fit of the structure given the data, but also penalizes complicated structures with many parameters to learn. The search begins from an empty graph. At each step, the greedy algorithm performs an edge operation (adds, deletes or reverses a directed edge) that increases BIC maximally.

Model averaging

We use the bootstrap approach to assess the confidence of network structures learnt from a few hundreds of instances. Accuracy is a measure of confidence on the presence of an edge and its direction in the BN structure [9]. For a number of iterations, the algorithm re-samples the same number of instances, N as the dataset, D, with replacement. It further learns the network structure from this re-sampled dataset. The structures resulting from each iteration are averaged to help identify the nodes and edges which appear in at least half of them. We use only those edges which have edge strengths more than 0.5 and probability of edge direction more than 0.5. The edge strength signifies the confidence on the direct dependence relationship between two nodes and is estimated as its empirical frequency over the set of networks learned from bootstrap samples. The probability of the edge direction is computed conditional on the edge being present in the network.

Integration of multiple views

We learn the dependence model of the multi-view data by selectively combining nodes and edges from the view-specific BNs. In the second phase of structure learning, edges between latent variables from different views are established. From each view-specific BN, we segregate the nodes that form the Markov blanket (MB) of the clinical status node. The set of children, parents, and spouses of the node X is its MB [9]. In a BN, a variable is conditionally independent of all the other variables given its MB. Since the bootstrap approach iterates a number of times while resampling of the training data with replacement, we have as many candidate structures as there are iterations. If the edge between nodes X and Y is not present in any of the candidates, the edge strength of $E_{X,Y}$ is 0. If it appears in all the candidates, the strength is 1. Since the edge strength, Γ is a positive value between 0 and 1, it can be regarded as a probability of the validity of the edge in the BN, i.e., $\Gamma_{E_{X,Y}} = \frac{|E_{X,Y}|}{n_{iterations}}$. Thus, we follow a Bayesian approach with only the MB nodes from view-specific BNs and edges across views to be learned afresh with a default uniform prior and edges within views learned with a prior probability.

Parameter learning and inference

We learn the parameters of the integrated BN structure through maximum likelihood estimation with Laplace smoothing over the n_{train} training samples. We compute the predictions of the clinical status by averaging likelihood weighting simulations. The predicted value is the one with the highest conditional probability for a discrete target, and the highest expected value of the conditional distribution for a continuous target.

Experiments

Data: We work with a dataset of 589 subjects from ADNI which includes their background variables: demographic (4), genotypic (SNP~900) and medical history (25), and markers: grey matter volumes from baseline MRI (90), and cognitive measures: Mini Mental State Examination (MMSE) and

Clinical Status (AD/MCI/CN). Table 2 shows the demographics of the subjects included in our study.

Setup: We use the Stan probabilistic programming language to build view-specific abstractions and decide on the dimensions through multiple cross-validations [14]. We build and represent the BNs programmatically using the bnlearn R-package [9]. The integrated BN is used to predict the clinical status (2- AD, 1-MCI and 0-CN). For all the classification problems, we learn one BN structure per view with disease status as the target variable. This is followed by structure and parameter learning for the integrated BN for different view combinations. We report the performance of all models averaged over 5-fold cross validations. We evaluate the classification of a concatenated data vector comprising data from the three modalities, viewing it as a baseline study.

Table 2. Subject Demography

	AD (n = 128) 66 M, 62 F		**MCI (n = 287)** 179 M, 108 F		**CN (n = 174)** 98 M, 76 F	
	Mean	Range	Mean	Range	Mean	Range
Age	75.4 (±7.3)	58.4-87.7	75.3 (±7.2)	55.1-88.8	75.2 (±5.2)	62-84.7
MMSE	23.77 (±1.9)	20-26	27.12 (±1.6)	24-30	29.04 (±1.2)	25-30

Assumptions: We learn view-specific BNs using only the constraints that apply to the variables within. As the disease state is a categoric variable in classification, we discretize its possible parent variables such as "Age", "Years of education" according to the rules of CGBN. Only views with more than 5 variables are subject to the extraction of low-dimensional abstractions. We use a subset of SNPs (~900) as previously reported in [3]. Each SNP is matched to the gene/s located within a distance of 20kb. We learn a latent score for each gene per person using PCMs and use these for further processing.

Results

BMF captures the dense correlations among 90 regions of interest (RoI) captured into 25 latent factors. Figure 2 depicts the weights of the top 10 features (y axis) on the 25 factors, with longer bars indicating higher absolute weight in the corresponding color-coded factor. Left Amygdala has the longest bar, and hence the highest absolute weight. The latent factors are interpreted based on the hemisphere, lobe and area of the brain surface where the constituent RoI belongs. In Figure 3, the discrimination and difficulty parameters of the ICC for MMSE questions are elaborated in the left and right subplots. The five most discriminating questions are related to attention in computing alphabets in a series (MMO, MMR, MMW), language (MMWATCH), reading (MMREAD) and orientation (MMSTATE) while the five most difficult questions are alphabets in a series (MMD, MMO, MMR), orientation (MMONFLR) and immediate recall (MMTREE).

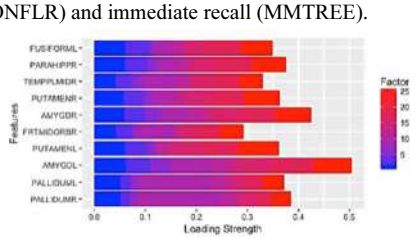

Figure 2. RoIs with highest absolute weights on factors

Table 3 shows the genes abstracted from their corresponding SNPs and factored brain RoIs that report the 5 highest associations with AD (p-values <= 0.05). Table 4 compares the performance of our approach for the multiclass classification of AD vs. MCI vs. CN with the baseline, single views, and the state-of-the-art classification for AD [7]. Figure 4 presents the integrated BN structure of demography and the abstractions from marker views of MRI, MMSE and background views of genes and medical history. The MRI factors are color-coded in navy, genes in yellow, clinical status (DX) in red, demographic variables in pink, medical history in ivory and MMSE in green.

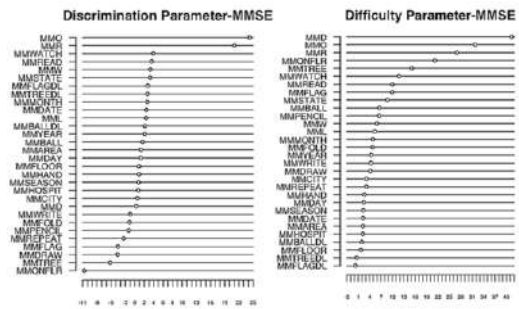

Figure 3. Discrimination and difficulty of MMSE (low-high)

Table 3. Genes, Brain areas identified by our model as associated with AD

Gene	p-value	Brain Area	p-value
APOE	<.001	Left Hippocampal	<.001
TOMM40	<.001	Right Hippocampal	<.001
SLC6A11	<.001	Left Amygdala	<.001
IL16	<.001	Right Amygdala	<.001
FGD6	.002	Left Insula Medial	<.001

Table 4. Key performance metrics for classifying AD/MCI/CN

Study/Data	**Accuracy%**	**Precision**	**Recall**
MMSE	71.7	0.58	0.91
Baseline	59.44	0.64	0.58
(Our work)	**80.18**(±8.89)	**0.73**(±.06)	0.68(±**.09**)
[7] Used MRI, PET	72.9	NA	NA

Discussion

Most clinicians use only total MMSE scores to assess AD staging. This reports an accuracy of 71.7%. Our method achieves an accuracy of 80.18% along with a precision of 0.73 and a recall of 0.68. The reported measures are averaged over predictions of AD, MCI and HC subjects by the model. The performance of the baseline (vertical concatenation of views) is not very impressive due to the inclusion of more features compared to training samples, i.e., *'large p small n'* that leads to model overfit. It underperforms grossly while working with 589 individuals and ~1030 features. The results in Table 4 show that our method fares better than the state-of-the-art approach to identify the stage of AD [7]. By categorizing the data views and defining edge directions, we are also able to visualize and interpret the model structure (refer to Figure 4). We notice that MRI factors are correctly modeled as interacting mostly through the disease variable and form a connected network. As we include only the variables from the Markov blanket (MB) of the disease variable, the less relevant ones are filtered out from each view due to the conditional independence property. The inclusion of the background features from genes, medical history and demography in the final BN in the MB of the clinical status variable (DX) implies that they are not

overshadowed by the markers. We also compare our results with a recent work [8] which used BN structure learning to predict the MMSE scores using a highly selective list of 16 biomarkers from various modalities. They report a mean square error of 2.81, while we achieve 2.44 ($\pm$0.29). Feature selection from each modality is done manually in their prediction model. Our approach also facilitates relevant biomarker discovery. The latent factors extracted from the marker and background views and visualization of correlated features lead to hitherto unexplored associations with the clinical status. Finally, in Figure 5, we report the impact of significant clinical features in the MB of the clinical status variable in the network we learnt. We examine the probabilities of a clinical status of AD or MCI conditioned on different values of the variables (scaled/standardized for continuous variables) in the MB of the clinical status. The results show that lower grey matter volume of the left hippocampus and insula region are indicative of a higher probability for cognitive impairment. The presence of APoE and TOMM40 SNPs strongly increase the chance of cognitive impairment and so does a lower education, MMSE score and higher age. These results are reasonable based on published evidence.

1	0.76	0.69
2	0.92	0.72

Figure 5. Conditional probabilities for cognitive impairment

The CGBN framework, however, does have several restrictions on the nodes and their distributions. In particular, only direct conditional dependencies can be viewed. There could be hidden or non-linear associations that are not explicitly captured.

Conclusion

We have introduced a multi-view disease staging framework that takes into account the dependence semantics among the variables from disparate data sources. Our model achieves comparable and sometimes better prediction performance in identifying individuals at different stages of AD as compared with the state-of-the-art approaches. Moreover, our framework is scalable, takes into account the heterogeneity and the multitude of the data types, modalities, and quantities. It also serves as the basis of a general approach to clinical decision support with interpretable recommendations from multi-view data.

Abstract

Methods for cardiac tissue engineering and application in experiments are core technologies developed at the Institute of Pharmacology and Toxicology in Göttingen. As is the case in many academic research laboratories data capture and documentation may be improved to latest methods of digital research. A comprehensive information system infrastructure is the foundation of further advances toward automation of lab processes. A data management system concept is proposed and prototypically deployed that enables traceability of assets within the lab and reproducibility of published assays and results. The prototype integrates existing electronic lab notebook, experiment result database, and a newly introduced research data management system by means of a custom developed portal and integration component. The architecture concept and developed integration tools explore connection of routine experimental work in a biomedical research lab to a universal infrastructure of data.

Introduction

Biomedical research laboratories in industry and academic environments are challenged with an ever-increasing complexity and quantity of data to be handled. Engineered human tissue models are, for example, pushing into high-throughput drug screening [1], precision medicine [2], and clinical tissue replacement therapy applications [3]. Laboratory automation technology and data science methods are introduced into the biomedical lab domain. Complementary to this bottom-up need for digital transformation, regulatory and political initiatives to improve data management in research demand adherence to quality standards and promote infrastructure development to facilitate an interconnected ecosystem of data [4]. Both the potential benefits and the methodological pitfalls of "big data" applications in biomedical research are well documented [5] with an overall expectation that given expert handling and realistic interpretation of computational models and predictive methods, significant scientific progress is possible. Driven by everyday needs in the development of biotechnological methods for generation and application of engineered myocardium, we investigate the prerequisites and best practices for capturing laboratory process and experimental data, and enabling integration with cross-organizational data-driven research.

Background

The Institute of Pharmacology and toxicology of the University Medical Center Göttingen (UMG) has a long-standing history in the generation of engineered human myocardium (EHM) induced pluripotent stem cells following a well-defined protocol [6]. The primary functional parameter of EHM samples are force and frequency of contraction (FoC, R-R) which directly report on quality and maturity of tissues and are evaluated during *in vitro* compound screening experiments, see Figure 1. The technological challenge currently faced is to develop scalable methods for generation, cultivation and analysis of EHMs that are compliant with Good Manufacturing Practice (GMP). Our key approach is the automation of the entire process by removing human interventions in handling and documentation stepwise one after another.

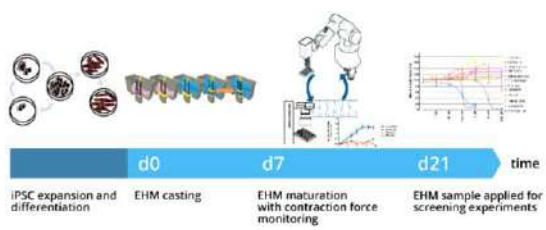

Figure 1 – Simplified process of engineered heart muscle generation and substance screening. (CC-BY-SA 4.0 T. Meyer, M. Suhr)

Automation of complete drug screening experiments depends on the same atomic laboratory processes as EHM generation, routine change of culture media and FoC measurement. A video-optical method for simultaneous measuring of 48 EHM samples on a microtiter culture-plate is developed on site, enabling major gains in process efficiency. Currently, EHM generation protocol steps are executed manually by lab personnel and are documented in paper notebooks and the electronic lab notebook (ELN) RSpace [7]. The video-optical FoC measurement is performed by a high-resolution camera attached to a hardware frame-grabber for near real-time transformation of the optical signal into time series data. Raw output from the camera system is processed using a custom MATLAB program to calculate functional parameters. The tool stores results in a MySQL database along with experiment parameters and metadata like EHM sample source materials (base cell line, generation protocol, batch ID, creation date, type and geometry of culture-plate, etc.). The database schema has been designed and frequently expanded to enable fine-grained documentation and planning of EHM generation and

experiments with process automation in mind. Data is stored describing assets like culture-plates, cell lines, chemical substances, and personnel involved as well as the execution of experimental steps.

These laboratory processes initiate a typical scientific data life cycle routine. Beginning with the planning and creation of primary data, several stages of processing, publication, and archiving are traversed before allowing re-use of result data for new investigations [8]. Such research data management (RDM) activities are supported by sophisticated infrastructures and systems for ETL processes, data publication, and data sharing [9]. Goals for technical implementation have been coined the FAIR principles, calling for research data that is findable, accessible, interoperable, and reusable [10]. Advanced RDM tools achieve compliance with the FAIR criteria but usually on a per-project basis and not as a basic tool for everyday documentation and data capture in the laboratory. Considering the overall trajectory towards interconnected systems of FAIR data across organizational and discipline boundaries [4], on-site data management infrastructure is needed that allows for user-friendly, FAIR-compatible, data provenance preserving, and possibly regulation compliant everyday experimental work in a constantly changing ecosystem of experimental settings and lab automation.

Objectives

Based on the EHM use case, we explore the preconditions and available tools for a laboratory RDM infrastructure enabling acquisition, storage, and sharing of raw data and metadata created during the process. Essential quality requirements for a resulting system architecture are usability in a laboratory environment and software sustainability in a highly specific area of biomedical research, i.e. drawing on lean human and financial resources for information technology. Ideally, the concept should be flexible enough to be reused for different experimental scenarios in biomedical research laboratories.

Methods

Literature search is conducted to (a) determine mandatory quality standards for data processing systems in the given experimental context, and to (b) collect reported best practices for RDM in similar biomedical contexts and tools available for prototypical implementation. Through iterative manual screening of articles' title, abstract, and full text, the result set is refined. Based on frequent interviews and discussion sessions with the involved biomedical researchers, laboratory processes are modeled as basis for formation of a system requirements catalog following recommendations from the requirements engineering field [11]. Combining the insights from the literature search, we propose a concept for an architecture of RDM tools to meet the requirements of a biomedical research lab and implement a prototype supporting the EHM generation use case.

Results

Goals and Requirements

Taking into account content and scope of application of multiple "GxP" guidelines [12], we include implications for information systems from GLP in the requirements engineering process, namely: user access control mechanism, audit trailing, metadata storage, data integrity and quality checks, as well as validation of interfaces, archival, and backup procedures [12]. From the analysis of data management best practices and available tools we derive six goals for a comprehensive system: (CG1) to enable research process, (CG2) to maximize usability, (CG3) to ensure information security, (CG4) to favor dynamic extension, (CG5) to maximize sustainability, and (CG6) to increase reporting quality of results. Based on the conducted literature and requirements analyses as well as the defined goals, we defined primary system requirements that imply general usage scenarios for information systems in the given context. This set represents the functionality of a socio-technical system to operate core processes at a biomedical research laboratory.

Tools

The literature search results revealed 10 distinct software tools and frameworks for data management in a research laboratory. Multiple of these are no longer actively developed since original publication. Among open source projects, two at least partially closed-source commercial products are reported (LabMatrix, LabKey Server) which have not been further considered for application in this exploratory case study. We exclude tools that are tailored only for minor or too specific aspects of the system requirements. Final candidate tools that enable both experimental data capture and FAIR-compatible data sharing are openBIS [13] and SEEK [14] from the "FAIRDOM" ecosystem.

Architecture Concept

Laboratory information systems are commonly divided into three categories: user-centric ELN, operative data- and process-centric laboratory information management system (LIMS), research result-centric scientific data management system (SDMS) [15]. The requirements specified exceed the functionality offered by any single system especially with regard to the need for extensibility: constantly changing experimental settings and analytical processes require a system that can be flexibly integrated and extended with new modules and functionality while at the same time meeting quality requirements like interoperability and sustainability with given resources.

Machina and Wild discuss three models for system integration in drug discovery research [15] which is very similar to the given environment: "ELN-centric" integration is driven by the idea to unify all user interaction with different subsystems through the interface provided by an electronic lab notebook. Modular integration describes the interconnection of sub-modules from neighboring systems like ELN and LIMS enabled by a distinct integration system. The service-oriented integration approach relates closely to the Service-Oriented-Architecture (SOA) paradigm of software design [16] with multiple independent modules (services) providing encapsulated functionality and communicating through messages. We combine aspects from these integration models into an architecture concept as follows: The available tools for the research lab data management system are self-enclosed software systems with internal modular structure as presumed in the modular-integration approach. To ensure operative flexibility and longevity of the systems, extensibility is maximized by applying the SOA paradigm. We propose a service-oriented integrated system architecture constructed around five logical components:

- **Electronic laboratory notebook** (ELN). A system for manual laboratory work documentation and collaboration in GxP-compliant manner.
- **Laboratory information management system** (LIMS). A leading system for laboratory asset registration and management.

- Multiple **experiment-specific subsystems** providing services for custom settings that cannot be implemented with ELN and LIMS.
- **Data integration and analysis system** (DIAS). A system for integration of data from disparate sources, visualization and analysis.
- **Research data management system** (RDMS). A system for research project planning, high-level documentation, result and data sharing.

To achieve integration of these components, three auxiliary building blocks complete the concept:

- **Portal**. A (web-based) central access point for all functionality that provides a unified graphical user interface.
- **Service integration layer**. The control center for service-based integration, connecting services and subsystems and exposing functionality via API or relaying GUI to the portal service. Central shared services like user management, authentication, and authorization should be realized within the integration layer to harmonize subsystem behavior.
- **External services**. An arbitrary number of external services and systems relayed to the overall system through connector services in the integration layer.

Communication between services and subsystems should be realized through application programming interfaces as the SOA paradigm proclaims. Subsystem user interfaces can be integrated into the portal-based unified GUI. If subsystems do not provide API or GUI, it should be possible to customize services within the integration layer to provide surrogate functionality. Figure 2 depicts a graphical representation of the architecture concept.

Prototype Implementation

With regard to the goal of enabling especially the EHM experiment-specific workflows, ELN and RDMS are the components to be implemented with priority: ELN because it enables coherent documentation of manually executed workflow tasks; RDMS because the planning and publishing capabilities enable improvements for both organization of work and FAIR-compliant publication of results. The existing RSpace instance is to be integrated and a local instance of SEEK will be set up as part of the prototype system.

The MySQL database system developed for the EHM compound testing experimental data capture and storage and the MATLAB program for analysis of video-optical contraction force measurements are heavily interwoven in the current form. Instead of replacing these operational systems in an early phase of the project, they are to be integrated as a first experiment-specific subsystem.
