The second criterion of the "Get Base Indicator" statement is "Are diuretics or abnormal electrolyte or abnormal renal observations in prefetch". This criteria contains three main components which are the diuretics medication requests involved, the abnormal electrolyte observations involved, and the abnormal renal observations involved.

We apply the same approach to detect the diuretics medication requests involved by checking the existence of Aldosterone Antagonists and Loop Diuretics in the Medication Request. For the remaining components, a similar approach for the abnormal electrolyte observations and renal observations has been used to detect the abnormal level of Potassium, Magnesium, Calcium, and Renal.

Condition	Observation

Evaluation

We prepared FHIR resources (Table 1) to cover all cases of two decision trees and tested around 170 FHIR resources in STU3 version for 21 different patients on 14 cases of Digoxin-Cyclosporine and 7 cases of Warfarin-NSAIDs decision tree to support the draft IG. We also performed the evaluation at the Connectathon held at the 32nd Annual Plenary & Working Group Meeting of HL7 held in September 2018.

The evaluation was done using Postman[6] and CDS Hooks Sandbox[7], a tool developed by CDS Hooks team demonstrate how CDS Hooks would work with an EHR system. In brief, the clinician enters the medication, e.g., Ketorolac Tromethamine 10 MG Oral Tablet, for the specific treatment, and the CDS Hooks Sandbox then invokes the "medication-prescribe" hook to send the request to the PDDI-CDS services endpoint (e.g. {baseUrl}/cds-services/warfarin-nsaids-cds). After the PDDI CDS service processes the request, the CDS Response cards are returned. Finally, the CDS Response cards is presented by the CDS Hooks Sandbox.

Discussion

We were able to implement a PDDI CDS service using CQL, FHIR, and CDS Hooks. This shows the feasibility and that CQL was sufficiently expressive to cover to realistic use cases. We suggested enhancements to CDS Hooks that would enable it to support PDDI CDS using the minimum information model, and the combination of tools indeed performed PDDI CDS as a

[6] https://www.getpostman.com

[7] https://sandbox.cds-hooks.org

Figure 4– The screenshot of CDS Hooks Sandbox tool to test our PDDI-CDS services through CDS Developer Panel

service for two patient use cases. One of the limitations is a lack of tools supported for CQL because the community who is using CQL and CQL itself is entirely new. Therefore, it takes a lot of time in debugging to find out the problem.

As described in the Concept section, we need two components including FHIR server and CQL engine to implement CDS services. There are many FHIR server implementations including HAPI FHIR, FHIR .NET API[8] and others. However, HAPI FHIR is the most stable and popular implementation. It has a well-written documentation and full FHIR version support. Apart from that, there are less choices for CQL engine and we chose CQL-Evaluation-Engine from Database Consulting Group. This implementation is based on CQF-Ruler open source developed by Database Consulting Group, and Level 1 implementation of the draft PDDI-CDS Implementation Guide developed by HL7 Clinical Decision Support Work Group.

The Level 1 Implementation uses a single CDS service call and response with the medication-prescribe hook. As a future work, we plan to implement Level 2 implementation which we are working with the CDS Hooks developers to define the new medication-select hook and clarify how DetectedIssues will be returned in the card responses.

To create the CQL artifacts, the CDS Authoring Tool[9] is a promising candidate which is a component of the CDS Connect project funded by the Agency for Healthcare Research and Quality (AHRQ). The CDS Authoring Tool introduces an interface for composing CDS logic step by step using simple forms and exporting it as CQL artifacts using the HL7 FHIR DSTU 2 data model.

Conclusions

Based on the PDDI-CDS IG, we successfully implemented PDDI CDS services supported the Level 1 implementation of PDDI-CDS IG. The implementation follows strictly the CDS Hooks specification which enables EHR system to interoperate and exchange the data by using FHIR STU3 standard to enhance the better clinical diagnostic decision making. In the future, we will focus on the Level 2 implementation to help advance the standards including the new mediation-select.

Abstract

The review of pathology test results for missed diagnoses in Emergency Departments is time-consuming, laborious, and can be inaccurate. An automated solution, with text mining and clinical terminology semantic capabilities, was developed to provide clinical decision support. The system focused on the review of microbiology test results that contained information on culture strains and their antibiotic sensitivities, both of which can have a significant impact on ongoing patient safety and clinical care. The system was highly effective at identifying abnormal test results, reducing the number of test results for review by 92%. Furthermore, the system reconciled antibiotic sensitivities with documented antibiotic prescriptions in discharge summaries to identify patient follow-ups with a 91% F-measure – allowing for the accurate prioritization of cases for review. The system dramatically increases accuracy, efficiency, and supports patient safety by ensuring important diagnoses are recognized and correct antibiotics are prescribed.

Keywords:

Clinical Decision Support Systems, Data Mining, Emergency Medicine

Introduction

The failure to follow-up on pending test results when patients have been discharged from hospitals is a potential threat to patient safety [1][3]. Poor test result follow-up can significantly impact patient safety and clinical care, including missed diagnoses and suboptimal patient outcomes [3]. The Emergency Care Research Institute (ECRI) underscored the problem of "Test result reporting and follow-up" as one of the top 10 patient safety concerns in healthcare organizations [4].

This is especially problematic in Emergency Departments (EDs) where there can be a significant number of pending test results when patients have been discharged from the hospital. The current manual process in EDs for checking test results for abnormalities, then ensuring patients with abnormal results are appropriately followed-up is sub-optimal [5][6]. The process is labor-intensive, un-prioritized by its nature, and has negative impacts on patient care and staff workloads. Specifically, the current process 1) potentially delays the follow-up of critical abnormal cases because all test results need to be reviewed then reconciled against the patient's disposition recorded in the ED; 2) consumes valuable clinical hours that could be better spent engaged in direct patient care; and 3) is prone to errors due to the time intensive nature of work trying to find the "needle in the haystack" of results, in addition to ongoing pressures of clinician workloads.

Furthermore, the process of checking test results in EDs has not kept pace with the rapid growth and expansion of hospital services due to increasing population, aging, and chronic diseases. This has placed increased pressures on "systems" and staff workloads, leading to reduced efficiencies and reduced direct clinical contact hours with patients potentially compromising patient safety and care.

Proposed is an automated solution that changes the way EDs detect and report abnormal test results. The system initially focused on the review of microbiology test results as these can take up to several days to be reported upon, by which time a patient will have been discharged from the ED. These test results often contain information on the results of culture strains present and their antibiotic sensitivities, both of which make a significant impact on ongoing patient safety and clinical care.

In particular, contributions include 1) 'trigger' algorithm to identify abnormal microbiology test results and related antibiotic sensitivities from pathology reports; 2) extraction of antibiotic prescriptions documented in ED discharge summaries using text mining based 'trigger' keywords derived from clinical terminology semantics based on SNOMED CT[1] to reconcile against the antibiotic sensitivities; and 3) automate a protocol with a prioritized listing of cases to support the test result follow-up checking process. The solution overcomes the labor-intensive and error-prone nature of test result reviews to enhance patient safety and efficiency.

Background

Clinical decision support (CDS) systems have the potential to improve clinical efficiency and patient safety [7][11]. These systems have been applied across diverse settings and range from information management systems through to clinical alerts, and diagnosis and/or treatment recommendations. Despite the significant body of literature on CDS systems, automation in the context of test result reviewing has been limited.

Health system processes and test result management systems have been implemented with the aim to improve test result review processes [3]. However, physicians are still unsatisfied with how they manage test results [5][6]. For example, an end-to-end workflow is much desired along with the ability to filter normal (irrelevant) results to help prioritize the workflow. This

[1] Systematized nomenclature of medicine – clinical terms

suggests that current systems do not include robust CDS features or functions such as prioritization and/or filtering to the end user [8].

Automated notifications of abnormal test results can significantly reduce the number of results for review. Abnormality detection from pathology and imaging test results range from 'trigger' algorithms that use clinical logic on structured electronic health record (EHR) data to identify abnormalities [12][15] through to advanced computational approaches such as machine learning to identify abnormalities from unstructured narrative EHR data [16][18].

Furthermore, the abnormality task can be extended to also reconcile or link the abnormal findings in radiology reports with the patient's disposition recorded in ED information system to provide decision support to the manual review process [16].

Here, the proposed solution for microbiology test result reviews leverages previous work on 'trigger' algorithms and reconciliation to develop an end-to-end test result reconciliation solution. Microbiology test results most frequently report on bacterial antimicrobial (or antibiotic) susceptibility. Antibiotics have been used to treat infections or diseases caused by bacteria and have saved many lives since their introduction. However, antibiotics may not be effective when overused due to antimicrobial resistance. This "antimicrobial stewardship" problem is a global problem and like "Test result reporting and follow-up," it was also identified as being within the top 10 patient safety concerns in healthcare organizations [4]. This end-to-end solution can aid in ensuring that appropriate antibiotic prescription continues through the treatment of the infection thus fulfilling the needs for antimicrobial stewardship.

Methods

The workflow for identification and reconciliation of abnormal microbiology test results with ED discharge summaries will be presented along with the proposed methodology for automating it. The workflow was adapted from an actual test result review process within an ED in Brisbane, Australia.

Data

The dataset was obtained from The Prince Charles Hospital (TPCH), Brisbane, Australia[2]. The dataset comprised 31,787 ED encounters (pertaining to 15,916 unique patients) from July 2013 to December 2014 (18-month period). A separate dataset of microbiology test results, ordered from the same hospital and ED, was obtained from a state-wide pathology information system and comprised 29,503 microbiology pathology HL7 messages (pertaining to 18,560 patients) from a wider 4-year time period. The ED encounters and microbiology test results were matched based on their unique patient identifier and test result order date is within the patient's ED admission and discharge date/time. A total of 16,867 ED encounters had matching microbiology test results over the dataset time period.

A subset of abnormal test results and matching ED discharge summaries (142 cases) was manually reviewed by ED senior medical officers to determine their follow-up requirement. Eighty percent of the cases (113 cases) were used for system development while the remaining cases were used for testing (29 cases). An additional 282 cases were subsequently obtained to assess the generalisability and robustness of the system via a pilot study. Table 1 presents a summary of the gold standard dataset.

Table 1 – Gold standard dataset for abnormal microbiology test result reconciliation

Dataset	Follow-up	No follow-up
Development set	78 (69%)	35 (31%)
Test set	20 (69%)	9 (31%)
Pilot set	211 (75%)	71 (25%)

Abnormal test result identification and filtering

The TPCH ED, on a daily basis (including weekends), would print out the microbiology test results and place them in a dedicated area for sorting. Results must be sorted by hand to identify abnormal results requiring follow-up from those that do not. This process was not without errors. A typical day may find the sorting pile overlooked or half completed due to clinical demands. Other errors include failure to recognize abnormal results from distraction or incorrect interpretation of results.

The proposed system addressed the abnormal test result identification issue by utilizing the concept of the trigger algorithm [12][15]. Triggers were applied to the microbiology test results to identify abnormal results and related antibiotic sensitivities. The presence or absence of antibiotic sensitivity results in pathology HL7 messages was used as the trigger.

The set of abnormal test results could be further filtered based on the patient's discharge destination. Patients who were admitted into the hospital as an in-patient would not be required to be followed-up as they would be appropriately followed-up by other clinicians in the hospital. To achieve this, the system again applied triggers to the discharge destination field in the ED information system to identify patients who were not admitted to any of the hospital wards. A list of all possible ED discharge destinations with their follow-up requirement was provided for the discharge destination filtering.

The processing and filtering of pathology reports resulted in a significant reduction in the number of test results requiring review by the ED.

Abnormal test result reconciliation

The next stage of the review process was abnormal test result reconciliation whereby abnormal test results must be correlated against the clinical record. The ED clinician searches for patients with abnormal test results, one by one, in their ED medical record to determine if patients were required to be followed-up due to an inappropriate diagnosis or treatment. This correlation process was also not without errors. For example, appropriate action may not have been taken due to failure to recognize the misdiagnosis or incorrect treatment.

This stage involved the application of text mining and clinical terminology semantics for the extraction of antibiotic prescriptions documented in ED discharge summaries for reconciling against antibiotic sensitivities in pathology test results. To extract antibiotic prescriptions in discharge summaries, a 'trigger' keyword list containing antibiotic names was compiled. This was used to match occurrences of these keywords in discharge summaries.

A baseline list of antibiotic 'trigger' keywords was derived from the list of possible antibiotic sensitivities identified in microbiology test results (e.g. Trimethoprim, Co-trimoxazole,

[2] Research ethics was obtained from the Metro North Hospital and Health Services Human Research Ethics Committee.

and Di(Flu)cloxacillin). Antibiotic names and their expanded forms (e.g. dicloxacillin and flucloxacillin for Di(Flu)cloxacillin) would form candidate antibiotics to use as 'trigger' keywords.

An extended 'trigger' keyword list was compiled by supplementing the antibiotic names with also their brand names. Here, the Australian Medicines Terminology (AMT)[3] and the SNOMED CT expression constraint language (ECL)[4] was used to generate the list of trade names. Ontoserver [19], a clinical terminology server with support for SNOMED CT and AMT as well as SNOMED CT's ECL, was used to generate the list of antibiotic trade names.

ECL templates were devised to return a list of trade names given 1) a single active antibiotic ingredient, and 2) more than one active antibiotic ingredients. An example ECL for a single antibiotic ingredient `2691011000036102|Trimethoprim|` is as follows:

```
^ 929360021000036102|Trade product reference set|
AND >> (
  ( ^ 929360031000036100|Trade product unit of use
reference set| : (
      700000081000036101|has intended active
ingredient| = 2691011000036102|Trimethoprim|
      ) AND [1..1] 700000081000036101|has intended
active ingredient| = * )
)
```

Ontoserver provides an ECL high-level reference[5] to aid in the interpretation of the above expression. In brief, the ECL returns a list of trade names (from `Trade product reference set`) that contains medications (from `Trade product unit of use reference set`) that have the specified antibiotic as its active ingredient. The `[1..1]` constrains the results to medications with only a single ingredient.

If multiple antibiotic ingredients were applicable to a certain antibiotic sensitivity test, then the above ECL can be adapted to include additional antibiotics using the `OR` operator. An example ECL extract for 'Di(Flu)cloxacillin' would be as follows:

```
...

700000081000036101|has intended active ingredient| =
  ( 2018011000036104|dicloxacillin| OR
    2115011000036102|flucloxacillin| )

...
```

For cases where an antibiotic has more than one active ingredient such as 'Co-trimoxazole' which contains both `2605011000036103|sulfamethoxazole|` and `2691011000036102|trimethoprim|`, then the following ECL was applied:

```
^ 929360021000036102|Trade product reference set|
AND >> (
  ( ^ 929360031000036100|Trade product unit of use
reference set| : (
      700000081000036101|has intended active
ingredient| = 2605011000036103|sulfamethoxazole|,
      700000081000036101|has intended active
ingredient| = 2691011000036102|trimethoprim|) )
)
```

The resulting list of antibiotic 'trigger' keywords was used to extract antibiotics documented in discharge summaries.

Discharge summaries often document the antibiotic treatments administered during the ED encounter. Intravenous (IV) medications for certain antibiotics can only be administered as IV-only. These IV-only antibiotics are generally not the full course of antibiotics and thus not relevant for reconciling against antibiotic sensitivities in test results. A list of all IV-only antibiotics was provided for antibiotic filtering. The resultant non-IV-only antibiotics would be used for the next stage of reconciliation.

The reconciliation of antibiotic prescriptions extracted from discharge summaries against antibiotic sensitivities from test results applied the following rule-based logic. The patient would not be followed-up if they were prescribed with an antibiotic that had a corresponding antibiotic sensitivity in their test result of 'sensitive'. However, the patient would require follow-up if any of the following reconciliation events occur:

- The patient has not been prescribed any antibiotics.
- The prescribed antibiotic was not tested (and thus its antibiotic sensitivity was unknown).
- The prescribed antibiotic resulted in an antibiotic sensitivity of 'resistant.'

The logic would be applied to each culture strain (or bacterial organism) identified in the test result.

Evaluation Measures

The efficiency of the system was evaluated based on the resultant number of test results identified by the system for clinical review (normalized on a weekly basis) compared to the full set of test results that would have been manually reviewed.

The reconciliation phase to determine whether or not a patient required follow-up was evaluated against the gold standard. The effectiveness of the system was measured using sensitivity (or recall) and positive predictive value (PPV or precision). To provide a single, overall evaluation measure, precision and recall were combined into a third evaluation measure, F-measure.

Results

A total of 16,867 ED encounters had matching microbiology test results over the dataset time period. This averages to ~216 test results per week, which an ED clinician would need to sort and review the test results.

Abnormal test result identification and filtering

The efficiency of the system in filtering irrelevant test results is tabulated in Table 2.

The proposed trigger to filter normal (irrelevant) test results from abnormal test results resulted in 2,605 abnormal test results – an average of 33 reports per week requiring review. The trigger was confirmed by ED clinicians to be accurate in identifying abnormal from normal test results.

[3] AMT is a subset of SNOMED CT-AU (Australian extension) for medicines commonly used in Australia.

[4] ECL is a formal language for defining bounded sets of clinical meanings represented by pre-coordinated or post-coordinated expressions.

[5] https://ontoserver.csiro.au/shrimp/ecl_help.html

Table 2 – System efficiency results in terms of reducing the number of abnormal test results review

	Number of test results	Weekly number of test results
Full manual review	16,867	216
+ Abnormality identification	2,605	33 (↓ 85%)
+ Discharge destination filtering	1,379	18 (↓ 92%)

When the abnormal test results were filtered based on the ED discharge destination, the number of test results that actually required clinical review was reduced to 1,379 (18 reports per week).

Abnormal test result reconciliation

To further provide clinical decision support to the test result review process, the reconciliation of antibiotic prescriptions extracted from discharge summaries against antibiotic sensitivities in test results allows for the prioritization of cases for clinical review. Table 3 presents the classification effectiveness of the proposed reconciliation approach.

Table 3 – System effectiveness results in classifying the follow-up requirement

Dataset	PPV	Sensitivity	F-measure
Development set	0.802	0.936	0.869
Test set	0.905	0.950	0.900
Pilot set	0.858	0.943	0.898

Discussion

The automated identification and prioritization of abnormal microbiological pathology reports for clinical review will bring about benefits in cost efficiencies, quality of care, and performance.

Noteworthy, was that a simple solution based on triggers was able to substantially reduce the number test results for review. Results show a 92% reduction in microbiology test results that required review.

Furthermore, the system was able to accurately identify the follow-up requirements (F-measure of 90%) for the prioritization of cases for clinical review. The very limited differences in performances between the development, test and pilot dataset show the generalisability and robustness of the proposed antibiotic extraction approach using 'trigger' keywords and a rule-based reconciliation logic.

Error analysis on the development dataset revealed four error categories: 1) antibiotic misspellings in discharge summaries (4 cases); 2) context of antibiotic mentions (3 cases; e.g., previous prescriptions and non-IV-only administered antibiotics); 3) extrapolation of prescribed antibiotics with sensitivity results (4 cases; e.g., cephalexin prescription considered a correct prescription for an organism sensitive to Cefazolin test result); 4) missed identification of antibiotic mentions in discharge summaries (1 case); and 5) gold standard inaccuracies confirmed to be human errors (7 cases). These error categories form avenues for future work to improve system performances.

Conclusions

The proposed IT solution combines text mining and decision support technologies for the novel identification and reconciliation of abnormal microbiology test results in EDs. It has the potential to dramatically increase the accuracy and efficiency of microbiology test result review to support patient safety by ensuring important diagnoses are recognized and correct antibiotics have been prescribed. The increased efficiency will allow significantly more clinical hours devoted to the direct treatment of patients presenting to hospital EDs to increase their quality of care.

Next steps include the planning and development of end-user software that would allow for appropriate presentation without impeding on clinical workflow [7][20]. The clinical decision support system would then be implemented and trialed by clinicians in actual practice.

The proposed 'triggers' and reconciliation logic is applicable to any software system using HL7 communications. This would allow changes to be made among different pathology systems or EHRs to provide the notification and reconciliation of abnormal test results. It can also be applied to other areas of pathology as well as the reporting of radiology test results, which are similar in processes.

Abstract

Clinical practice guidelines (CPGs) are indispensable in the practice of evidence-based medicine. However, the cost of effective CPG dissemination strategies is prohibitive and not cost-effective. Therefore, scalable strategies using available technology are needed. We describe a formal model-driven approach to design a gamified e-learning system for clinical guidelines. We employ gamification to increase user motivation and engagement in the training of guideline content. Our approach involves the use of models for different aspects of the system, an entity model for the clinical domain, a workflow model for the clinical processes and a game model to manage the training sessions. A game engine instantiates a training session by coupling the workflow and entity models to automatically generate questions based on the data in the model instances. Our approach is flexible and adaptive as it allows for easy updates of the guidelines, integration with different device interfaces and representation of any guideline.

Keywords:

Practice Guideline; Statistical Model; Computer Games

Introduction

Over the past three decades, the concept of evidence-based medicine has become the pre-eminent paradigm in informing clinical decision making. Evidence-based medicine is the conscientious, explicit, and judicious use of best evidence in making decisions about the care of individual patients [1]. The volume of published medical literature is immense and it is practically impossible for a clinician to read and appraise all the available evidence. This has led to efforts to systematically appraise the literature and provide summaries of the evidence in the form of clinical guidelines that can be more easily consumed by healthcare workers.

Clinical guideline are statements that include recommendations intended to optimize patient care. They are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options [2]. Guidelines serve a variety of functions such as improving effectiveness and quality of care, decreasing variations in clinical practice, and decreasing costly and preventable mistakes and adverse events [3].

Development of clinical guidelines is not by itself enough. For a health system to derive value from available guidelines, effective dissemination and implementation strategies have to be employed to facilitate the integration of the guideline recommendations in clinical practice. Dissemination refers to the methods by which guidelines are made available to potential users, while implementation refers to ensuring that the users act on the recommendations [4]. Currently, there is no consensus on the most effective dissemination strategies although the use of a multifaceted dissemination approach has been found to be more effective than single interventions [5,6]. Further, the passive distribution of printed educational material on care guidelines was found to be less effective than active approaches such as educational outreaches [7].

Despite the observed effectiveness of educational outreaches as a dissemination strategy, these often require significant financial and human resource commitment that might not be readily available in low resource settings. For example, the Emergency, Triage, Assessment and Treatment plus Admission care (ETAT+) course is a 5.5 day course developed in Kenya to train healthcare workers on the guidelines for emergency paediatric care. During its initial implementation, the cost of the whole training for 32 participants using 5 facilitators cost $5000 for facilitators and meals, not to mention the cost of having providers away from work and the often associated additional costs for trainings provided at a conference facility [8]. This is neither scalable nor sustainable.

To address these dissemination challenges, new, innovative and cost-effective strategies that leverage contemporary technologies need to be employed [9]. A study conducted in Kenya showed that ownership of mobile phones among healthcare workers was nearly universal with 98.6% of respondents reporting mobile phone ownership and 75% reporting using their mobile phones to access work-related information [10]. This provides an opportunity to use the mobile electronic platforms to conduct educational outreach in a scalable, cost effective and automated fashion.

In this paper, we describe a formal model driven approach to the design of a gamified elearning system for clinical guidelines. Gamification is the use of game design elements in non-game contexts [11]. It uses game-based mechanics, aesthetics and thinking to engage people, motivate action, promote learning and solve problems [12]. The term "Gamification" is relatively new and has been used to describe the use of game-based concepts and techniques outside recreational activities, with the goal of increasing the motivation and engagement of the participants and improving the results. The benefits of gamification are an increase in motivation and engagement, which can be applied in education or work-related contexts.

To be effective, gamification of guidelines would require flexibility and adaptiveness as the users have various learning styles. In this paper, we describe an innovative model-driven approach for dissemination of a gamified eLearning system for clinical guidelines, and the resultant prototype of this system.

Methods

Model Driven Engineering

To design our gamified training system, we aim to use a model driven engineering (MDE) approach. MDE is a system development paradigm that promotes the use of models as the primary artefacts that drives the whole development process [13]. An MDE approach provides several advantages that we leveraged for our purposes. First, it improves communication by exploiting abstraction and domain-specificity which can target different audiences. Secondly, MDE facilitates separation of the specification of system functionality from the specification of the implementation of that functionality on a specific technology platform. This is especially significant since technology platforms are in a constant state of flux, changing frequently in response to business needs and technological development. By adopting MDE, the business logic of the system and its application technologies can evolve independently of each other. Implementations execution is mad easier by abstraction on different platforms while maintaining the structure and behaviour of the system.

In MDE, models are specified using modelling languages. A modelling language is defined by a metamodel (a model of models) and is a set of all possible models that conform to this metamodel [14]. There are two types of modelling languages, namely: (1) General Purpose Modelling Languages (GPLs) and (2) Domain-Specific Modelling Languages (DSLs). GPLs, as the name suggests, tend to be general and with poor support for domain-specific notation. Conversely, DSLs are tailored to a specific application domain that offers appropriate notations and abstractions. DSLs are thus more expressive and easier to use with concomitant gains in productivity and maintenance costs [14]. The abstract syntax of the DSL is a conceptualization of all the concepts, abstractions and relations underlying the domain represented as a model which acts as the metamodel of the modelling language.

A metamodel architecture introduces a generic pattern of metamodelling hierarchy in which models at each level are specified by a modelling language at the level above it and conform to the corresponding metamodel of the language. Figure 1 illustrates a metamodelling hierarchy where a model M_i at a certain level *i* (e.g. M_0, M_1 etc) conforms to a metamodel M_{i+1} at the level above until a model M_j has itself as metamodel, called a reflexive model.

However there are several aspects to design in a software model which requires the co-ordination of multiple models. These aspects include the design of information systems that have several sub-systems that communicate with each other. Rabbi et al. proposed to use an integration of multiple metamodeling hierarchies to co-ordinate various aspects of a system [15]. Our approach is also based on the idea of coordination of multi-metamodeling hierarchy where we integrate entity models, workflow models and models that represents the gaming aspects of a training program. Below, we describe each of these models and their integration within our model.

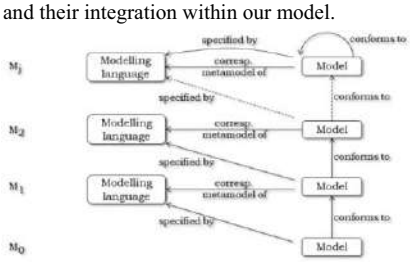

Figure 1:Generic pattern: modelling languages and metamodels [16]

Entity Model

In order to conceptualize the clinical encounters, we define an entity model relevant to the medical domain. This involves identification of the significant concepts in the clinical encounter, with a clear delineation of their attributes and relations (Figure 2). The figure shows a constraint [preCondition] implied over the relations on patient, diagnosis, and treatment. The semantic of the constraint specifies that "for every treatment, patients' diagnosis needs to be confirmed".

This clinically-relevant entity model forms the data model from which the game engine populates instances in the workflow model (see below).

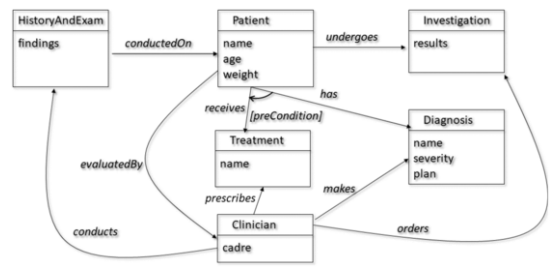

Figure 2: A simplified entity model of the clinical encounter domain

Workflow Model

Once the entity model is defined, we define the workflow model. Clinical practice guidelines can run into tens or hundreds of pages and are usually summarized in algorithmic flow charts that show the process of treatment for a given scenario. Our approach leverages the flowchart structure of the guideline summaries to design our workflow model.

Figure 3 demonstrates the use of the metamodelling hierarchy to depict the flow of tasks during a clinical encounter using an use case of asthma. At level M_2, we have a meta-metamodel showing the abstraction of how tasks flow from one to the next. Level M_1 shows a generic abstraction of the process of a clinical encounter from the initial assessment, diagnosis, treatment and evaluation of the treatment, after which the treatment can be repeated or the patient reassessed afresh to review the diagnosis. Finally, at level M_0, we show an instance of the recommended flow of tasks when treating a child with asthma.

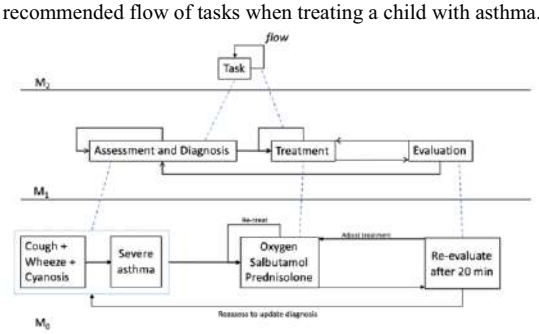

Figure 3: Workflow model showing the flow of tasks during a clinical encounter

Game Model

The design of gamified e-learning systems should be undertaken in view of the core concepts of games i.e. goal-oriented activities with reward mechanisms and progress tracking [17]. To become familiar with guideline content,

learners need to know how to treat the different aspects of a disease condition as outlined within the guideline. Game models use reward mechanisms and progress tracking aids in order to increase the users engagement and motivation.

The game engine in our model automatically generates questions from the entity and workflow models to instantiate a training module. The questions are categorized according to the learner's skill level (beginner, intermediate, advanced). The model also specifies a *learner profile* that tracks the learner's activities. Figure 4 shows the model for the game engine.

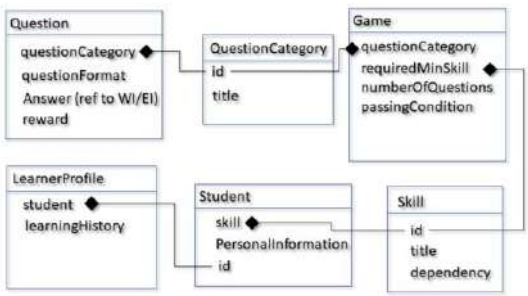

Figure 4: Game model

Integrated Training Model

The training model is built by coupling and coordinating the entity and workflow models discussed above based on the principles introduced by Rabbi et al [15]. The states of the training module (*TM*) are defined by a set of elements that include a pair of workflow instance (*WI*) and an entity instance (*EI*): $TM_i = <EI_i, WI_i>$. This coupling of models is illustrated in Figure 5. Here, we show a part of the entity model with values from a given scenario where based on the *History & Examination* findings, a *Diagnosis* of Severe Asthma is made and its *Treatment* specified. The flow of how this process should happen is shown in the workflow model.

The game engine instantiates a training session by generating questions based on the entity model and workflow model. For example, it could initially generate a scenario based on the patient details and history and examination findings and ask what the diagnosis is. If answered correctly, it will move on to the next task and ask about the treatment. A training session is composed of a sequence of training modules and is evolved from the initial state of a training flow and progresses based on the answer provided by the user.

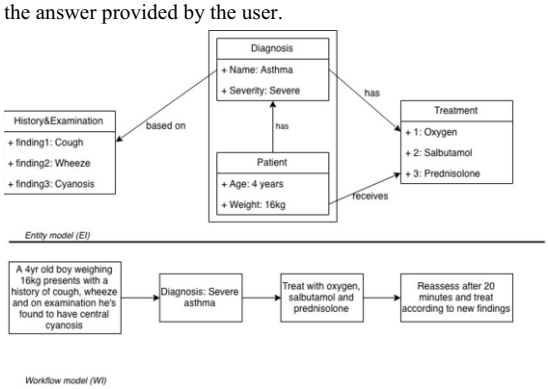

Figure 5: Coupled entity and workflow models

Figure 6 illustrates the idea of the progression of the states of training session. Depending on the answer given by the user a game engine consults with the training flow and evolves the state of the training session. We use the diagram predicate approach for representing the status of our training modules and their transformation [18]. Two annotations **< Enabled >** & **< Disabled >** are used to represent the current status of the training modules. A training module TM_0 when annotated with the **< Enabled >** predicate indicates that the training module is currently active and is being considered for training. Once TM_0 is completed successfully, it is disabled and TM_1 is enabled. This continues until the training session is over. If a wrong answer is given the training module is repeated with hints until the correct answer is given.

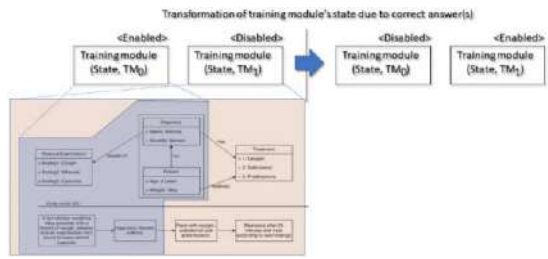

Figure 6: Progression of the states of the training session

Model Based Analysis

Since our approach is based on models, there are lot of opportunities to make sure the guideline scenarios being represented by the models are correct. We use model transformation rules to control the flow of training sessions. Transformation rules are often used in an MDE approach to encode the knowledge of a transformation that can be analyzed. This allows us to perform reasoning over the models. This means anylizing the models for validity, semantic consistencies and inconsistencies. For example we can perform reasoning over the models to answer the following questions:

- Are there sufficient number of questions to run a training session?
- Classify the questions over different stages e.g., identify questions that belong to the 'Diagnosis and Assessment' stage of a guideline training.
- Can we use a computer system such as that one by Alloy to randomly produce a scenario and generate questions [19]? How can we make sure that the scenarios are valid instance of a guideline?
- If there are certain number of questions to be asked in a session, what informaiton are common among the questions?
- How can we find out an order of the questions that complies with the order of the guideline?

We have applied DPF constraint checking [18] to find answer to some of the reasoning questions mentioned above. The fundamental idea of DPF constraint checking is based on the principle of category theory. Several techniques have been studied in [20] to produce valid DPF instances that satisfies the constraints in the metamodel. However, the technique has not been applied for multilevel metamodeling. In future, we will enhance the technique presented in [20] and use Alloy to randomly produce valid guideline scenarios.

Modular Architecture

The vision of this approach is to develop general components that can be utilized in the development of training programs for different guidelines. Figure 7 shows the overall architecture of our system. The training management module contains reusable elements that control the flow of questions in a training session

and keeps usage logs. The entity models are the elements that should differ from one training program to another, however their metamodel should remain the same. The game engine components of the architecture is responsible for integrating with other systems. As an example, in this architecture, we show how the game engine is being interfaced with the dialogflow framework of Google assistant and the React framework [21] [22].

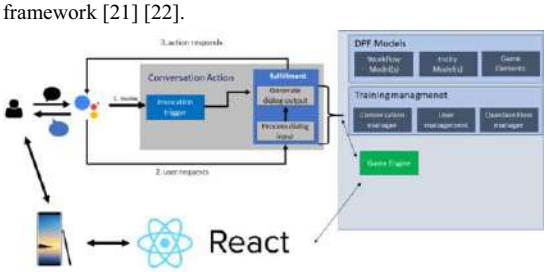

Figure 7: Overall architecture of the MDE approach

Learning Analytics

In our implementation, we utilize learning analytics for providing better training environment for the user. The training program records the history of training sessions. Therefore, we can perform some analysis over the training data such as whether the questions are too easy or too difficult for learners. While presenting questions to the user, the system does not only know how many questions the user has correctly answered, but also the time taken by the user to finish a training session. This allows the trainers to adjust the difficulty of the training sessions. Learning analytics are to identify the part of a training session that students often struggle with and the outcome of a session. A dashboard for the trainers with visualization can then be used to show the progress of the trainees. The goal is to make the training programs adaptable for various levels of difficulty to increase learners' interest to the sytem for practicing use of guidelines. This adaptability cannot be achieved without use of the learning analytics. The application of MDE enables achievement of this requirement as all the training programs share an abstraction. Building a visualization is therefore achievable in general across different training modules. With this model, machine learning techniques can also be applied to automatically adjust the difficulty of training sessions.

Results

The approach we describe in this paper has been materialized through a prototype tool for the gamification of CPGs. The specific use-case we employ is based on asthma care guidelines [23]. The model based approach for game engine allows us to develop and/or customize a new training program by making changes in the model. The MDE approach for modularizing different components of the system and its seperation from the user interaction allows us to integrate with various frameworks of user interaction such as Google's Dialogflow and React Framework [21] [22]. Since the model for the guideline and gamification remains the same, adding various techniques such as mobile-based interaction and voice-based interaction requires very small effort. With the prototype tool we show the potential of using MDE approach supporting different learning style of students. With the proposed idea of applying learning analytics for providing adaptive training to the trainee will provide better training results.

One indirect result of our approach is the support for innovating technologies. The generalized game engine can be integrated with new platforms such as Amazon Echo, integration with IoT devices that are used in clinical setup e.g., robot doll patients.

Another result is the support for ICT research in the training of practitioners. Data science and machine learning techniques can be used to understand the learning pattern of students and adapt them for better learning outcome.

Discussion

This work presents a model-driven approach to the design of an elearning system for clinical guidelines. Most current research on the use of gamification in medical education is focused on the effect of the educational games in knowledge and skill acquisition and on their acceptability. Akl et al present an educational game for teaching clinical practice guidelines to internal medicine residents [24]. In their description, domain experts developed multiple choice questions based on clinical guidelines which were then uploaded into the system via a question editor. This approach is inefficient in both the manual development of questions, and in the static nature of available questions. Our model-based approach allows for questions to be generated automatically, and the learner analytics platform helping to adapt the questions to the strengths and weaknesses of the learner. The automation of different aspects of the system means that once it is set up, it will require minimal resources to maintain, hence saving costs.

Our modular approach provides several other advantages. It makes it easier to update guidelines as only parts of the entity and workflow models change while the rest of the system remains the same. It is flexible also enough to allow for integration with various devices supporting different means of user-interaction and the abstraction of the clinical processes allows for the representation of any guideline. Further, the use of gamification will potentially enhance the learning experience by increasing student engagement with the learning material as reported in several studies [11,17,25].

There are a number of limitations to the gamified elearning system we describe in this work. First, full training of guideline content that requires the learning of some physical skills - such as performing cardiopulmonary resuscitation (CPR) – cannot be fully performed using our system as our system can only train on guideline content that do not require hands on training. Secondly, dissemination and implementation of clinical guidelines is a continuum that cannot be separated. Our system only addresses the dissemination half of that continuum and is not enough to bridge the gap between recommended and actual practice. Finally, there are several non-technological barriers to adherence to clinical practice guidelines, [26] and our system only addresses two of these barriers: lack of awareness and lack of familiarity with the guidelines.

In the near future, we plan to enhance our prototype tool for the development of other clinical guidelines. We wil also evaluate the acceptability and effectiveness of the proposed technique as a dissemination strategy for clinical guidelines within resource-limited settings.

Conclusions

We set out to design a gamified e-learning system for the training of clinical practice guideline content. Our approach allows for a flexible, adaptive and potentially cost-effective e-learning system.

Abstract

Electronic Health Records (EHRs) are at the heart of reforms aiming for improving the efficiency and quality of citizens healthcare services. Although there is still some skepticism, open source (OS) EHR is a growing phenomenon in health informatics. Given the widespread adoption of OS software (OSS) in several domains, including operating systems, and enterprise systems, the repeated shortfalls faced by healthcare organizations with dominant proprietary EHRs create an opportunity for other alternatives, such as OSS to demonstrate their abilities in addressing these well-documented problems, including inflexibility, high costs, and low interoperability. However, scholars have expressed extensive concerns about the sustainability of OS EHR. Recognizing that OSS project sustainability relies on their governance arrangements, this case study reports on the evolution of the governance and sustainability of a Japanese OS EHR project and provides rich insights to other open source EHR initiative stakeholders, including physicians, developers, researchers, and policy-makers.

Electronic Health Records, Japan, Medical Informatics

Introduction

In order to deal with the unsustainable increasing cost of health care, aging population, and chronic diseases burdening their population, all industrialized countries are investing in Electronic Health Record (EHR)[1]. However, Health Care Organizations (HCOs) have been slow to implement EHR in most OECD countries because of their high cost. In addition, the large majority of HCOs have adopted proprietary EHRs and are facing repeated shortfalls with those tools, including dissatisfaction with costs and interoperability issue [2]. This situation creates an opportunity for Open Source Software (OSS) to demonstrate its abilities in addressing those challenges. In the context of Japan, the Japanese Medical Association (JMA) estimated that EHR implementation costs in all medical providers would amount to US $180 billion over a 10-year period, which is not affordable for Japan without a significant reduction in costs. JMA also suggested the implementation of OSS as one of the options to overcome the obstacle [3]. However, although open source projects have been launched at a rapid pace in a growing number of medical clinics and hospitals, scholars expresse extensive concerns about the sustainability problem [4]. Thus, it's paramount to understand the factors that may impede wide adoption of the open-source medical informatics tools.

Recognizing that OSS projects governance affects the project sustainability [5], we report on a case study of the governance and sustainability of OpenDolphin, a Japanese open source EHR project. The source code can be found on GitHub: https://github.com/dolphin-dev/OpenDolphin. A screenshot of the OpenDolphin interface is presented in Figure 1.

Figure 1— OpenDolphin Interface

This study was guided by the following questions: (1) how did the governance of OpenDolphin EHR evolve over time?; (2) how did the governance of the project enable or constrain OpenDolphin EHR sustainability?

Conceptual Background

The framework is adapted from de Laat [6] three stages (see Figure 2) and Markus [7] governance dimensions (e.g., vision and goals, ownership of the assets, etc.).

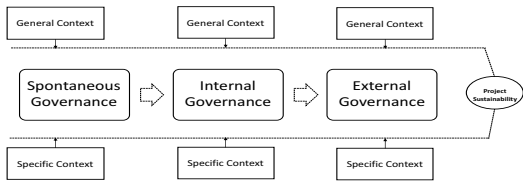

Figure 2— Research Framework

General Context of Healthcare in Japan

Over the past decades, the Japanese healthcare system has been cost efficient and achieved significant progress in terms of life expectancy, infant mortality, and the eradication of communicable diseases [8]. Moreover, whole system reform has been undertaken in order to preserve its in the future [9], and the promotion of Medical ICT is one of the pivotal measures in the growth strategy of the Abe Government known as "Abenomics" [10].

Specific Context of Medical Technology in Japan

In order to deal with the challenges associated with the countrywide plan of health IT diffusion, the JMA declared its intent to develop OSS as their "infostructure" in 2000. This momentum towards OSS has influenced the development of OSS projects in the medical field in Japan, including the OpenDolphin project. Overall, the adoption of EMR by medical

providers in Japan is imbalanced. Whereas the adoption rate is about 70% for large hospitals (>400 beds), it is below 14% for small hospitals (<200 beds) [11]. Thus, Japan lags behind when compared with other OECD countries. The prevalence of electronic health record in clinics in Japan is low and is estimated to be 16.5% [12] then about 30% [11]. Overall, the lack of financial resources is one of the most important barriers to EHR adoption [11].

Methods

OpenDolphin EHR was developed within the Dolphin project. It's an open-source client system for regional health information systems as a response to the recognition of the inability of the Japanese marketplace to sustain the objective of 60% of diffusion of EHR in Japan within 5 years, as announced by the government [13]. The main contributor to the development of OpenDolphin is OS-Service Corp, a for-profit organization; and as of 2017, the system was used by over 300 clinics in Japan.

We relied on five sources of evidence: semi-structured interviews, written documents, a short questionnaire, and field notes from researchers. In addition, all research team members participated in a conference organized by the JMA and related to open health informatics in Tokyo.

In total 7 key informants from the OpenDolphin community were interviewed (see Table 1). In-depth semi-structured interviews were deemed appropriate for this study because it focuses on perceptions and meanings of informants [14]. The same interview grid was used for all interviews and covered questions related to the theoretical framework. Each interview lasted on average one and a half hour. During the interviews, the research team took notes that were later developed into detailed field notes. A short questionnaire was used to collect demographic and factual information.

Table 1—Informants Characteristics

Name	Role/Education	ODolph	OSS	HIT

Data analysis started as soon as data collection began and was conducted in an iterative manner, mainly based on the fundamental principle of the hermeneutic cycle [15]. Given that we aimed to understand the governance and its implication for the sustainability of OpenDolphin 'through the meanings that informants assign to them' [14], we read to get familiar with the collected materials. More specifically, interview transcripts were read by moving back and forth between the whole and parts of the studied phenomenon. In the same manner, interview transcripts were read between informant statements and the research framework. After several iterations, we applied data display techniques [16]. Then, a narrative approach was employed to describe the case in the form of a 'narrative report' [17] that helped us to develop an in-depth and global view of the OpenDolpin history, governance, and sustainability.

Results

We draw on the conceptual framework to present the results.

Phases 1 and 2: Spontaneous and internal governance

The development of OpenDolphin project began in 2001, following a tender launch by the Japan Ministry of Economy, Trade and Industry (METI) and targeting regional medical associations. In Japan, medical associations are built upon a three-layer model corresponding to the architecture of the country's administration [18]: the regional medical associations at the regional level, the prefectural medical associations at prefectural level, and the Japan Medical Association at the national level. All these organizations operate cooperatively, yet each and everyone has an autonomous structure.

The tender was awarded to the "Dolphin project" led by a consortium formed by three universities (Miyazaki University, Kumamoto University, and Kyoto University) and one regional medical association (Tokyo Medical Association). They received a fund of 60 million yen—about $570,000 US. One of the key reasons why the consortium won was that it proposed to adopt the Medical Markup Language (MML) for the Dolphin project, so as to facilitate the exchange of data between EHR systems within regions and beyond. In fact, MML was developed in order to generate a set of standards through which medical data, within Japan and hopefully internationally, can be stored, accessed, and exchanged among different physical locations [19]. The MML was created in Japan from research and funded by the Japanese Ministry of Health and Welfare [20].

Vision and Goals. From the outset, the OpenDolphin project's goal was to electronically emulate the user experience of the paper medical record at a low cost. However, instead of trying to simply achieve a high level of functional coverage, the goal was to create good user experience emphasizing simplicity, ease of use, and usability. In addition, OpenDolphin was envisioned to be compatible with different operating systems used by clinics in Japan. A statement from Akyo (a fictitious pseudonym given to the main contributor to the initial project) illustrates the vision: we wanted to have a "*clinical user-oriented EHR with UX [user experience] resembling that of a notebook*".

Ownership of the Assets. The ownership of the asset was sealed by the grant awarded by the METI, which requires the research output and the software, to comply with a Bayh-Dole Act-like regulation adopted by Japan in 1999. The Bayh-Dole Act is a US federal legislation enacted in 1980 and co-sponsored by Senators Birch Bayh and Robert Dole. It allows universities, nonprofit research institutions, and small businesses to own, patent, and market any inventions resulting from federally funded research programs within their organizations [21]. Hence, the GNU General Public License (GPL) version 2 was the *de facto* choice.

Software Development Processes. The project started in 2000, following a requirement specification stage that took about half a year, which was followed by a software development stage with two full-time developers, including one senior (here identified as Akyo) and one junior and lasting about a year. Afterward, about six months later, the junior developer left the project and from then on, the senior developer took charge of all the software development tasks. The software was delivered to the research team in 2001 and was released to the public the same year. Another principle that guided the development of

OpenDolphin was "*DIY (Do It Yourself)*". This principle stemmed from the fact that, according to Akyo, "*there are various doctors with different needs, so the project needs to work as a platform on which DIY (Do It Yourself) offers solutions to the needs not answered by the project as-is when created*".

Community Management, Leadership, and Finance. During this first phase, Akyo was the only contributor for OpenDolphin. However, due to the newness of OpenDolphin EHR and the absence of a community of users and developers, it was adopted by 23 clinics. The revenue generated from the services related to adoption and the use was not enough to support Akyo as a professional software developer. He left and started to conduct small business activity. At that time, the fees for services related to OpenDolphin was entirely at Akyo's discretion. Meanwhile, four medical doctors from clinics that adopted OpenDolphin started to contribute to software development at a very high level of expertise, including developing new functionalities.

Use of Information and Tools. At this stage, the following tools were used: Repository: GitHub (dolphin-dev/OpenDolphin); Development tools: NetBeans, SourceTree, SublimeText, TeraTerms, BitBucket (only for certain parts of the software).

Given the small size of the community, only Twitter and Email were used to communicate with other actors. According to Akyo, during this stage, he was the only person who could answer the coming questions by email.

Technologies and Translation Language. The selection of technologies was guided by key principles, including high interoperability, freedom, and low cost. Hence, the following technologies were selected: database (PostgreSQL), development language (Java), application server platform Wildfly (JBOSS), and client application (Apache MAVEN for XML). At this stage, OpenDolphin was available only in Japanese.

During this stage, the OpenDolphin project accomplished some achievements that confirmed its position as a promising open source EHR: (1) the successful connection with ORCA (Online Receipt Computer Advanced) system in 2001; (2) the release of a MacOS version in 2006; (3) the launch of an ASP service in 2007; (4) the achieved compatibility with the iPhone and the iPod Touch in 2009.

Phase 3: External governance

As of 2009, OpenDolphin has a small community of developers, users, and support providers. The same year, OS-Service Corp, one of the support providers who have been involved with OpenDolphin for few years, suggested cooperating with Akyo for the aim of "scaling up the services related to OpenDolphin". Thus, Akyo joined OS-Service Corp and the OpenDolphin project moved from a community-managed to a corporate-managed governance model. Since assuming responsibility for OpenDolphin formal governance, OS-Service Corp has been taking or planning to take new initiatives aimed at developing and sustaining the OpenDolphin project and products.

Vision and Goals. OS-Service Corp is planning to create an EHR with a combined hospital management system (HMS). According to Akyo, historically, HMS has been the foundation upon which the EHR system is installed. He indicated that they are considering the opposite, in other words, to have the EHR as the foundation system, and implement the HMS functionality on top of that.

Ownership of the Assets. In the meantime, the license had been moved from *GNU General Public License (GPL) version 2 to GPL version 3*. In order to develop its business, OS-Service Corp created a new version of OpenDolphin named OpenDolphinPro, a more commercial version that is also distributed under GNU GPL license. OpenDolphiPro is packaged with services provided by OS-Service Corp.

Software Development Processes. With the arrival of OS-Service, the software development team increased to eight with four internal developers within OS-Service Corp and four medical doctor users who contribute actively at a very high level of expertise.

In order to improve the sustainability of the OpenDolphin project, OS-Service Corp is moving from JBoss AS (Application Server) 6 to server 7. In fact, the development of JBoss AS 6 has been stopped. JBoss AS 7, now known as WildFly, is a complete rewritten server that is faster and easier to configure. With the intention of reducing the risk related to this technological transition, OS-Service Corp has partnered with Red Hat Corporation in Japan in order to use their deployment methods and development environments as references. In addition, OS-Service Corp has introduced an agile development method to improve the efficiency, as stated by OS-Service Corp manager: "We are employing an agile development method where the project manager goes through the details of every request, and uses them to assign required members to do the development. Because of this, we do a much faster implementation than development, based on the waterfall model".

OS-Service Corp has also implemented a formal process for handling requests from clients. There is now a dedicated customer support division that collects detailed requests from the users, and passes the requests on to the development division after deciding on the design through meetings. The new functionalities ensuing from these endeavors are generally implemented in OpenDolphinPro and released as minor updates. Thereafter, these functionalities are integrated into the regular OpenDolphin version.

Base on their experience, the OS-Service Corp team stated that "having the software always up to date is ideal. However, given that OpenDolphin differs from web applications (in the sense that clinics have source code updated at different levels), there is a need to consider the special circumstances from each individual clinic". In order to properly manage this situation, the decision to update the software for a clinic is made by the customer support division based on the assessment of each clinic's environment and structure.

Community Management, Leadership, and Finance. At this stage, the number of resellers nationwide is increased to 27. The OpenDolphiPro sold by reseller is packaged with services provided by OS-Service Corp. Since the initial release, OpenDolphin has always been sold by salespeople who directly visit the target clinics. However, according to OS-Service Corp, from this point on, the company will put more emphasis on the cloud version of OpenDolphin. Accordingly, the company is swiching to a digital strategy and expecting to sell faster than the past. In fact, between 2009–2016, with one sales executive, OS-Service Corp was selling at a rate of 30–40 clinics per year through clinic visits and sometimes 50 clinics a year. The sales target of the cloud version is set at 100 per year. It's worth mentioning that the sales executive has left the company and since then, OS-Service Corp is struggling to attract new clients.

At this stage, it important to mention that, OS-Service Corp is just above the break-even point and the management team is taking various initiatives with the expectation to depart from that. The break-even point is reached when a company's total costs equal its total revenue.

The management of OS-Service Corp has come to realize the need to create a partnership with various actors in order to

increase its community at large. One of the initiatives planned is to connect with the Medical Open Source Software (MOSS) meeting held twice a year in Japan which brings together medical informatics experts, advocates, and supporters.

Use of Information, Communication, and Tools. The tools in use at this stage are the same as the previous one. Repository: GitHub; Development tools: NetBeans, SourceTree, SublimeText, TeraTerms. Whereas the OpenDolphin version is managed on GitHub, the OpenDolphinPro is managed on OS-Service Corp premises.

Technologies and Development Language. As stated earlier, OpenDolphin client was written with Java but the client rewritten in JavaScript. This initiative stems from the fact that JavaScript is primarily a client-side scripting language designed to run in the internet browser without having to be compiled like Java. In addition, OS-Service Corp is planning to add artificial intelligence (AI) components in OpenDolphin. Regarding to language translation, OS-Service Corp is planning to develop an English version of the software so as to move into the international market and extend its market reach.

During this stage, the OpenDolphin project made some achievements that confirmed its position as a promising open source EHR: (1) the release of a comprehensive documentation named OpenDolphin Perfect Guide in 2016; (2) the release of three iOS apps (DolphinPro, VisitTouch, Super EHRTouch); (3) the launch of authentication based on SSO (Single Sign-On); (4) the establishment of compatibility with iPads in 2010; (5) obtaining the status of certified partner solution for IBM Japan in 2011; (5) the completion of connection between ORCA and OpenDolphin cloud solution in 2013; (6) the celebration of the 10th anniversary OpenDolphin cloud ZERO (pay-as-you-go system) in 2014.

Among the most important achievements is the fact that, even if OpenDolphin EHR was at first targeting medical clinics, it has successfully expanded its market share from small hospitals.

Discussion

Open source software is recognized as a growing phenomenon with a promising potential in the medical informatics field. Nonetheless, scholars have expressed extensive concerns about open source software sustainability [4]. Although the body of knowledge related to open source in health informatics has kept growing, there have been few empirical investigations of open source clinical information systems in the context of industrialized countries outside of the western world. Our study reports on an empirical instance of open source EHR that is developed and used in an industrial country outside the western world. It contributes to deepening our understanding of the governance evolution of OS EHRs and how it enables or constrains the sustainability of the OS projects. Our results reveal that the model provided by de Laat [6] is useful in explaining the evolution of the governance of OpenDolphin. However, we are able to match only two phases out of the three suggested by the model, as the first two phases are difficult to separate in the case of OpenDolphin.

Our data reveal that the turning point from the "spontaneous and internal" governance phase to the "external governance" was triggered by the concern about the sustainability of OpenDolphin. In fact, by the time Akyo received OS-Service Corp's offer, he had already noticed the ineffectiveness of the governance model, even though the main concern of OpenDolphin during the first phase was related to the inefficiency of the business model.

Watson and Boudreau [22] distinguished four different business models of OSS production or distribution: open community, corporate distribution, sponsored OSS, and second-generation OSS. Open community is a model for which the development and support of the software mainly rely on volunteers with limited commercial interests, while corporate distribution is a model that takes advantage of quality products developed by open community models, "improving distribution methods for these products, and providing complementary services in order to make these OSS products more accessible to a broader market." [22]. Examples of such models include RedHat and SpikeSource. Sponsored Open Source is models of OSS projects sponsored by corporations or foundations or both. Examples of such models include Apache Web Server with Apache Foundation and Eclipse with IBM. The second-generation model is also known as professional open source—is composed of firms that are considered hybrid because their models are between a corporate distribution and sponsored OSS. Of note is the fact that second-generation firms "typically own or tightly control the software code and can exploit their intimate knowledge of the code to provide higher-quality service that could potentially competing service providers" [22]. Examples of such open source projects include MySQL and JBoss.

The deal with OS-Service Corp had an impact that went beyond the business model and *de facto* induced new governance arrangements. The analysis also reveals a high degree of dependency between the business model and the governance model. It also suggests that, during the first phase, OpenDolphin was a technological success but not an economic success. Of note is the fact that, during the first phase of governance, the community of software developers has never really grown beyond Akyo. One possible explanation might be that there were few initiatives undertaken to attract contributors. OS-Service Corp brought the needed resources to sustain technological success and convert it to economic success. Our data reveals that the involvement of OS-Service Corp has altered the "business model" of the OpenDolphin project, moving it from "open community" to "sponsored OSS project" as explained below.

At the beginning of the third phase, OpenDolphin has experienced rapid growth by attracting a large number of clinics each year (30–40 per year through clinic visits). However, since the departure of the sales executive who was in charge of sales, OpenDolphin growth has been stagnant, despite sales activities being managed by OS-Service management. Even if the stagnation can be partially attributed to the departure of the sale executive, OS-Service management feels the need to make some changes in the way they deal with their main market segment formed by a medical clinic. In fact, OpenDolphin situation is surprising for at least five reasons: (1) the OpenDolphin EHR seems to be appreciated by medical doctors who are using it; (2) the market has a great potential for growth due to the low rate of adoption of EHR by medical clinics in Japan (about 30%); (3) the rate of adoption of EHR by newly opened clinics is high (about 80%); (4) the choice of OSS by the Japan Medical Association as their "infostructure" in 2000 and the release of ORCA, an open-source software used by medical clinics in Japan, has created a fertile ground for OS to expand at least in primary care organizations; (5) OpenDolphin was created as part of a project led by regional medical associations, which gives it a certain level of proximity to the medical field in Japan.

Going back to the stagnation of the OpenDolphin growth, our informants identified a characteristic of the local market that may explain why OpenDolphin, a product that meets the needs of medical clinics and does so at a low cost, is struggling to

attract newly opened medical clinics, knowing that the cost is one of the main barriers to the adoption of EHR by small hospitals and clinics. In Japan, a consultant on behalf of a medical doctor usually handles the process of opening a new clinic. Since consultants' fees are calculated as a percentage of the total costs of the project, including the costs associated with the acquisition of an EHR, consultants may have the tendency not to recommend OpenDolphin because of its low cost.

In order to strengthen the sustainability of the OpenDolphin project, the management at OS-Service Corp has decided to put more emphasis on the OpenDolphin cloud and digital marketing, with the aim of attracting more medical clinics. The management team seems to recognize the limitation of both the current business and the governance models. The initiatives they are undertaking may substantially alter the governance and the business models, hence the question arises as to whether other options may exist, in terms of governance models and other business models from which OpenDolphin can choose. When contrasting OpenDolphin characteristics with the four open source business models suggested by Watson and Boudreau [21], it's illuminating to recall that OpenDolphin goes through two of them (the community model and Corporate Distribution model). Given that the Second-Generation allows the firm to own or tightly control the code source, this option does not apply to OpenDolphin because of the characteristics of the GPL license. Hence, within our theoretical background, the only remaining option is the Sponsored model. If OpenDolphin has to become a sponsored project, OS-Service Corp may become the corporate sponsor in the first case or be associated with a foundation in the second case. Each of these options will allow OS-Service Corp to share the costs of developing new functionalities.

Overall, the governance of the OpenDolphin project has evolved as a consequence of the alteration of its business model so as to strengthen its sustainability. However, the results appear to be mixed. It does not seem easy for OS-Service Corp to handle, by itself, all the challenges faced by OpenDolphin. Our study reveals that it is not only the management of OS-Service feeling the needs, but also some of the elements are already in place waiting to be highlighted and combined in order to create an OpenDolphin ecosystem that will help strengthen its sustainability. This ecosystem may include OSS experts, advocates, and supporters among both health IT decision makers and Health IT policymakers.

Conclusions

Our results indicate that governance does enable or constrain the sustainability of OpenDolphin but, considering the business model also provides a broader understanding of the sustainability of the OSS project. One of the main limitations of this study is related to the methods, this is an interpretive single case study. Thus, caution should be exercised in interpreting these results in other contexts.

Fit Between Individuals, Tasks, Technology, and Environment (FITTE) Framework: A Proposed Extension of FITT to Evaluate and Optimise Health Information Technology Use

Mirela Prgomet[a], Andrew Georgiou[a], Joanne Callen[a], Johanna Westbrook[a]

[a] Centre for Health Systems and Safety Research, Australian Institute of Health Innovation, Macquarie University, Sydney, Australia

Abstract

Evaluating and optimising 'fit' between technology and clinical work is critical to ensure the intended benefits of technology implementations are achieved. Using a mixed method approach (structured observation, interviews, field notes) we collected data regarding users, tasks, technology, and factors impeding technology use from a sample of 38 clinicians on two wards at an Australian hospital. We used the FITT framework to assess the relationships between users, tasks, and technology.

Our findings showed that even when adequate fit between users, tasks, and technology was attained additional factors related to the environment (including the temporal rhythms of a ward, infection control rooms, or space limitations) ultimately affected technology use. Thus, we propose the fit between individuals, task, technology and environment (FITTE) framework as a means to evaluate and optimise technology use by explicating the relationships between users, tasks, technology, and the environment in which they operate.

Introduction

Health information technologies (HITs) undoubtedly have the potential to make care delivery more efficient and effective. However, HITs can also result in unintended consequences, including: unfavourable workflow issues; paper persistence; changes in work practices (such as altering of the pace and sequencing of clinical activities); and only partial support for the information needs and work practices of clinicians [1; 2]. Researchers indicate that the 'fit' between technology and clinical work is what leads to HITs being either used and incorporated into routine, worked around, or rejected [3]. Where there is a mismatch between technology and work practices, the intended benefits of the HIT may not be achieved.

Research investigating fit between technology and clinical work has, by and large, focused on software applications with limited consideration regarding hardware computing devices. In order to achieve optimal beneficial outcomes from HITs, it is also essential to ensure the right fit of hardware devices. Fixed computing devices, such as desktop computers, may constrain the work practices of clinicians by mandating where information can be accessed or documented. Mobile computing devices, on the other hand, are not tied to one location but rely on battery and wireless connectivity, and have different screen sizes and data input mechanisms (keyboard, stylus, and/or touchscreen), all of which impact their usability. Considering that computers play an integral part in the success of software implementations, how fixed and mobile devices fit into and support clinical work practices warrants attention.

Theoretical Frameworks

The Technology Acceptance Model (TAM) and Task-Technology Fit (TTF) model are two prominent theories that describe potential means by which to explore the notion of fit between technology and work practices. TAM has been widely used in health care and employs the constructs of perceived usefulness and perceived ease of use as determinants of: attitudes towards using technology; intention to use technology; and the actual use of technology [4]. Findings from Holden and Karsh's seminal review of TAM, and its application in health care literature, underscored TAM's value as a theoretical framework to assess the relationship between users and technology [3]. However, the review also pointed to the need for additional constructs to allow for further relationships to be explored. Dishaw and Strong, likewise, highlight that a shortcoming of TAM in aiding understanding of the use of technology may lie in the absence of an explicit construct examining tasks [5]. They indicate that, unlike TAM, the TTF model provides explicit inclusion of a task–technology construct.

The TTF model looks at task characteristics and technology characteristics, which together determine task–technology fit and influence technology utilisation [6]. The premise of the model is that technology will be used if it adequately supports the demands of a task. In applying the TTF model to assess the fit of a picture archiving and communications system (PACS), Lepanto et al. concluded that "TTF is a valid tool to assess perceived benefits, but it is important to take into account the characteristics of users" [7]. Others have similarly indicated that a limitation of TTF is that it does not explicitly include a construct that examines user characteristics [5].

Ammenwerth et al.'s propose Fit between Individuals, Tasks, and Technology (FITT) as a framework that encompasses the interactions of users and technology (i.e. TAM concepts) and tasks and technology (i.e. TFF concepts), and the interaction between users and tasks [8]. FITT was developed specifically for the health care domain and was based on an analysis of literature on technology adoption. FITT posits that the use of technology is dependent on the fit between the attributes of the individuals (users), attributes of the tasks, and attributes of the technology.

The framework defines individuals as either an individual user or a user group. Examples of user attributes include: knowledge of the technology; motivation to execute tasks; openness to new ways of working; cooperation within a team; and organisational context. Tasks comprise whole tasks or work processes (such as, documentation or order entry), the attributes of which can

include: organisation of tasks; activities and their interdependence; and task complexity. Technology is defined as any tool required to execute a task; encompassing both computer-based and paper-based tools. Examples of technology attributes include: usability of the tool; functionality of the tool to support a given task; integration of tools; and availability of tools. Where fit between attributes of the users, tasks, or technology is lacking, problems with the adoption of technology arise [8].

The article where FITT was introduced was focused on a retrospective analysis of a case study that assessed the adoption of a nursing documentation system in three wards to test and validate FITT [8]. Application of FITT was shown to facilitate understanding of the relationships between users, tasks, and technology, and the factors leading to either the failure, or the successful adoption, of technology in each ward. For example, a factor that affected overall fit in the paediatric ward was identified as the fit between tasks and technology dimension, whereby the unavailability of mobile computing devices or fixed computing devices located at the patient bedside disrupted the workflow of nurses who were accustomed to undertaking documentation at the patient bedside. By pinpointing the issues affecting the use of technology, FITT helped to determine areas where changes could be introduced in order to optimise fit.

The aim of our research was to (i) evaluate clinicians' use of fixed and mobile computing devices using the FITT framework and (ii) identify factors affecting the optimal use of devices.

Methods

A mixed method approach comprising structured observation, interviews, and field notes was used for data collection. Observation can be particularly valuable for determining whether technology is used in expected or unexpected ways, while interviews can complement observation by providing clarification about what was seen in the field.

Data collection was conducted on two wards (a surgical and a general medical ward) at a 320-bed teaching hospital in Sydney, Australia. The hospital had several HITs, including: an electronic medical record (for documenting discharge summaries); computerised provider order entry (for test ordering and results viewing); an electronic medications management system; and PACS. Tasks such as recording vital sign observations and progress notes were paper-based. Both fixed (desktop computers) and mobile computing devices (computers on wheels (COWs)) were available on the wards. Some doctors also had tablet computers that were connected to the hospital's information system.

A paper-based data collection form was developed and used to capture variables regarding users, tasks, and technology, including the: activity being conducted (i.e., ward round, medication round, or outside of round); task being performed (e.g., administer medication, order medication, order test, document progress notes); technology used to perform the task (e.g., desktop computer, COW, paper medical record); and factors impeding the use of technology. The data collection form was also used to document free text field notes and interviews. Definitions for the observed work tasks were based on classifications used in previous observational studies [9; 10].

A sample of 38 clinicians (26 nurses (19 female) and 12 doctors (6 female)) were observed for 90 hours and 45 minutes. Medication administration rounds accounted for 45 hours and 10 minutes, ward rounds 28 hours and 50 minutes, and outside of rounds 16 hours and 45 minutes of the observation time. In total, 4,423 clinical tasks were recorded: 2,321 during medication administration rounds, 1,444 during ward rounds, and 658 outside of rounds. Twenty-seven clinicians also participated in informal interviews, providing explanations regarding observed events.

Clinicians were observed in the course of their daily work (between 7am and 5pm, Monday to Friday). Each observation session lasted a maximum of two hours. There were no set criteria for the selection of observed clinicians; they were chosen at random from those that were on the study ward on any given day that observations were conducted. Informal interviews were carried out opportunistically when clarification was needed and the situation allowed. Ethics approval for the research was obtained from the hospital Human Research Ethics Committee.

The quantitative data were analysed in SPSS using descriptive statistics to calculate frequencies of the collected variables, including: tasks conducted by doctors and nurses; devices used to conduct tasks; and locations in which tasks were conducted. Qualitative data from interviews and field notes were analysed for common themes, particularly regarding the factors affecting device use. FITT was applied in order to assess the relationships between users, tasks, and technology.

Results

FITT: Doctors, Tasks, and Technology

Doctors and Tasks

Doctors' work differed on ward rounds and outside of rounds. Ward rounds were conducted in teams, with doctors moving from one bedside to the next as they reviewed each patient. Ward round tasks occurred across several locations, including the patient bedside, the corridors, and while doctors were in transit between locations.

The main types of tasks doctors conducted on ward rounds included reviewing the patient record, reviewing test results, documenting progress notes, ordering medications, and ordering tests. Outside of rounds, tasks were largely conducted independently and doctors were observed conducting 93.8% (n=212) in a stationary location. The main tasks observed outside of rounds included reviewing the patient record, documenting discharge summaries, ordering medications and ordering tests.

Tasks and Technology

The hospital's hybrid information system required doctors to have access to both computing devices and paper-based medical records. For ward rounds, mobile devices fit the mobile nature in which tasks were conducted by meeting doctors' information needs as they moved throughout the ward. Of the tasks completed on a computer on ward rounds (n=762), almost all were completed with the use of mobile devices (n=759; 99.6%). The mobile cart design of the COWs also provided a convenient means to store items, allowing doctors to transport several paper-based medical records at a time.Outside of rounds, desktop computers provided a better fit. Of the computerised tasks conducted outside of rounds (n=120), the substantial majority were completed on desktop computers (n=116; 96.7%). The desks on which the computers were stationed provided space to set opened paper-based medical records so that paper-based and electronic information could be viewed at the same time.

Doctors and Technology

While conducting ward rounds doctors had one COW to use amongst the team. One of the junior doctors used the COW on the medical ward, while the senior doctor leading the ward round used the COW on the surgical ward. Thus, on the surgical ward, the junior doctors were observed using paper to document

details regarding the test orders, medication orders, or medication modifications and the information was entered electronically after the ward round.

Several doctors expressed a preference for electronically available information ,as paper-based records were often misplaced and time had to be spent searching for them. While searching for a printed pathology form that he ultimately failed to locate, *Doctor 4* stated that a benefit of information being computerised was that the pathology form could have just reprinted. Doctors also reported a preference for accessing electronic information via mobile devices, with two doctors further explaining that they needed mobile devices for ward rounds as their work practices are mobile *(Doctor 1 and 7)*. While doctors said they liked the COWs, many conveyed a desire for tablet computers: *Doctor 3* stated it would be easier to conduct his work with a tablet computer than with the COWs, which were bulky and had battery issues.

FITT: Nurses, Tasks, and Technology

Nurses and Tasks

Nurses were observed to largely undertake their work independely during medication administration rounds and outside of rounds. Nurses on medication rounds were constantly on-the-move throughout the ward, often going from a patient's bedside, to the medication room to obtain medications, and back to the bedside.

Nurses' main types of tasks on medication rounds included accessing information to prepare medications, documenting administration of medications and reviewing patient records. When conducting tasks outside of rounds nurses tended to have a base location (at a desk or parked COW) where they completed most tasks (n=382; 88.4%). The main tasks observed outside of rounds included reviewing the patient record, documenting notes and patient observations (such as vital signs).

Tasks and Technology

As with doctors, the hybrid information system required nurses to use both computing devices and paper-based medical records. Mobile devices suited mobile tasks of medication round by providing nurses access to information while moving around the ward. Of the computerised tasks on medication administration rounds (n=1,966), the substantial majority were completed using COWs (n=1,885; 95.9%). Desktop computers were considered not to be conducive to medication round tasks *(Nurse 2 and 9)* and were rarely used.

Outside of rounds both mobile and fixed computing devices appeared suited to undertaking tasks. Despite the availability of several desktop computers throughout the ward most of the computerised tasks conducted outside of rounds (n=92) were completed on COWs (n=58; 63%),. As tasks conducted outside of rounds were predominantly non-mobile, the COWs were largely observed being used in a stationary manner. Nurses were often observed in the corridor using the COW as a bench to complete paper-based records.

Nurses and Technology

Several nurses perceived that it was quicker and easier to complete tasks using paper *(Nurse 4, Nurse 5, Nurse 8, and Nurse 11)*. Nurses sometimes used a computing device to access information regarding medications, which they transcribed onto paper and then used the information to prepare the necessary medication. Nurses explained that when they only needed to prepare one or two medications (particularly for medications such as paracetamol or vitamins) they found it quicker and easier not to wheel a COW around with them *(Nurse 12, Nurse 20, and Nurse 21)*. Nurses were also observed using printed handover sheets and scrap pieces of paper to document notes, such as self-reminders, or to temporarily document vital sign observations that they later transcribed into the paper-based medical record.

The general consensus, however, was that the computer system, particularly mobile devices, provided several benefits over paper-based medical records. A key benefit identified by the nurses was the ease of access to patient information and clinical information when the need for it arose *(Nurse 12, 13, 15, 16, and 19)*. Not having to carry around several paper-based records at a time, being able to stow other necessary items in the COW (such as medications and wound dressings), and not needing to search paper-based textbooks were also seen as benefits *(Nurse 2, 12, 13, and 15)*. *Nurse 2* explained that if there were special instructions on how to administer a medication then that information would appear on the system next to the medication order, and saved time in not having to look in a textbook. The nurse also liked having a COW to conduct medication round tasks, and preferred to sit down and use the desktop computer for tasks outside of rounds.

Other Factors Affecting FITT: Environment

Temporal Rhythms

The timing of medication rounds and ward rounds and the number of available mobile devices was found to influence device use. On the surgical ward eight nurses concurrently undertook the morning medication administration rounds. As there were eight COWs on the ward, nurses explained that there was competition for the use of COWs for morning medication rounds, as doctors were conducting their morning ward round at the same time. *Nurse 8* referred to this competition as a "battle", which doctors often won. *Nurse 2* reported that when no COWs were available she would use a desktop computer and transcribe details onto paper about patients required medications so that she could take the information with her. She would then prepare the medications, administer them to her patients, and locate an available computing device to document the adminstration of the medications. Doctors similarly conveyed it was sometimes a struggle to access a COW when ward rounds occurred at the same time as medication administration rounds *(Doctor 2, 5 and 7)*.

Space Limitations

During medication rounds, nurses were generally observed positioning the COW beside the patient bedside so that they were in reach of the patient's bedside drawers (where most medications corresponding to the patient's specific needs were kept). However, several instances were observed where lack of space directly beside the patient bedside was an issue and the COW had to be positioned elsewhere in the room. Similarly, doctors on ward rounds would usually use the COW at the foot of the patients' bed but when lack of space directly at the bedside was an issue doctors had to find adequate space to use the COW elsewhere within the patient room.

Infection Control

In instances where the patient was quarantined in an infection control room both doctors and nurses were observed having to use COWs in the corridor just outside the patient's room. This often required them to walk back and forth between the patient bedside and the COW when needing to access or document information.

Low Battery

On occasions when low battery was an issue, nurses plugged the COW into an available power outlet either in the patient room or in the corridor, and moved between the patient bedside and the COW when they needed to access to document information. Doctors were observed plugging the COW into a power outlet in the corridor while they engaged in discussions

in between visiting patients. When moving on from the corridor to visit their next patient, doctors were observed unplugging the COW from the power outlet in order to take the device with them to the bedside despite the low battery.

Discussion

We found that clinicians' use of devices could be largely attributed to a relationship between attributes of the tasks and attributes of the technology. The mobile nature of ward rounds and medication administration rounds suited the mobile nature of COWs, while the substantially less mobile nature of tasks conducted outside of rounds suited the stationary nature of desktop computers. However, this relationship alone did not account for all the device use behaviours that were observed.

Ammenwerth et al.'s fit between individuals, task, and technology (FITT) framework, posits that the optimal use of technology is dependent on the interaction between three key dimensions: attributes of users, tasks, and technology [8]. A distinctive feature of the FITT framework, compared to other theoretical frameworks aimed at understanding technology use, is the emphasis on the interaction between users and tasks and the subsequent impact that this interaction has on the use of technology. Application of the FITT framework in this present study aided in the identification of distinct differences between the attributes of the observed user groups and how they conduct tasks. Nurses were found to largely conduct their work independently and, hence, could select the computing device that they perceived provided the best fit for their tasks. Doctors, on the other hand, worked in teams during ward rounds, thus device use amongst the team was influenced by the team leader. When junior doctors were not the primary users of the COW it meant they had to document patient treatment decisions on paper, which they then had to enter electronically after the ward round. These findings highlight that, irrespective of a congruent relationship between mobile computing devices and the mobile nature of ward rounds, user attributes affected optimal fit. Thus, validating Ammenwerth et al.'s argument about the importance of the user dimension when examining the use of technology.

Nonetheless, even when adequate fit between the attributes of users, tasks, and technology was attained additional factors related to the environment were found to affect the use of technology. Environmental attributes included: department type (levels and timing of ward activities); physical environment (space, layout, power outlet locations); or organisational policies and procedures (infection control requirements).

Environment Factors Affecting Use of Technology

One of the key factors found to affect the use of devices was the temporal rhythms of the ward. When the timing of ward rounds and medication administration rounds coincided it resulted in more clinicians requiring the concurrent use of COWs than were available. Nurses that were not able to access a COW reported instead having to use a desktop computer. As desktop computers were not available at the patient bedside, where information was largely needed during medication administration rounds, nurses would transcribe information from the desktop computer onto paper. Although transcribing allowed information to be taken to the bedside it also introduced the potential for errors, as well as negatively impacting efficiency as a result of the additional documentation.

The presence of infection control rooms on a ward was also found to affect the use of devices. In cases where a patient was isolated, clinicians could not take the COW into the room. Instead they had to leave the COW outside the room and walk between the patient bedside and the COW when needing to access or document information. Similarly, battery issues and lack of space at the bedside, often due to the presence of other medical equipment or furniture, impacted clinicians' ability to use COWs at the bedside. Andersen et al., who observed clinicians' use of devices on hospital wards, similarly found that lack of space was a critical factor preventing the use of COWs at the patient bedside [11]. A survey of nurses reported that a lack of space resulted in the need to undertake double documentation: using paper to document information at the bedside and then copying the data onto the COW [12].

The commonality amongst the identified environmental factors is that they restricted the ability of clinicians to use COWs at the patient bedside and, hence, impacted on the use and optimal fit of computing devices. This meant that, not only were the benefits associated with having a mobile device at the bedside, such as ease of access to information, subsequently lost but the potential for errors was introduced due to clinicians having to work around the restraints imposed by these factors. Often temporary paper resources, such as nurses' handover sheets or scrap pieces of paper were used as an interim means by which clinicians overcame factors affecting the use of computing devices. Examples included nurses transcribing information from desktop computers onto paper when COWs were unavailable or junior doctors' documentation of treatment decisions when senior doctors were using the COW. Temporary paper resources used in such instances have been described as "transitional artefacts" which are used to bridge a gap between clinical workflow needs and formal electronic documentation [13]. The persistence of temporary paper resources in such cases could potentially be decreased, or even eliminated, by addressing environmental factors hindering direct electronic information access or input. For example, evaluating ward activities to identify peak periods of demand for technology and either ensuring sufficient device availability or adjusting the timing of activities. Similarly, providing a dedicated device, that can be sanitised, within each infection control room.

Extending the FITT Framework: FITTE

The above findings highlight the importance of examining environmental factors as an entity in and of themselves and suggest the need for an extension to the FITT framework. While the dimensions of individuals, tasks, and technology were found to be critical in assessing fit, ultimately it was factors within the environment, such as the temporal rhythms of a ward, the presence of infection control rooms, or space limitations, which influenced the optimal use of technology. Presently, the FITT framework enmeshes factors related to the environment (or context) of a setting as an intrinsic part of the user attribute. Yet, context is recognised to be a critically important factor affecting the use of technology [14; 15].

The addition of a separate and overarching "environment" dimension to the FITT framework would aid in the assessment of factors related to the context in which users, tasks, and technology operate. Thus, we propose the FITTE framework: whereby optimal adoption and use of technology is determined by the fit between individuals, tasks, technology and environment (Figure 1). The distinction of environment as a separate dimension is necessary as it is likely that this is where the key differences between different sites and settings lie. As such, an environment dimension may help to explain why a technology that works in one setting does not show the same success in another setting. Future research could look at using a multi-dimensional work observation tool, such as the Work Observation Method By Activity Timing (WOMBAT) [16], to obtain data about users, tasks, technology and environment that could be evaluated through the lens of the FITTE framework.

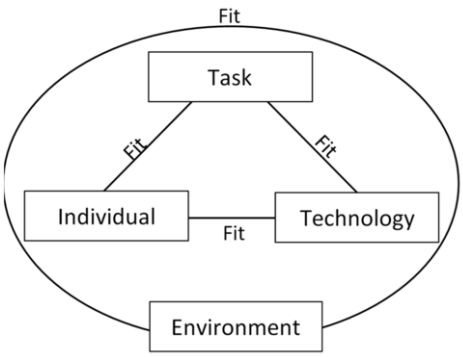

Figure 1 – FITTE Framework: Optimal Adoption and Use of Technology Depends on the Fit between Individuals, Tasks, Technology and Environment.

Limitations

As with any observational research there is a possibility of introducing the Hawthorne effect, where participants modify their behaviour in the presence of the researcher. While it cannot be known whether participants changed their behaviour, given that the focus of the study was examining how computing devices fit clinicians' work and that no assessment of quality was being made, any magnitude of behavioural change is likely to have had minimal influence on the study findings.

Conclusions

Due consideration needs to be given to all the factors that may affect device use, as technology can significantly impact the efficiency and effectiveness of clinical work practices, both in intended and unintended ways. In particular, it is important to identify the environmental nuances that may affect the ideal fit of computing devices. The FITTE framework provides a means to evaluate the use of technology by explicating the relationships between users, tasks, and technology, and the environment in which they operate to identify factors leading to either the failure of or the successful adoption of technology.

Abstract

This study aimed to explore the use and expectation of smartphone applications about pregnancy among pregnant women using a survey method. A total of five hundreds pregnant women from 3 hospitals in the city of Chengde in hebei province in China were randomly selected to conduct a questionnaire survey. The study found that 61.48% of pregnant women used at least one pregnancy apps, mainly for fetal development information (83.3%) and maternal changes information (65.3%); only 8% of pregnant women worried about the security of personal information very much. The main expected functions of pregnancy apps are prenatal examination reminder (65%) and fetal monitoring (54.7%). Also, 77.3% of pregnant women hoped that information provided pregnancy apps should be recognized by relevant authorities. It indicated that pregnancy apps in the market in China was not able to meet the needs of pregnant women and needed further improvement in future.

Keywords:

Pregnant women; Smartphone; Mobile Applications

Introduction

In 2013, WHO listed "using mobile health applications (apps) to provide health education and behavior promotion for patients" as one of the twelve functions of mobile health [1]. In 2015, China government put forward "Internet plus" action plan and in 2016 "healthy China 2030" program outline also led the medical, nursing and other industries to use Internet information technology to promote health reform and improve public health literacy.

In recent years, with the implementation of the "comprehensive two-child" policy and the popularization of the concept of eugenics in China, the large group of pregnant and lying-in women in China will have a strong demand for health care professional guidance in the next years. As information technology play more and more roles in people's daily life, Pregnancy related apps has become one of the convenient choices for pregnant women to acquire health knowledge and promote health behavior.

Researches on apps in smart phone applied to maternal health management has been increasing all over the world since Apple launched AppStore in 2008, but most Chinese studies focused on the introduction, comparison and analysis of the function of these apps [2-4]. While a few studies involve quantitative evaluation of the application effect of such apps [5,6],The studies considering pregnant women's need and using experience are limited.

In view of that, this study investigated the pregnant women's status quo and demand for pregnancy apps, aiming to understand its current situation and existing problems, which can provide reference for future similar researches or further development of high-quality, professional pregnancy apps.

Methods

Sample

In this study, a simple random sampling method was used to select 500 pregnant women who were from 3 hospitals in Chengde from May 2017 to October, and 488 questionnaires were collected effectively, with an effective recovery rate of 97.6%. The inclusion criteria of respondents are: (1) pregnant women visiting obstetric outpatient or inpatient; (2) using smart phones; (3) understanding the contents of apps in smart phones; (4) volunteered to participate in the survey. The human ethics committee of Chengde Medical University Approved the study.

Measurements

Anonymous questionnaire was used to investigate pregnant women's usage and expectation for apps in pregnancy management. The questionnaire was designed on the basis of referring to relevant literatures, and consulting obstetric experts and software engineers. Then, after revising the questionnaire and finishing the test of reliability and validity through pre-investigation, this questionnaire could be applied to the formal investigation. The internal consistency of the questionnaire (Cronbach's alpha coefficient) was 0.781, and the content validity value (CVI) was 0.825. The main contents of the questionnaire include: (1) the general demographic characteristics of the respondents, such as age, occupation, education level, place of residence, pregnancy history, gestational weeks and so on; (2) the usage of apps in pregnancy management; (3) the expectation of apps in pregnancy management.

Data Analysis

SPSS 19.0 statistical software was used to input and analyze data. The statistical analysis methods are mainly general descriptive analysis and chi-square test.

Results

Demographic characteristics

Among 488 respondents, 300 pregnant women (61.48%) had installed and used at least one pregnancy app; therefore, this study only investigated and analyzed the use and demand of pregnancy apps among 300 pregnant women. The demographic characteristics of the total of the 300 respondents are presented

in Table 1. The age of the respondents was 26.74±0.81 years old, between 18 and 38. And 66% of pregnant women had their occupations, while 34% of them were housewives. Outpatient pregnant women accounted for 82.3%, pregnant women from ward accounted for 17.7%.

Table 1. Respondent demographics (n=300)

Age (n,%)	Residence (n,%)	Education (n,%)	gravidity (n,%)	parity (n,%)	Gestational age (n,%)
18-23: 38(12.7)	Rural: 52(17.3)	<Final high school: 36(12.0)	once: 161(53.7)	no: 184(61.3)	<12 weeks: 64(21.3)
24-38: 117(39.0)	Suburbs: 51(17.0)	High school: 69(23.0)	twice: 80(26.7)	1 time: 101(33.7)	13-28 weeks: 110(36.7)
29-33: 97(32.3)	Town: 197(65.7)	Undergraduate: 178(59.3)	3 times: 41(13.7)	2 times: 15(5.0)	29-40 weeks: 126(42.0)
34-38: 48(16.0)		graduate/above: 17(5.7)	4 times and more : 18(6.0)		

Use of pregnancy apps

The Survey showed that 216 (72.0%) of 300 pregnant women who had used pregnancy apps installed one pregnancy app and 84 (28.0%) installed two or more pregnancy apps. The frequency of the use of pregnancy apps by pregnant women was: 60.0% of these respondents had used pregnancy apps every day; 20.3% had used every week or so; 4.6% every month or so; 3.3% only once or twice; and 11.7% of them cannot remember how often they used apps.

Table 2 shows the respondents' reasons for their used of pregnancy apps. The main reason for using an app was to understand the information about fetal development (83.3%) and about changes in women's bodies during pregnancy (65.3%).

Table 2.Reasons for using pregnancy apps (respondents could nominate more than one reason)

Reason for use	n	%
Information about fetal development	250	83.3%
Information about changes in body in pregnancy	196	65.3
Tracking fetus	154	51.3
Tracking own body	108	36.0
Keeping tracking of appointments/ medical information	90	30.0
Continuous recording of prenatal examination results	54	18.0
Online discussions with other pregnant women	51	17.0
Uploading/storing pregnancy photos	5	1.7
Uploading / storing fetal ultrasound images	4	1.3

In addition, 29.67% of the respondents had unloaded pregnancy management apps after installation, and 12.7% of them did not continue to install the new apps. After reinstallation, 87.3% pregnant women still used their apps. The reason why pregnant women unloaded apps were mainly finding better apps (29.2%), fatigue after usage (15.7%), and the anxious or worried content in apps (13.5%). And 11.2% and 10.1% of pregnant women believed that the information provided by pregnancy apps was inaccurate and useless respectively.

The survey found that 40.7% of pregnant women never checked the source and accuracy of information provided by pregnancy apps. When asked whether they worried about their personal information leakage (such as name, identity card number, phone number, address, etc.) during the use of apps

Table 3. The comparison on the degree of concern of pregnant women with different demographic characteristics about the personal information leakage in pregnancy apps (n)

demographics		the degree of concern of pregnant women about information leakage					X^2	P
		never	a bit	medium	very	not sure		
Age	18~23	16	15	3	1	3	14.931	0.245

* P<0.05, there was a statistically significant difference.

or not, 26.7% of pregnant women replied "never worry about it"; 43.7% felt "a little worried", 15.7% "worried generally", only 8% "very concerned", and 6% of them were not sure about this problem. Moreover, there was a statistically significant difference in the degree of concern about the safety of personal information when using apps in different places of residence, educational level and job conditions, as shown in Table 3.

Expectation for a pregnancy app

According to this survey, 96% of pregnant women would like to install a completely free pregnancy app in their phone, and only 4% of them could accept a paid high-quality version of app. For the interface characteristics of app, 62.7% of pregnant women hoped that the interface should be simple and easy to operate, and 36.3% of respondents also desired no-implanted-advertisements apps. Table 4 showed ideal feature in a pregnancy app.

Table 4. Ideal features in a pregnancy app (respondents could nominate more than one feature)

Feature	n	%
Keeping tracking of appointments/ medical information	195	65.0
Fetal movement monitoring	164	54.7
Common symptoms and mitigation methods during pregnancy	137	45.7
making an appointment for registration	131	43.7
Health care guidance for pregnancy, diet, exercise and rest	129	43.0
Information about changes in body in pregnancy and fetal development	112	37.3
Monitoring of uterine contraction	106	35.3
Weight monitoring	97	32.2
Recommending a doctor	64	21.3
Communication platform with other expectant mothers / new mothers	49	16.3
Timely feedback and guidance to users' questions	46	15.3
Entertainment (Mother and baby mall, games)	35	11.7
Name the baby	35	11.7
Predict baby image	27	9.0

In addition, 61.7% of pregnant women did not want the using app involved upload or share personal information, 29.3% of them felt that they were willing to upload or share personal data if the security of user information can be enough ensured. And 77.3% of the respondents hoped that the information provided by pregnancy apps should be approved by the relevant authorities while 16% of the pregnant women did not take this for granted. Moreover, there is no statistically significant difference among pregnant women with different age, educational level and residence on the demand of security, privacy and authoritative information about pregnancy apps.

Discussion

This study showed that utilization rate of apps for pregnant women in Chengde in China was 61.48%, which was lower than that of apps (73%) in Australia in 2016 [7], but higher than that of pregnant women (55.4%) in Korea in 2015 [8] and the utilization rate of pregnant women (59%) in Ireland in 2015 (59%) [9]. In this study, 60% of pregnant women used pregnancy apps every day, while only 26% of pregnant women in Australia used it every day [7]. A qualitative study in Germany showed that 60% of pregnant women used apps (1 times / week) regularly [10]. This may be related to the using habits of mobile phones in different cultures and social backgrounds.

The popular reasons for pregnancy apps was to acquire the information of fetal development (83.3%) and changes of body during pregnancy (65.3%), and 30% of pregnant women used apps to remind prenatal examination during pregnancy Keeping and track appointments, which was similar to the results of survey made by Lupton [7]. The study of Yeonkyu [8] in South Korea indicated that the most frequent use of pregnancy apps among pregnant women tended to be the risk of pregnancy and the symptoms of pregnancy. A study in India also showed that the frequency of mobile phone app used by mothers in families with higher or lower family income was higher than that in families with middle or lower income. It may be due to the fact that high income families were not willing to share their experience with others through mobile apps [11].

Table 2 showed that only 8% of pregnant women were very concerned the safety of personal information when using apps. Moreover, the degree of worry of rural women was lower than that of rural and urban residents. Therefore more attention of pregnant women's privacy and information safety in mobile health needs to be paid, especially in pregnant women with low educational level, full-time mothers and rural women.

In the study, 29.2% of pregnant women had to unload former app if they found better similar app, and 11.2% of pregnant women believed that the information provided by some apps was inaccurate, and 40.7% of pregnant women never checked the source and accuracy of information provided by pregnancy apps. All of these hinted that the quality of apps in Chinese market was not uniform, the users' information security literacy was relatively low, and the lack of relevant apps supervision, management and evaluation mechanism. In 2015, BinDhim [12] and other studies also found that although the US Food and Drug Administration (FDA) and the British National Health Service (NHS) had established a certain health related apps evaluation mechanism, 77% of users did not evaluate the credibility of apps developers, which further indicated the importance and urgency of improving the public's e-health literacy.

Most pregnant women wanted to install free apps for pregnancy management, which embodied the public's need for the accessibility and popularity of mobile health. 62.7% of pregnant women hoped that the interface is simple and easy to operate, and 36.3% of pregnant women also desired that apps would not be implanted with advertisements. A survey in Germany also showed that all respondents preferred an easy-to-use interface in Wed-based applications and did not want to be held up with time-consuming technical issues [10]. A South Korean survey on the needs of pregnant women's dietary guidelines app found that the right age pregnant women had more ability to access to information, higher demand for app's design, convenience and content diversity than those with advanced age [13].

As for the main feature of pregnancy apps, 65% and 54.7% of pregnant women would like to have the function of antenatal examination and fetal monitoring, which was not consistent with the main reasons of apps in the study. This indicated that pregnancy apps in Chinese market had not been yet able to meet the actual needs of pregnant women, present pregnancy apps needed to be further improved. Some similar apps products in

other countries which include gestational apps with increased fetal movement monitoring, uterine contraction monitoring, weight and blood pressure monitoring, and gestational diabetes diet management as well as providing health education for pregnancy.

Yeonkyu's research showed that pregnant women had more needs for expert opinions on diet and drug management in pregnancy apps during gestation period [8]. Two Australian researches also showed that pregnant women had a strong desire for health care information provided by health care professionals and gynecologist experts [14]; and hoped that apps could help them to assess their weight, nutrition and health status and it should be linked to reliable websites, which could provide short answers to their daily concerns [15]. Molly's study showed that 89% of pregnant women had a clear desire to use smart phone app to guide them to maintain healthy weight during pregnancy in united states [16]. According to Maren' study of in Germany, 87% of pregnant women wanted applications to be implemented in routine pregnancy care in order to detect and prevent serious pregnancy conditions already at an early age; besides, 23% of women requested sharing data among health care professionals(ie, physician and midwives) or even health insurance companies through standardized networks, in that case they would not have to fill out another form each time [10].

Furthermore, 61.7% of the respondents suggested applications should not be involved in uploading or sharing personal information. And 77.3% of pregnant women hoped that the information provided by pregnancy apps needed the approval of the relevant authorities. So health care organization and authoritative agency in China should pay more attention to the supervision and legislation about mobile health field, in view of the specific requirements for the design, function, supervision and evaluation system of apps in future.

Conclusions

The usage rate of pregnancy apps among pregnant women is acceptable, pregnant women's consciousness for information safety is low, and the demand for professional and authoritative apps is high. There are differences between the reasons and needs of apps use. It indicates that pregnancy apps in the market in China is not able to meet the needs of pregnant women, so the function of pregnant apps needs further improvement.

This study chose only pregnant women who took routinely antenatal care in 3 top hospitals in city of Chengde, not involving in those who had no regular prenatal appointment and those who lived in the remote areas in this city due to the limit of time, manpower and material resources. However, these groups of pregnant women are more likely to suffer from some adverse pregnancy outcomes, such as low birth weight newborn, gestational complications, neonatal death, etc. Under the background of the rapid development of information technology and mobile health globally, maternal and child health in impoverished and remote regions should be paid more attention and benefited a lot. Therefore, further researches will be required to explore suitable pregnancy applications for pregnant women in consideration of different demographic characteristics as well as their using experience and expectations.

Abstract

Healthcare systems worldwide are investing in networked health IT systems that link healthcare providers across multiple organisations. Much of the policy arguments in favour of such investment rely on the assumption that networked health IT will lead to improved patient safety. As part of the first stage of a realist review to determine how and in what contexts networked, inter-organisational health IT does lead to improved patient safety, we elicited stakeholders' theories from the literature that reveal possible answers to this question. A key mechanism appears to be that the information provided supports improved decision making. Greatest benefits are likely to be found in relation to medication information, in scenarios where the patient is less able to provide accurate information about their medications themselves. However, access and use of this information depends on ease of access, clinicians' perception of the likelihood that the desired information will be available, and clinicians' trust in the information.

Keywords:

Health Information Technology; Health Information Exchange; Patient Safety.

Introduction

Healthcare systems worldwide are investing in networked health IT (HIT) systems that link healthcare providers across multiple organisations. For example, large-scale shared electronic health record projects have been undertaken in the United Kingdom (UK), the United States (US), Canada, Australia, Sweden, Estonia, Singapore, and Hong Kong [1; 2]. Much of the policy arguments in favour of such investment rely on the belief that networked, inter-organisational HIT will lead to improved patient safety [3-7], defined by the World Health Organisation as 'the prevention of errors and adverse events to patients associated with healthcare' [8].

How networked, inter-organisational HIT will lead to such improvements is rarely explicated in the policy literature, beyond the assumption that if clinicians have access to more information they will access and use that information, which in turn will result in better decisions and safer patient care. For example, in 2012 the Department of Health in England published a document entitled 'The Power of Information: Putting all of us in control of the health and care information we need', which set out a ten-year framework for transforming information for health and care and relies on the notion that 'not sharing information has the potential to do more harm than sharing it' [3]. Similarly, a report by the US Department of Health suggests that health information exchange (HIE) can improve safety 'by improving the timeliness and completeness of important patient health information' [5].

At present, there is a lack of evidence to support these claims [1]. Others have previously noted that networked, inter-organisational HIT is a complex intervention [9], meaning that it is aimed at producing change in the delivery and organisation of healthcare services and comprises a number of separate components that may act both independently and interdependently [10; 11]. These components are not only technological but also organisational and social, and they can all impact the extent to which the technology is successfully introduced and subsequent process and patient outcomes. It could be argued that networked, inter-organisational HIT is more complicated than a complex intervention because it spans several settings, with distinct organisational and social cultures and norms in each one. Previous research has revealed that there is significant variation in the use of information provided by networked, inter-organisational HIT, in terms of the amount and type of information that is accessed [9]. Given the complexity of the intervention, such variation is to be expected and raises the question: how and in what contexts does networked, inter-organisational HIT lead to improved patient safety?

We are currently undertaking a review of the literature with the purpose of answering this question. Using the methodology of realist reviews [12; 13], we will elicit, test, and ultimately refine theories on this topic. In this paper, we report on findings from the first stage of the review, the theory elicitation stage. These theories will be tested, using evidence from empirical studies, in subsequent stages of the review.

Methods

Realist review is an approach to synthesising evidence that represents a divergence from traditional systematic review methodology. Realist reviews identify theories of how an intervention is intended to work, for whom, and in what circumstances, and then test and refine those theories through consideration of primary studies [12]. For realists, interventions themselves do not produce outcomes. Rather, interventions offer resources; outcomes depend on how recipients respond to those resources, which is highly dependent on context. Realist theories, referred to as Context Mechanism Outcome (CMO) configurations, explain how different contexts trigger particular mechanisms (the reasoning and responses of recipients) which, in turn, give rise to a particular pattern of outcomes, where C + M = O. For example, from a realist perspective, networked, inter-organisational HIT in and of itself will not result in

improved patient safety. Rather, it is how clinicians respond to and make use of (or not) the resources that networked, inter-organisational HIT provides that will determine the impact on patient safety and how they will respond is likely to vary according to context, such that a doctor in a busy emergency department may respond differently than a nurse in an outpatient clinic. Realist approaches have much to offer the health informatics community, providing a means to not only determine if HIT interventions provide benefit in terms of outcomes, but to understand why and in what contexts such benefits may occur [14].

A realist review involves several stages. An important initial stage in a realist review is 'theory elicitation', where reviewers explore the literature with the explicit purpose of identifying theories [13]. It is only once the theories have been identified that identification of primary studies takes place. Searching should be purposive and iterative, driven not by the intervention but by the theories. This can provide particular benefit when undertaking a review on a topic where there is limited evidence, as is the case with networked, inter-organisational HIT, because the reviewer can draw on evidence from other domains where the intervention is different but the underlying theory remains the same. For example, networked IT systems to support the exchange of data between organisations have been introduced in a range of industries, such as government, manufacturing, and banking, for the purpose of process improvement, which may be based on similar theories of how networked, inter-organisational IT can lead to benefit [15].

Here we report findings from the theory elicitation stage of the review. Three main searches were undertaken for this purpose, one focusing on government policies and official reports, one focusing on opinion leaders in the area of HIT and patient safety, and one focusing on academic and practitioner literature concerned with networked, inter-organisational HIT and patient safety.

Search Strategy

Searches were conducted using synonyms for HIT, e.g. medical records, combined with synonyms for networked IT, e.g. computer networks; Health Information Exchange (HIE), defined as "the electronic movement of health-related information among organizations according to nationally recognized standards" [16]; and interoperability, defined as "the ability of different information technology systems and software applications to communicate, exchange data, and use the information that has been exchanged" [17]. In some searches, these were combined with synonyms for patient safety, e.g. adverse events, errors. These searches were conducted in February and March 2018 on the following databases: Medline (1946 to present), Embase (1996 to present), and Health Management Information Consortium (1983 to present). Full details of planned searches are available via PROSPERO (CRD42017073004).

Inclusion Criteria

Records were first screened based on title and abstract and then, where available, full papers of potentially relevant records were retrieved and screened. We aimed to identify papers that described stakeholders' theories about how and in what circumstances introduction and use of networked, inter-organisational HIT leads to improved patient safety. We did not restrict our attention to a particular form of networked, inter-organisational HIT such as HIE. No restrictions were placed on the type of healthcare setting.

Data Extraction, Analysis, and Synthesis

To provide an overview of the relevant articles, a short description of each was presented and summarised in a table format. Furthermore, we abstracted out any theories or assumptions, or fragments of theories, concerning the mechanisms through which networked, inter-organisational HIT improves patient safety and/or the contexts in which this may occur. Given the focus of this phase of the review on eliciting theories rather than testing them, when considering empirical studies we focused on the discussion sections, in an attempt to identify authors' theories about why networked, inter-organisational HIT did or did not result in the intended outcomes. In an attempt to construct initial theories, similar theories or theory fragments were grouped together.

Results

The searches reported here identified 375 records, of which 34 records were found relevant. For two of these, only abstracts were available, leaving 32 articles. Stakeholders' theories are likely to be found in editorials, letters, commentaries, and news articles and so these are often the focus of the theory elicitation stage of a realist review [13]. This was the case with our review; the majority of publications were editorials [18], letters to the editor [19-22], commentaries [23-25], and news articles [26]. However, the publications also included original research studies that sought the opinions of HIT policy and opinion leaders [27] and clinicians [28; 29], reports on experiences and lessons learned from the introduction of networked, inter-organisational HIT [30-33], and two systematic reviews [1; 34]. The publications covered a range of networked HIT, including shared EHRs [1; 18; 22-24] and networked picture archiving and communications systems [19].

The included articles discussed barriers to the introduction of networked, inter-organisational HIT – e.g. patient consent to sharing, cost, incompatibility of systems, information held within paper records – as well as drivers for it, such as financial incentives and patient expectations [1; 15; 18-20; 24; 25; 29; 31-35]. However, our concern was not with what constrains or leads to the introduction of networked, inter-organisational HIT but, once it is in place, the contextual factors that support and constrain its use and subsequent impact.

While some articles considered potential risks to patient safety that may be introduced by use of networked, inter-organisational HIT [22; 31], largely the articles reflected the same belief in the potential for improved patient safety that is promoted within the policy arena. Similar to the policy literature, how this would be achieved was often not explicated. For example, an interview study with Canadian HIT policy and opinion leaders reported that:

'clinical data sharing across the continuum of care was believed to be critical for improving safety and effectiveness, especially electronic prescribing and drug management in the near term.' [27]

Only one of the articles referred to a theoretical model that might explain the impact of networked, inter-organisational HIT. Bowden & Coiera [1], in their systematic review of the impact of accessing primary care records during unscheduled care, refer to information value theory [36], which would suggest that networked, inter-organisational HIT can only have impacts on care when the information it provides to clinicians triggers a change in a decision that has the potential for a better (higher value) outcome.

Despite the lack of explicit theory within the remaining articles, we were able to identify two key mechanisms through which authors anticipated that networked, inter-organisational HIT

would lead to improved patient safety: through clinicians making use of the information provided by networked, inter-organisational HIT to inform their decisions about patient care and through clinicians making use of networked, inter-organisational HIT to better coordinate patient care. We consider these two mechanisms in further detail below.

Improved Decision Making

A key anticipated mechanism is that clinicians will respond to the provision of accurate patient information by using that information in their decision making, resulting in improved decision making – although what is meant by 'improved' is rarely articulated – and consequently increased patient safety. For example, Alvarez [23] states:

'providing access to reliable electronic patient encounter data will result in improved diagnostic capability for providers and consequently more appropriate treatment.' (p.34)

A context where networked, inter-organisational HIT was considered to be particularly beneficial for decision making was the emergency department [1; 37; 38], due to the lack of up-to-date medical records at the point of care [31].

In terms of the information to be accessed, a patient's medication history was considered to be particularly important [23; 29; 31]. This was especially the case for patients with mental health issues, where information regarding mental health medications was perceived not only to be critical for decision making but often difficult to obtain accurately from patients [31]. Similarly, information on medications for elderly patients was seen as important, again due to anticipated difficulties in obtaining accurate information from the patient themselves. However, what information will be accessed is likely to depend on the stage in the patient journey, with information on medications, allergies, and diagnoses being the focus during triage and immediate treatment, while access to the full patient record is potentially useful later in the patient's care [1].

Other contextual factors that appear to determine whether information will be accessed and used include the ease of accessing patient information and the clinician's perception of the likelihood that the desired information will be available [31]. Where ease of access is not achieved, this may be overcome by having other staff, such as those in training, searching for information. Related to ease of access is the extent to which the networked HIT is integrated into existing workflows [26; 31]. To use the information, clinicians have to be confident that the information is accurate and up to date [22; 31; 34].

Experience of individuals may also influence the likelihood of clinicians accessing information via networked, inter-organisational HIT, with those with experience of using networked HIT typically being more positive than those without [34]. The benefits to be obtained may also vary according to levels of experience and specialism. For example, Alvarez [23] suggests that sharing of radiology images will benefit smaller hospitals by providing them with timely access to high-quality interpretations by radiology specialists.

Improved Coordination of Care

When reviewing the literature retrieved using the search term 'interoperability', an additional mechanism was identified, whereby the ability to share information provided by networked, inter-organisational HIT is used as a means of communication, leading to improved patient safety through increased coordination of care. While we were only able to elicit theory fragments, we report it here because it represents an alternative theory to the one concerning improved decision making that underlies much of the policy literature.

The e-Health Stakeholder group, a multidisciplinary group established in 2012 with the aim of discussing and contributing to the development of HIT policy at EU level, published a report entitled 'Perspectives and Recommendations on Interoperability' [2]. The report suggests that faster access to patient health records not only enables better decision making but also improved care coordination between multiple clinicians. Because of the fragmented nature of healthcare, where a patient's journey can involve multiple clinicians, there is the potential for miscommunication or error, with communication breakdown or failures in healthcare being one of the most frequent causes of adverse events [30; 39]. Networked, inter-organisational HIT can facilitate communication between clinicians working in different organisations through, for example, the transfer of hospital discharge reports to a patient's general practitioner (GP) or requests from the GP for a hospital appointment, to improve the coordination of care [30].

Beyond the scenarios described above, we were unable to elicit much from the literature regarding the contexts in which this mechanism would be triggered. However, in contrast to the decision making mechanism described above, it appears that this mechanism has less relevance to unplanned care and greater relevance to longer term care, such as palliative care and management of long term conditions such as diabetes [30]. We can also anticipate that some of the contextual factors identified in relation to the decision making mechanism, regarding ease of access of information and trust in that information, also apply here, in order for the clinician receiving the information to incorporate it into care planning for the patient.

Discussion

We have undertaken the first part of a realist review to identify stakeholders' theories regarding how and in what contexts networked, inter-organisational HIT may result in improved patient safety. The findings reveal two possible mechanisms through which improved patient safety may be achieved, one concerned with decision making and one concerned with care coordination, the relevance of which depends on the care context. Drawing together the theory fragments from the literature, two initial theories, formulated as CMO configurations, are presented in Table 1. Given realist evaluation's concern with identifying what works, for whom, in what circumstances, these theories describe what is needed to produce a positive outcome. The implication is that, in the absence of the necessary contextual factors, the mechanism that produces the desired outcome will not be triggered.

Recommendations for Future Work

Evaluation of complex interventions requires a strong theoretical foundation [40]. Bowden & Coiera [1] argue that future evaluations of networked, inter-organisational HIT need to based on appropriate theory, something that is absent in previous studies. We would agree with this and add that, ideally, not only the evaluation but also the introduction of networked, inter-organisational HIT, and HIT more generally, should be based on appropriate theory that explicates how the intended benefits are expected to be achieved. Doing so provides a way for knowledge, in terms of what works and how, to cumulate; if we become explicit about the theories that underlie the introduction of HIT, we can then test those theories, using the refined theories to inform future implementations.

Table 1 – Initial theories

Context		Mechanism			Outcome
		Resource	Response		
Emergency care Patient is unable to provide accurate medication information Information is easy to access, accurate and up to date	+	Access to medication information	Clinicians access medication information and, trusting that information, use it to inform their decision making	=	Improved decision making Reduced medication errors Increased patient safety
Long term care provided by clinicians spread across multiple organisations Information is easy to access, accurate and up to date	+	Ability to share information	On receiving information, clinicians access it and, trusting that information, incorporate it into their care planning for the patient	=	Improved coordination of care Increased patient safety

Strengths and Limitations

A strength of this work is that we have demonstrated how, when the introduction of HIT is not based on explicit theory concerning how the intended benefits will be achieved, the theory elicitation stage of a realist review provides a means of unearthing stakeholders' theories. The resulting theories can be tested and refined through the use of primary studies, as we will do, or they can be tested and refined through the collection of empirical data [41].

Nonetheless, what is presented here is only the first stage of a realist review and so we can make no claims about the truth of the theories that we have elicited from the literature. However, while the initial theories do not necessarily reflect our views, they do reflect commonly held views in one or more academic and practitioner communities.

Conclusions

Worldwide, there are efforts to introduce networked, inter-organisational HIT. While such HIT promises many benefits in terms of patient safety, these are not always achieved. We have undertaken a realist review to identify stakeholders' theories regarding how and in what contexts networked, inter-organisational HIT may result in improved patient safety. One of the key mechanisms identified in the literature is that access to 'additional' information available through networked inter-organisational IT systems can support enhanced decision making. This mechanism was more likely to yield benefits in relation to medication information, particularly in scenarios where the patient is less capable to provide accurate information themselves. However, different factors can determine the clinician's decision to access and use these systems, such as ease of accessibility, perceived usefulness of the information provided, and their trust that the information is available, accurate, and up-to-date.

Abstract

Management of the complex chronically ill patient is highly problematic. This is due to the need to complement recommendations in clinical guidelines with recommendations based on treatments performed on a representative set of patients. It is necessary to identify conflicts between the recommendations of different guidelines designed for handling specific chronic diseases. The PITeS-TIiSS project (code PI15/01213) aims to overcome this problem by designing and deploying an ontology-based personalized clinical decision support tool. This helps to improve personalized decisions and reduces variability in clinical practice in an integrated care environment. This paper describes the methodology followed in developing the ontology used to infer clinical knowledge and to develop and implement the support tool. The tool will access the information provided by the Electronic Health Record of Andalusian Health Public Service, the main healthcare provider in a region in Spain with more than eight million inhabitants.

Keywords:

Polypharmacy, Decision Support Systems, Clinical, Chronic Disease

Introduction

The high prevalence of chronic diseases in the population has led to an increase in the number of people living with complex chronic disease or multiple diseases. They are considered to be the leading cause of death worldwide (60% of the total) [1].Complex Chronically ill Patients (CCP) are patients with multimorbidity [2]. Drug use in CCP and elderly persons often requires specific knowledge of clinical, functional, and care areas. The complexity of patients with chronic diseases makes them a risk group that is more susceptible to errors and, therefore, adverse reactions [3].

A study of 12 clinical practice guidelines (CPGs) conducted by the National Institute of Health and Care Excellence (NICE) in the U.K. highlights multiple potentially dangerous interactions between the recommendations of these guidelines. The results show the need to adopt innovative and interactive mechanisms for the production and dissemination of clinical guidelines to facilitate informed decision making in the treatment of CCPs [4]. They also suggest the need to advance the interaction between electronic clinical guidelines and basic medical knowledge in order to allow the guides to be adapted to a specific patient. This results in adapted treatment of the disease [5].

A personalized clinical decision support system (PCDSS) was designed to overcome these problems. The incorporation of this type of tool into clinician workflows is one of the main strategies to prevent errors in decision-making in integrated care environments [6]. The proposed tool focuses on the reduction of variability and on fair and personalized clinical practice in the field of integrated care of CCPs. In this case, an ontology was used to infer specific clinical knowledge [7].

An ontology is a formal and explicit specification of a shared conceptualization. It helps to model by first identifying the relevance of concepts and their explicit definition and related constraints. In addition the ontology can be read by a machine and can capture consensual knowledge [8].

The CDSS are handly tools in clinical practice. However, in the area of pluripathological patients they are not as flexible as they should be. This is why it was decided to use ontological reasoning for tool modeling. Galopin et al. have found that there are fewer treatment conflicts between the different diseases with ontological reasoning [9].

Velickovski et al. [10] proposed a CDSS for CCPs that focused on the diagnosis and prevention of chronic obstructive pulmonary disease. The key difference with the present proposal is that it does not use ontology as the primary basis for the development of the decision support tool.

Böttiger et al. [11], on the other hand, proposed a tool focused on drugs and adverse reactions. Its main aim was to prevent and avoid possible interactions and adverse effects on polymedicated patients. Again, these researchers did not use the ontology for the development of their proposed tool.

A CDSS in which an ontology was used as the central element in development was proposed by Zhang et al. [12], which focused on the diagnosis, evaluation, and treatment of patients with diabetes mellitus 2. The key difference between this proposal and ours is that the former focuses on complex chronic diseases, while the present proposal focuses on the different drugs used to treat complex chronic diseases. Also, the recommendations provided in the present research are justified because they show the items selected initially by healthcare professionals.

Methods

Objectives

This study is part of the PITeS-TIiSS project [13], funded by the Spanish Carlos III Institute of Health and whose specific objectives include the following:

- Define a methodology to represent and implement evidence-based integrated care plans. These would incorporate recommendations and personalized

treatment for CCPs based on the most appropriate CPGs and the evaluation of the results of previously applied therapies.

- Applying the methodology described above in the setting of CCPs. The aim is to produce a set of recommendations, clinical pathways and specific protocols.
- Avoid increasing the time spent using the tool during medical care.

The aim is to integrate the tool into the workflow of the health professional. This facilitates access to information provided by the Electronic Health Record (EHR), known as DIRAYA [14], of the Andalusian Health Service, the main health services provider to Andalusia (a region in southern Spain with a population of more than eight million inhabitants). This is one of the largest registration systems in Europe. The project will benefit from a service-oriented architecture based on an internal communication bus (using open source Mirth Connect software). This bus will incorporate new modules and improve performance by reusing integrations with many EHR services (e.g., patient identification, clinical authentication and the option to query relevant health data sets). This design reduces development cost by reusing common components and enables research on implementation of Integrating the Healthcare Enterprise (IHE) [15] and ISO 13606 [16] interoperability standards in several projects.

Study of the Knowledge Bases

Initially, within the framework of the PITeS-TIiSS project, a generic scenario focused on the integrated care of CCPs was defined. In this scenario, the sphere of care was shared by two centers: "Virgen Del Rocío" University Hospital (HUVR) and a primary care center in the HUVR area.

Given the disease prevalence, the information available in the EHR and the availability of patients, the prescription decision scenarios defined for the validation of the technological developments in this project were the following:

- Scenario 1: Atrial fibrillation. Treatment with anticoagulant drugs.
- Scenario 2: Secondary prevention of cardiovascular disease.Treatment with statins.

Subsequently, together with clinical researchers, we identified and exhaustively analyzed a series of knowledge bases related to the selected scenarios. To this end, the clinical researchers identified the guidelines and pathways used in clinical practice, as well as other cross-sectional knowledge tools to support decision making in these diseases. The knowledge bases, currently in use in conventional integrated care, were identified and collected in the protocols of the HUVR and its affiliated centers. These bases were as follows:

- STOPP/START Criteria: This tool is used to detect an elderly patient's prescription medication. Also to indicate which, according to their individual conditions, is the most correct pharmaceutical prescription for a patient. It has been used in other parts of Europe [17].
- LESS/CHRON Rules: This tool is used to guide the prescription of medicines in patients with chronic diseases. It is the result of a recent consensus on the medicine prescription [18].
- PROFUND Index: A widely used outcome prediction scalein Spain [19].
- CPGs: Guides developed systematically to assist healthcare professionals and their patients in maing decisions about appropriate care under specific clinical circumstances [20]. In order to obtain the most appropriate information on the defined decision-making scenarios, the clinical researchers finally recommended the use of two specific CPGs. Scenario 1 was studied using the CPG on Diagnosis and Treatment of Atrial Fibrillation [21]; Scenario 2 was studied using the CPG on dyslipidemias [22].

Given the complexity of the knowledge bases, some of conventions have been defined for this paper. A clinical statement is a text that makes a recommendation in the knowledge bases (e.g., warfarin should be prescribed if the patient has atrial fibrillation and his/her glomerular filtration rate is greater than or equal to 15 ml/min). Also, within this clinical statement, we can identify two premises (e.g., having a glomerular filtration rate greater than or equal to 15 ml/min) that compare a series of clinical concepts (e.g., glomerular filtrate) with numerical values, Boolean values, or other concepts. Once the resources to be analyzed were identified and the conventions defined, a set of tabulated information was extracted using a methodology based on the following steps: (1) The clinical statements are extracted from the different knowledge bases; (2) the clinical concepts associated with these clinical statements are identified and, once identified, (3) the questions to be shown to the healthcare professional for each of the previous concepts are established in the tool. Subsequently, (4) the premises associated with the clinical statement are identified, (5) the recommendation to be given by the tool when makng the specific clinical statement (e.g., prescribing warfarin) is noted, and (6) the existing relational logic between the concepts contained in a premise is identified and designed (by means of a propositional or Boolean logic system). Finally, (7) the logical relations are established between the premises that fulfill all (AND), only one (OR), etc. The whole process is carried out by the research team in a systematic and recurrent way until a consensus is reached among the clinical researchers.

In this case, the recommendations corresponded to the prescription and/or deprescription of the medicines in the two defined scenarios. They are shown in the tool developed according to the introduced patient information.

Before its implementation, the project was approved by an ethics committee made up of 21 members and chaired by Mr. Víctor Sánchez Margalet.

Information Modeling and Semantic Standards Mapping

Ontology was defined from the previous tabulated document and developed on the knowledge extracted from the knowledge bases. Ontology modeling has been selected as methodology since it allows a precise classification of a patient in diagnosis, care management and translational research. Compared to terminologies, the big difference is that ontologies define the relationships between concepts in a way that allows logical and computational reasoning. In addition, it allows conclusions to be drawn from related claims. Ontologies can help organize and analyze large amounts of data that are too large for a healthcare professional to handle [23].

Protégé was used to implement clinical statements, premises, concepts, and the relationships between them. The concepts were added to the ontology and, through the use of annotations in the ontology, the extracted concepts were mapped. To facilitate communication exchange, each concept was mapped with a semantic interoperability standard. This allowed all information to be semantically communicable. For this purpose, it was decided to apply FHIR [24] of HL7. Also, the concepts were terminologically mapped with SNOMED CT [25] to ensure semantic interoperability at the terminological level (See Figure 1). For those terms that were not assigned

codes in FHIR or SNOMED CT, they were assigned our non-standard code in order to map them in the ontology.

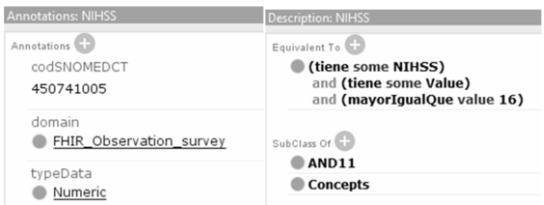

Figure 1 - Example of an annotated mapped concept and a concept-based premise

On the other hand, an internal logic was defined in the ontology, through the use of ObjectProperties, DataProperties, and the relationships between concepts (e.g., hierarchy, EquivalenTo, Class Axioms and others). In this way, it was possible to establish the premises defined in the clinical statements. For example, the NIHSS scale is greater than or equal to 16 (See Figure 1) and included in the tabulated document (through the use of annotations). In addition, an internal logic was redefined in the ontology between the different premises associated with the same clinical statement (See Figure 2).

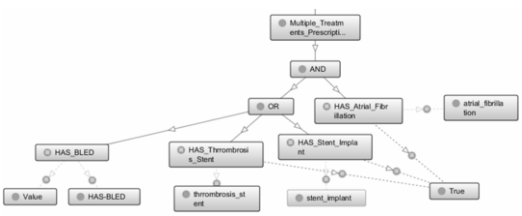

Figure 2 - Example of rule logic associations

Definition, Design and Implementation of the CDSS

Once the modeled information was available (mapped concepts, conditions, logic and recommendations), a PCDSS was implemented. For this purpose, the data of each patient was incorporated and the model designed to generate personalized prescription recommendations for each patient according to the sources analyzed was used (See Figure 3).

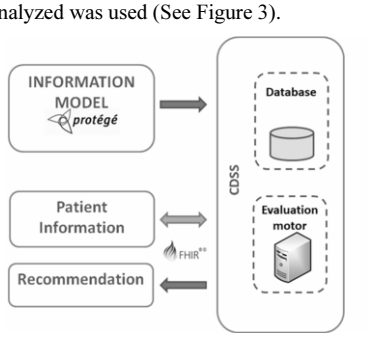

Figure 3 - System architecture

For the incorporation of data other than patient information, the system is able to automatically extract information from the previous model and incorporate it into the CDSS database. To do this, a Java project was created. The Owl API library was used to process the model created through the proposed methodology and was able to store the information so that it could be understood by the evaluation engine.

When the information arrives from a new patient, the tool created is able to (1) obtain the representative set of mapped concepts, (2) relating patient data to concepts through the use of reference terminology, (3) obtaining the premises defined in the information model, (4) evaluating each of the premises obtained with patient concepts and data, (5) evaluating the logic of the premises and clinical statements defined, and (6) giving a recommendation in real time.

Validation

First, clinical researchers validated the tool with retrospective data from real patients in the reference area of the HUVR. In addition, the clinical researchers conducted reviews of the recommendations throughout the tool development process.

In this way, it was possible verify that the PCDSS generated the most appropriate and personalized recommendations for each patient and that the data entered were correct in the clinical setting.

Results

A methodology was available to obtain clinical decision rules based on ontologies. The knowledge bases used were oriented to relevant medical decision-making scenarios in the context of integrated care.

The PCDSS was developed. The tool provides forms validated by clinical researchers that connected the questions in the form with SNOMED CT concept codes contained in the information model. The healthcare professional entered the patient information into the form, from which clinical recommendations are generated in the PCDSS.

The PCDSS was integrated into the workflow of healthcare professionals and an analysis was performed to determine whether the premises and logic of the clinical statements were met according to the data entered on the form. Besides, the PCDSS also generated personalized recommendations for the patient about prescription and/or deprescription of specific medications.

At the time this study was submitted, the PITeS-TIiSS project was in the experimental phase. The phases included clinical validation of the tool developed, training of clinical researchers and patient recruitment and follow-up.

Discussion

It is hoped that the tool will be very useful for support decision makingin clinical practice in both scenarios defined for treatment of CCP. The inclusion of clinical researchers from the HUVR reference area in this project, both in the definition of requirements and in the design of the technological infrastructure, has made it possible to design a tool adapted to the needs and preferences of healthcare professionals. The ontology played a key role in the design of the tool, as it served to model the information in natural, intuitive and understandable way after some adaptation processes. This was of great help to the developers, as it made it much easier for them to import the model into the CDSS. On the other hand, more time than expected has been invested in the modeling and implementation of the tool due to the desire to make it highly scalable from a functional point of view. In other words, the methodology allows the incorporation of recommendations on the prescription or deprescription of new drugs that in turn cross with previously modeled recommendations, with a minimum

impact on the previous model. A future identified line of work is to increase the scope of normalization of modeled concepts through SNOMED CT post-coordination.

Work is also underway to ensure that the tool is easy to use. In this way, the tool will allow the CDSS to include future scenarios for other drugs and, therefore, new recommendations, thus enriching the usefulness and knowledge base of the tool developed thanks to the functional scalability of the method.

Conclusions

In conclusion, thanks to the involvement of healthcare professionals, considerable progress has been made in a short time. Positive results have been obtained in various areas, as indicated below:

- Protocols have been established for the knowledge extraction phase, defining clear structures for the collection of information in the tabulated document. This has reduced modeling time, the number of meetings and the explanations necessary for healthcare professionals.
- The proposed methodology enables better use of the research team's time.
- Possible human errors have been reduced by including the models in the tool, thanks to the fact that a large part of this process is automated.
- According to the healthcare professionals, the use of the ontology has facilitated visualization and understanding of knowledge thanks to the relationships between concepts.

Once the validation has been carried out retrospectively, the pilot of the developed tool in this project will begin prospectively with real patients. This pilot will be carried out in the reference area of the HUVR in primary care and specialized care consultations (internal medicine)

Finally, once the pilot has been completed, the aim is to obtain data that will make it possible to check the reliability and effectiveness of the PCDSS through indicators. It is also intended to extract new knowledge from the decisions taken by healthcare professionals. The indicators used are as follows:

- Number and percentage of adverse events avoided in each group.
- Number and percentage of emergency visits in each group.
- Number and percentage of hospital admissions in each group.
- Number and percentage of avoidable referrals from primary care to hospital.
- Satisfaction of healthcare professionals.
- Quality of life related to the patient's health.
- Number of improvement proposals detected for the process of integrated care of CCP.

Acknowledgements

This research was funded in part by the Platform for Innovation in Medical Technologies and Health (ITEMAS Platform, codes PT13/0006/0036 and PT17/0005/0036) and by the PITeS-TIiSS project (code PI15/01213) of Carlos III Institute of Health, both co-funded by FEDER, European Regional Development Funds (European Union). Many thanks to other researchers for their useful contributions and suggestions. We are especially grateful to the researchers Francisco Núñez Benjumea, Jesús Moreno Conde, Samuel Salas Fernandez, Bosco Barón Franco, Lourdes Moreno Gabiño, and María José García Lozano, as well as to the other internists and biomedical informatics researchers of the Virgen del Rocío University Hospital.

Development, Implementation and Preliminary Results of an Electronic Reminder for HIV Screening Using a Service Oriented Architecture

Luciana Rubin, Natalia Pérez López, Alejandro Gaiera, Fernando Campos, Daniel Luna, Fernán Bernaldo González de Quirós

Department of Health Informatics, Hospital Italiano de Buenos Aires, CABA, Argentina

Abstract

30% of the Argentinian population and 58% of Plan de Salud HIBA patients are unaware of their HIV status. The Ministry of Health and US Preventive Service Task recommends physicians to assess HIV infection in persons aged 15 to 65. An HIV screening reminder integrated in an electronic health record (EHR) was created using FHIR to represent clinical information and CDS-Hooks to represent the exchange of information with a CDS service. The tool had a 1% intervention rate, and 67.4% acceptance rate. The number of HIV screening tests requested during the weeks after the CDSS implementation and in the same period in 2017 were obtained. 575 orders were requested in the 2017 period and 893 in the 2018. 89 (almost 10%) of these came from the electronic tool. The preliminary results indicate that this non disruptive, action oriented reminder can contribute to increased HIV screening orders.

Keywords:

Clinical Decision Support Systems, Electronic Health Records, HIV Infections

Introduction

In 2017 around 5,500 people became infected with HIV in Argentina, 6,500 were diagnosed with the virus (35% of them in advanced stages of infection), the perinatal transmission rate was 5% and 1,500 people died from causes related to the AIDS. With 122,000 people living in Argentina with HIV in 2017, 30% of whom were unaware of their situation. It is necessary to accelerate the pace of diagnosis to reach the goal of 90% diagnosis rate by 2020. This implies the need to increase efforts to actively offer HIV testing [1]. The Ministry of Health resolution 55-E/2017 [2] recommends reporting and offering HIV test. US Preventive Services Working Group (US Preventive Services Task Force) [3] also suggests physicians to assess HIV infection in adolescents and adults, aged 15 to 65.

In the Hospital Italiano de Buenos Aires (HIBA), only 42% of the Plan de Salud patients (HIBA's health maintenance organization) have a reactive or non reactive HIV result, leaving the remaining 58% with an undetermined HIV status.

Clinical decision support systems (CDSS) are one of the biggest benefits of electronic health records (EHR). Reminders are tools that can help physicians to order a diagnostic or therapeutic procedure adjusted to patient characteristics [4], and there is evidence that they can influence the physicians test-ordering behavior [5].

We could say that we are going nowadays through a fifth stage in the evolution of the CDSS, as a response to the problems presented in the four phases indicated by Wright [6]. This phase is based on the utilization of standards to share information between systems using service-oriented architectures implementations that adopts existing web-based technologies such as RESTful (REpresentational State Transfer) APIs [7].

Fast Healthcare Interoperability Resources (FHIR) [8] is the latest standard developed and promoted by the international organization Health Level Seven (HL7), permitting the exchange of information related to medical care. This includes clinical as well as administrative data, and contemplates a wide variety of settings: inpatient, ambulatory, emergency department, etc. FHIR helps us to achieve interoperability between systems, representing health data from heterogeneous sources using the same structure, this being the foundation for sharing information.

CDS-Hooks [9] is a standard that describes a "hook"-based pattern for invoking CDSS from within a clinician's EHR workflow. It triggers CDS calls from the EHR workflow returning as an answer information and suggestions for action.

The aim of this paper is to describe the development and implementation of an electronic reminder to physicians, integrated in an EHR, for HIV screening on the correspondent patients; using FHIR to represent clinical information and CDS-Hooks to represent the exchange of information with a CDS service.

The secondary aim is to describe the preliminary results of the tool's use without formal user training, and to describe the proportion of HIV screening requests in the weeks after the implementation and in the same period of the previous year.

Methods

Setting

HIBA is a non-profit healthcare academic center founded in 1853. It has a network of two hospitals with 750 beds (200 for intensive care), 41 operating rooms, 800 home care beds, 25 outpatient clinics and 150 associated private practices located in Buenos Aires city and its suburban area. Since 1998, HIBA has run an in-house-developed health information system, which includes clinical and administrative data. It has been recently certified by the HIMSS as level 7 in the Electronic Medical Record Adoption Model, being the first hospital in Argentina and the second in Latin America reaching this stage. The EHR is a fully-implemented web based, problem

oriented, patient centered record with customized functionalities depending on the level of care (outpatient, inpatient, emergency care and home care) and terminology web services [10][11]. Problems are referenced to SNOMED CT (Systematized Nomenclature of Medicine - Clinical Terms), the terminology standard used for health information contained in patient clinical data repository [12]

The hospital has a health insurance plan (Plan de Salud - PS) with 167,000 members. It is important to remark that these patients are enrolled with HIBA and get all their medical attention (laboratories tests, medical images, proceedings, etc) at the hospital.

The setting selected for the reminder implementation was the ambulatory.

Electronic Reminder

The reminder was created in a multidisciplinary team consisting of general physicians, health informaticians and engineers.

Its aim is to detect patients from 15 to 65 years without any HIV results, either positive or negative, HIV screening pending requests, structured HIV related diagnostics or HIV related medication stored in the EHR. If all these conditions are true for a patient with an appointment with some predefined specialty physician (for e.g., general practitioner, pediatrician, internal medicine, gynecologist) a non disruptive, action oriented reminder appears in the EHR header. The CDSS interface contains the following content (Figure 1):

- a sentence informing the physician about the patient's unknown HIV status (Figure 1: A)
- a "prescribe" button; action oriented option offering the screening test (fourth generation ELISA) (Figure 1: B)
- a "decline" button (Figure 1: C)
- a short explanation of the recommendation source with a hyperlink to the US Task Force website. (Figure 1: D)

The practitioner has three options: ignore the reminder (close it with the X button on the upper right side), accept the reminder and order the test from the same emerging window (from the prescribe button), or reject the reminder (from the decline button). In the last case scenario the practitioner is requested to choose between a set of structured and free text justification.

Figure 1 – HIV Screening electronic reminder interface. (A) patient's unknown HIV status, (B) "prescribe" test order button, (C) a "decline" button, (D) explanation of the recommendation and link to source.

The architecture of the tool focuses on the EHR that communicates with the FHIR server an the CDS service. When a physician enters in a patient's EHR ("patient-view" hook) and has an appointment with him, the EHR requests the FHIR server all the FHIR resources needed to call the CDS service (Figure 2). The EHR sends the request with the contextual data, like patient and practitioner identifiers. The FHIR server returns a bundle. This bundle has the FHIR resources packaged, such as "Patient", "Observation", etc. This FHIR server was implemented in HAPI FHIR.

When the EHR obtains the bundle, it calls the CDS service using CDS-Hooks standard. This call is made with the hook ("patient-view"), allowing the CDS service to execute only the rules related to that hook. The EHR also sends to the CDS service some contextual data needed for executing the rules. For example, the specialty that the physician is performing at that moment. The bundle and this contextual data are the inputs for the rules. The rule engine was implemented in Drools[13].

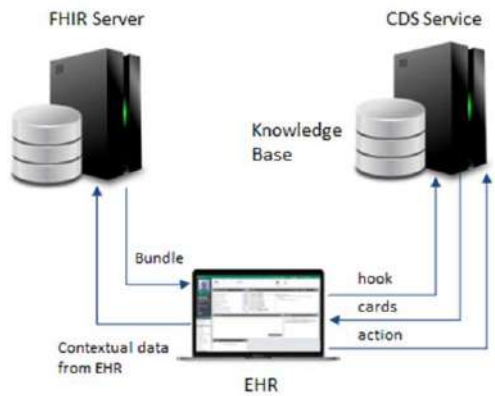

Figure 2 - CDS service architecture1

Once the rules have been executed and if they are true, the response is sent back to the EHR as information cards, suggestions for actions, etc. A log is also recorded for further analysis. In this case an action oriented suggestion card was used, suggesting the physicians to order the HIV screening test for the patient. When the EHR receives the response, it displays the recommendation so that the user can take an apprpriate action. Each card returned by the CDS service has a unique identifier that permits to monitor what happens with the provided suggestion (accept or reject it with their corresponding structured or free text justification) and is later used for analysis.

This architecture works, thanks to the use of HIBA's terminology server and the FHIR standard that enables the achievement of semantic and syntactic interoperability.

Data collection

The data was collected in the period of October 11 to November 21 of the year 2017 for pre-intervention and 2018 for post-intervention.

Two main analyses were performed.

[1] Images extracted from: https://pixabay.com/es/servidor-de-hardware-red-equipo-37258/ and https://es.wikipedia.org/wiki/Archivo:Database-152091_960_720.png

The first one was the extraction of the number of times that the reminder was triggered and appeared to the physicians, to how many patients, how many times it was intervened (defined as either click on the prescribe button or in the decline button), by how many physicians; as well as the justifications selected in case of declining the reccomendation.

The second analysis was to obtain the number of HIV screening tests requested during the following six weeks after the CDSS implementation and in the same period in 2017. The data considered was from the patients who didn't have any testing requests in the previous three months and didn't have any HIV results, in consistency with the rules implemented for the CDSS. Test requests received from the CDSS in 2018 were also determined. All of these analyses were made only for Plan de Salud patients.

Analysis

For the summary of the data, descriptive statistics were used. The categorical variables are reported as absolute and relative frequencies.

Results

Interface design, testing and deployment

The interface design was created with the User Experience team, through iterative mockups.

The tool was tested for a month in a testing environment, where rules were corrected as needed. Following which the final implementation was monitored with a random sample of patients showing 100% accuracy of HIV screening recommendations, as defined in the functional requirement.

On October 11, 2018, the services (FHIR server and CDS service) and the EHR were updated in the production environment. The physicians were informed about the new functionality through a notification placed in the EHR. As there was no formal training, it can't be guaranteed that the users have been able to internalize how to use the tool.

Preliminary results of reminder's use

Within six weeks of use since the implementation, following were the preliminary results.

The HIV test reminder was triggered 12,891 times to 470 physicians for 5689 patients.

An action was taken for 132 reminders (1% intervention rate), one for patient, by 58 physicians.

Of the 132 intervened reminders, 67.4% were accepted (HIV screening study ordered). The most frequent justification for rejecting the reminder was "The study will be ordered in the next consultation" and "The study was ordered by a different means" (Table 1).

Of all the medical specialties defined to receive the CDSS, the reminder was most accepted (measured by HIV screening tests ordered) by gynecology (34-38.2%), general practitioners (24-27.9%) , and internal medicine (11-12.4%).

Of the 2017 period, 575 ELISA HIV screening orders were requested. During 2018 period, the number increased to 893 ELISA HIV screening orders. 89 (almost 10%) of these were prescribed from the electronic tool.

Table 1 - HIV screening justification for CDSS rejections.

Justification	N:43
The study will be ordered in the next consultation	15 (34.9%)
The study was ordered by a different means	12 (27.9%)
Other (free text justification)	8 (18.6%)
The patient does not want to be tested	5 (11.6%)
The physician does not agree with the recommendation	3 (7%)

An intersting find in the 2017 period was that gynecology differed from the other specialties and only ordered 23 HIV screening tests. In the 2018 period after the reminder implementation, they ordered 61 HIV screening tests (2.6 times more), 34 of them (almost 56%) coming from the CDSS tool (Figure 3).

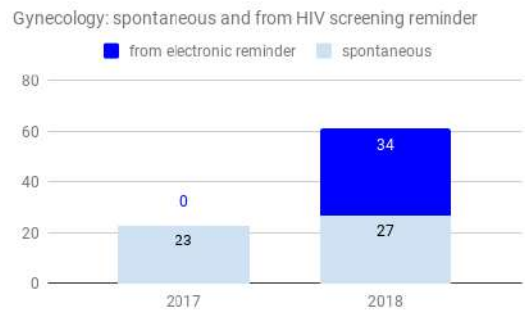

Figure 3 - 2017 vs. 2018 gynecology HIV screening orders

Discussion

This paper describes the development, implementation and preliminary results of an electronic reminder for HIV screening using a service oriented architecture to interact from the EHR with the FHIR server and the CDS service triggered by the physicians workflow inside the EHR.

The use of the same terminological standard in both EHR, the FHIR server and the CDS service, with adequate granularity, depth and breadth, was important for a successful implementation[14]. The incorporation of new technologies that ease the ability of outside digital tools to integrate into EHRs, as well as the utilization of standards for healthcare information exchange (such as FHIR), are said to be important enablers of a better health care model[15]. It is easy to envision that screening practices can be improved with education and electronic screening tools if they are ready to be implemented in health care facilities without the effort of development.

The preliminary results of this work show that the CDSS contributed to an increase of HIV screening test ordering in 2018. Clinical decision support systems have the potential to improve health care, especially when it is related with screening and diagnosing prevalent diseases. These results support the findings of three different studies which showed that an electronic reminder increased the HIV screening testing orders[16][17][18]. Also, similar informatics strategies

have been employed for HIV screening in cities with high HIV prevalence (New York and New Orleans), documenting significant improvements with EHR interventions[19] .

For these preliminary results it can be noted that the intervetion rate of the tool was low, but on the other hand, the majority of users who interacted with it ordered the HIV screening test, indicating that it was useful for them.

The low intervention rate could be related with a perceived stigma associated with an HIV diagnosis. The literature reveals that fear can be an important patient-driven factor in the avoidance of HIV screening[20]. This factor could influence both, the physician who has to suggest the screening recommendation and the patient who receives it. Nevertheless, this was contemplated when choosing only certains medical specialities to be recipients of the CDSS. Other reason to explain this low intervention rate could be that physicians may not be aware that this tool exists or know how to use the information within the CDSS [21], specially when non formal training was received. Lastly, the results are only based on six weeks of the tool's use. A year would be more appropriate time window to do further and more precise analysis, avoiding potential seasonal bias.

Another interesting thing was that the two most frequent reasons for rejecting the recommendation implied that the physician agreed with it but would perform it in the next patient consultation, or that had already ordered it by other means (for example, in a paper format). This indicates that the rejections don't imply a negative connotation towards the tool.

Analyzing the given periods in 2017 and 2018, the increase of HIV screening ordering was only partialy due to the CDSS. Educational programs of HIV screening awareness (not related with this CDSS) could have contributed to this finding. Several other factors may have contributed with the results.

The first one is the automatic provision of decision support. A systematic review identified it as a key factor for the success of CDSS based interventions [22]. Another factor identified is the integration of the CDSS to the already existing workflow of the patient visit, respecting the Five Corrects: "CDSS should be designed to provide the right information to the right person in the right format through the right channel at the right time."[23] and being a crucial part of a successful CDSS[24].

To guarantee certain rate of aceptability, we believe in an incremental and gradual rollout[25], incorporating one reminder at a time, instead of getting all the services available together. In this way we avoid overwhelming the user with new functionalities[26]. Also, as mentioned before, capacitation of users is fundamental to achieve success in CDSS implementations[24].

In addition, the tool was created by a multidisciplinary team which was aligned with the organizational motivation, another recommended best practice in the discipline[27].

Future Lines of Work

Future lines of work can be grouped in different themes:

Expand and improve the tool: Broadening and specializing the rules of the reminder, for example, not giving the recommendation for patients that are blood donors, as regular tests are performed on them in order to exclude infectious diseases. Also, it is required to exhaustively analyze the free text justifications to include other user cases.

Improve the analysis: With an appropriately large time window it will be easier to measure if there was an increase of patients with a known HIV status, and to determine if this was due to the use of the reminder. Another analysis improvement contemplated is to incorporate measures of patients (demographic information) and physicians (for example, how many years they have worked in the hospital and if they are residents, staff, etc). Systematic interviews will conducted for physicians who regularly reject or ignore the reminders in order to gather information about their behavior. Finally, a tendency analysis of the use of the tool is planned.

In order to raise awareness of the importance of HIV screening, it is absolutely necessary to improve the user training, with specific instructions for each medical specialty included within the scope of the reminder. Additionally of other consented reminders for preventive practices are the next step for this CDS program.

Conclusions

The preliminary results indicate that this non disruptive, action oriented reminder that appears in the EHR header, can contribute to the increased ordering for HIV screening.

However, significant opportunity for improvement remains. It is necessary to raise awareness about the importance of HIV screening so that the physicians decide not to refuse or ignore the reminder. It is also essential to make a careful analysis of the answers given by the physicians when they reject the reminder. It will be very helpful to analyze the free text that was introduced. With this information an evaluation will be made focused on whether the rules need some adjustment to include all the cases that may occur.

Effects of Computerized Guideline-Oriented Clinical Decision Support System on Antithrombotic Therapy in Patients with Atrial Fibrillation: A Systematic Review and Meta-Analysis

Ryota Sakurai[a], Kazuhiko Ohe[b]

[a] School of Medicine, International University of Health and Welfare, Chiba, Japan,
[b]Department of Biomedical Informatics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan

Abstract

A systematic review and meta-analysis was conducted to investigate the effects of computerized guideline-oriented clinical decision support system (CDSS) on antithrombotic therapy in patients with atrial fibrillation. PubMed, the Cochrane Library, and Web of Science were queried. Four studies were included in this meta-analysis. The proportion of appropriate antithrombotic therapy in accordance with clinical guidelines was significantly higher in the CDSS group than in the control group (risk ratio (RR): 1.03, 95% confidence interval (CI): 1.01 to 1.04, P = 0.004). Although the incidence of thromboembolic events was similar between the two groups (RR: 1.12, 95% CI: 0.88 to 1.42, P = 0.357), the incidence of major bleeding tended to be lower in the CDSS group compared with the control group (RR: 0.79, 95% CI: 0.61 to 1.01, P = 0.063). Computerized guideline-oriented CDSS may be effective for appropriate antithrombotic therapy as compared with control in patients with atrial fibrillation.

Keywords:

Computers, Decision Support Systems, Clinical, Atrial Fibrillation

Introduction

Atrial fibrillation is one of the most common cardiac rhythm disturbances and well-known as a strong risk factor of ischaemic stroke. Patients with atrial fibrillation are approximately five times more likely to have an ischaemic stroke compared to those without atrial fibrillation through all ages [1]. Accordingly, the prevention of ischaemic stroke in patients with atrial fibrillation is of great importance. Since the prevalence for atrial fibrillation has doubled in the last decade [2], more physicians have been involved in the treatment of atrial fibrillation, regardless of their specialties. As a result, especially in general or primary care, the need for clinical guidelines has been increasing. However, although antithrombotic therapy in accordance with clinical guidelines improves clinical outcomes as compared to undertreatment in high-risk patients for ischaemic stroke with atrial fibrillation [3], guideline-oriented antithrombotic therapy is underused [4-6]. Therefore, treatment adherence to clinical guidelines may be critical for care in patients with atrial fibrillation.

A computer-based clinical decision support system (CDSS) is thought to have the potential to improve clinical outcomes in patients with chronic diseases in the era of widespread electronic health record systems [7]. In this context, computerised CDSS, in conjunction with clinical guidelines, is expected to have a synergistic effect for management of atrial fibrillation, and the development of such CDSS will have a powerful impact on daily practice, especially for non-cardiology specialists. However, it has not been well characterized whether this type of CDSS is effective for atrial fibrillation, especially regarding appropriate prescription of antithrombotic agents according to clinical guidelines. To test the hypothesis that computerized CDSS implemented clinical guidelines improves appropriate antithrombotic therapy for atrial fibrillation in clinical practice, we conducted a systematic review and meta-analysis of clinical trials that compared computerized guideline-oriented CDSS with control.

Methods

Search Strategy and Eligibility Criteria

PubMed, the Cochrane Library, and Web of Science were queried for articles of any language from inception to November 2018. The search terms included “clinical,” “decision,” “support,” “system,” “atrial,” and “fibrillation.” For PubMed, the search details were ("decision support systems, clinical"[MeSH Terms] OR ("decision"[All Fields] AND "support"[All Fields] AND "systems"[All Fields] AND "clinical"[All Fields]) OR "clinical decision support systems"[All Fields] OR ("clinical"[All Fields] AND "decision"[All Fields] AND "support"[All Fields] AND "system"[All Fields]) OR "clinical decision support system"[All Fields]) AND ("atrial fibrillation"[MeSH Terms] OR ("atrial"[All Fields] AND "fibrillation"[All Fields]) OR "atrial fibrillation"[All Fields]). The same terms or relevant studies were also queried on the website of the U.S. National Institute of Health and relevant reviews. To increase internal validity, only randomized controlled trials were included in our study. The primary endpoint of our interest was the proportion of appropriate antithrombotic therapy in accordance with clinical guidelines. We also investigated the impact of CDSS on the incidence of systemic thromboembolic events, such as stroke, transient ischaemic attack or other thromboembolism, and major bleeding as clinical outcomes. If multiple follow-up reports existed in the same study, the outcomes during the longest follow-up period were analyzed. To investigate the usefulness of CDSS for physicians in daily practice, regardless of familiarity with care for atrial fibrillation, the inclusion criterion were the studies comparing the computerized guideline-oriented CDSS, defined as any that provide clinical support automatically generated by a computer according to clinical guidelines, with no CDSS. The exclusion criteria were the studies of CDSS not for physicians (nurses, patients, etc.) or not guideline-oriented CDSS.

Statistical Analysis

A random-effects model was performed to estimate the pooled risk ratio (RR). We chose RR, not odds ratio, since only randomized controlled trials were included and the proportion of appropriate antithrombotic therapy would be expected not so low as approximaled by odds ratio. The I^2 statistics and the Cochran's Q test were conducted to assess homogeneity among each study to confirm internal validity [8]. The possibility of publication bias was assessed visually at first by a funnel plot for asymmetry plotting of the standard error of log RR against the log RR. In addition, the Duval and Tweedie's trim and fill procedure would be conducted to estimate the possible impact of unpublished studies on the pooled estimate. A 2-sided P value of < 0.05 was considered to be statistically significant. In cases of the assessment of homogeneity, however, a 2-sided P value of < 0.10, instead of 0.05, was considered to be statistically significant [9]. If an I^2 statistic value was $> 50\%$, we also considered the results among each study as heterogeneous [10]. All analyses were performed using STATA 11.2 (Stata Corp., College Station, Texas, USA).

Results

Study Selection and Characteristics of Studies

This study was conducted according to the Preferred Reporting Items for Systematic reviews and Meta-Analyses as much as possible [11]. Figure 1 shows a flow chart of study selection. After excluding articles on basis of title and abstract screening, we further excluded 2 studies due to no endpoints of our interest and another study due to not being guideline-oriented. As a result, 18,646 patients (10,313 patients assigned to the CDSS group and 8,333 to the control group) in 4 studies were included in this meta-analysis [12-15].

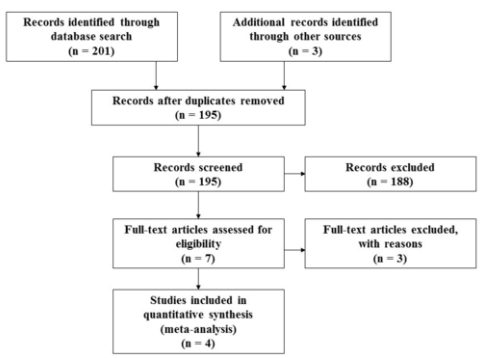

Figure 1– Flow Chart of Study Selection

The characteristics of studies are summarized in Table 1. All studies were performed as a cluster randomized controlled trial in outpatients. The follow-up period ranged from 8 months to 2.2 years. The targets of intervention were primary care physicians or general practitioners.

Pooled Estimates

Figure 2 shows the pooled estimate for the primary endpoint. Homogeneity was not rejected across individual studies by either the I^2 statistics or the Cochran's Q test ($I^2 = 0.0\%$ or P = 0.396).

Table 1– Characteristics of Studies

ACC = American College of Cardiology; AF = atrial fibrillation; AHA = American Heart Association; ESC = European Society of Cardiology; GL = guideline; GP = general practitioner; HRS = Heart Rhythm Society; pts = patients.

* clinical decision support system:control.

The proportion of appropriate antithrombotic therapy was significantly higher in the CDSS group (from 55% to 85%) compared with the control group (from 50% to 84%, RR: 1.03, 95% confidence interval (CI): 1.01 to 1.04, P = 0.004).

Figures 3 and 4 show the pooled estimates for clinical outcomes. Homogeneity was also not rejected across individual studies by either the I^2 statistics or the Cochran's Q test ($I^2 = 38.2\%$ or P = 0.203 for thromboembolic events, and $I^2 = 0.0\%$ or P = 0.456 for major bleeding, respectively). Although the incidence of thromboembolic events was similar between the 2 groups (RR: 1.12, 95% CI: 0.88 to 1.42, P = 0.357), the incidence of major bleeding tended to be lower in the CDSS group compared with the control group (RR: 0.79, 95% CI: 0.61 to 1.01, P = 0.063).

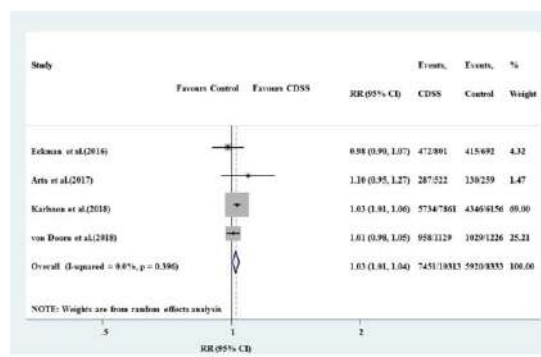

Figure 2– Forest Plot for the Proportion of Appropriate Antithrombotic Therapy

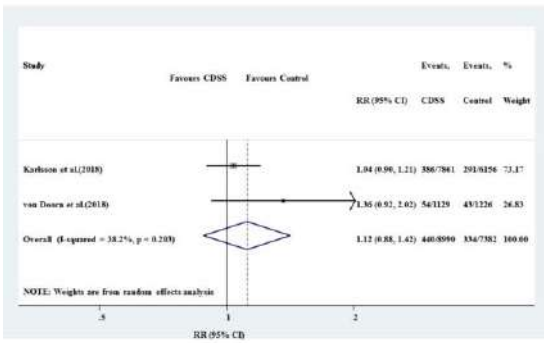

Figure 3– Forest Plot for the Incidence of Thromboembolic Events

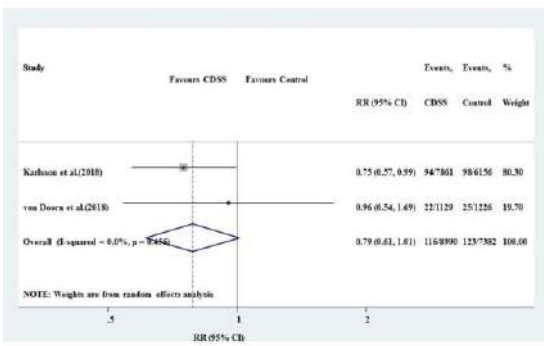

Figure 4– Forest Plot for the Incidence of Major Bleeding

Publication Bias

A funnel plot seemed asymmetric, especially for the incidence of thromboembolic events and major bleeding. Therefore, we conducted the Duval and Tweedie's trim and fill procedure, and the possible impact of an unpublished study favorable for control was suggested for the incidence of thromboembolic events and major bleeding, but not for the proportion of adherence to guidelines (Figures 5, 6, and 7).

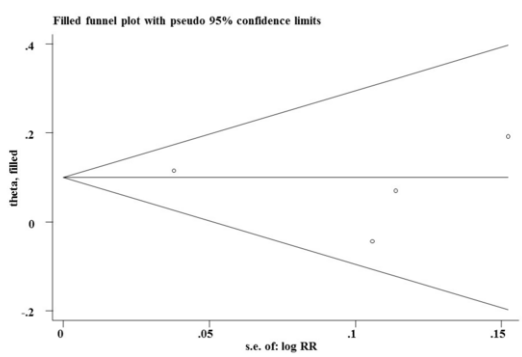

Figure 5– The Duval and Tweedie's Trim and Fill Procedure for the Proportion of Appropriate Antithrombotic Therapy

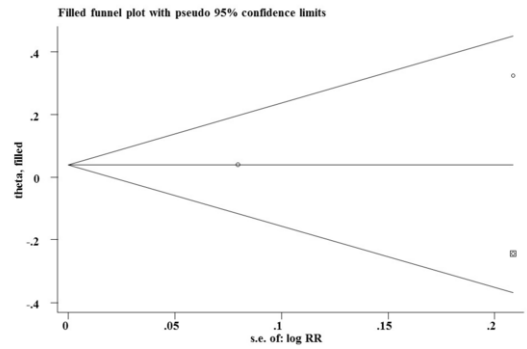

Figure 6– The Duval and Tweedie's Trim and Fill Procedure for the Incidence of Thromboembolic Events

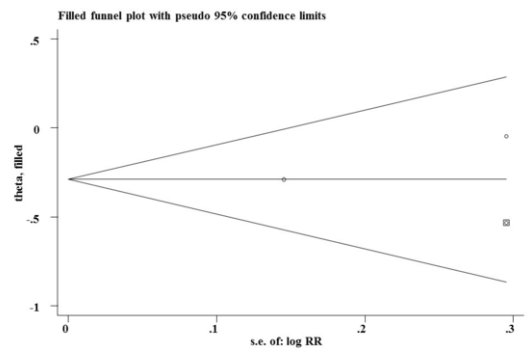

Figure 7– The Duval and Tweedie's Trim and Fill Procedure for the Incidence of Major Bleeding

Discussion

In this meta-analysis, computerized guideline-oriented CDSS demonstrated more favorable effects on the proportion of appropriate antithrombotic therapy as compared with control. Surprisingly, although the incidence of thromboembolic events was similar between the two groups, the incidence of major bleeding tended to be lower in the CDSS group than in the control group. Due to inclusion of only randomized controlled trials, heterogeneity among each study was not observed in any endpoints. To the best of our knowledge, this study reports favorable effects of computerized CDSS on guideline adherence in patients with atrial fibrillation by meta-analysis.

In real-world management of patients with atrial fibrillation, physicians must consider the risks of not only thromboembolic events, but also bleeding. There are several clinical guidelines incorporating some risk scores for stratifying patients, including the $CHADS_2$ or the CHA_2DS_2-VASc score for stroke risk, and the HAS-BLED, the RIETE, or the ATRIA score for bleeding risk. These clinical guidelines generally have numerous pages and are very complicated. In addition, patients with atrial fibrillation frequently have other cardiac diseases or comorbidities, such as coronary artery disease, valvular heart disease, hypertension, heart failure, thyroid dysfunction, and so on [2, 16]. In such complex clinical situations, especially in general or primary care practices, physicians may be extremely

troubled in making decisions by themselves. Accordingly, computerized guideline-oriented CDSS is helpful for non-cardiology specialists to deal with these situations, which may improve clinical outcomes in patients with atrial fibrillation. In fact, most studies included in this meta-analysis took bleeding risk into consideration as well as stroke risk [12-14], and this kind of CDSS may play an important role in decreasing the incidence of major bleeding, even with the similar incidence of thromboembolic events.

On the other hand, despite statistical significance, the range of the proportion of appropriate antithrombotic therapy varied from 55% to 85% in the CDSS group. From the viewpoint of physicians who use CDSS, the difficulties of handling computerized CDSS may be critical for adherence to clinical guidelines. Possible reasons for lower adherence to guidelines include a separate, nonintegrated CDSS apart from natural flow of patient care, requiring the click of a mouse to access information, too many tasks and too much information at once, and too many alert notifications contributing to alert fatigue [12-15]. To facilitate the use of CDSS and further increase adherence to guidelines, therefore, it is tremendously important for system developers to create and provide a fully integrated, simple, and user-friendly computerized guideline-oriented CDSS that is easily accessed by any physician within the limited time as part of clinical workflow, according to some standards or guidelines, e.g. ISO/IEC 25010 [17-19].

There may be several possible limitations in the present study. First, the number of studies included was relatively small in terms of a meta-analysis, partially due to possible publication bias. Therefore, the results, especially regarding the incidence of clinical outcomes, may not be conclusive. Second, the patient population may not be the same across individual studies. Therefore, we used a random-effects model instead of a fixed-effects model to calculate more conservative pooled estimate, although heterogeneity was suggested by neither the I^2 statistics nor the Cochran's Q test. Third, even an increased high internal validity, an external validity may be relatively low in a meta-analysis of randomized controlled trials with strict inclusion and exclusion criteria. Therefore, a real-world data such as registry may also be needed to validate our findings. Finally, due to the existence of several clinical guidelines, the quality of guidelines may not be the same. However, almost all guidelines are based on the $CHADS_2$ or the CHA_2DS_2-VASc score to recommend the treatment.

Conclusions

In this meta-analysis, computerized guideline-oriented CDSS is associated with more appropriate antithrombotic therapy in patients with atrial fibrillation as compared with control. To achieve further improvement of adherence to guidelines and clinical outcomes, it seems that the development of a fully integrated, simple, and user-friendly computerized CDSS in accordance with some standards or guidelines such as ISO/IEC 25010 would be more effective.

Abstract

ObsCare is an obstetric-specific Electronic Health Record in use in nine Portuguese obstetric departments. Like other EHRs, it faces major challenges related to semantic interoperability and data quality. openEHR is proposed to address those needs. This study aimed to describe a summary representation of Obscare workflow and to validate whether archetypes in the openEHR Clinical Knowledge Manager repository can represent ObsCare clinical concepts. The study included the phases: a) ObsCare form selection; b) Description of the workflow care process; c) Detailed data extraction; and d) CKM models analysis. 379 variables were analyzed: 219 were fully represented in CKM repository; 99 were partially represented and needed archetype modification; and 61 were not represented and need new archetypes. To conclude, our study showed that the openEHR CKM repository requires further enhancements to be able to fully answer to the needs of an obstetric-specific EHR, the ObsCare software.

Keywords:

Electronic health records; Obstetrics, Reference Standards.

Introduction

An Electronic Health Record (EHR) contains the results of clinical and administrative encounters by providers (e.g: physician, nurse, nutritionist, and so on) with or for patients that occur during episodes of patient care [1]. The use of EHRs presents several advantages such as availability, data integrity, reduced costs, improved quality of care and health outcomes and enhances the communication between providers and users [1]. The correct recording of health information is essential since it will determine the conduct and decision-making of health professionals, as well as be used as a source for research and audits [1]. Specialist validation of models of EHR information can increase data comprehensiveness and overall quality. Obstetrics is an excellent opportunity to study the potential of EHR implementation. However, general EHRs are inadequate to record and exchange clinical information in the obstetric field, mainly because they do not integrate the content of this clinical area in a structured way and without specific obstetrics contents. A correctly structured EHR can be more easily used by obstetrics-related healthcare professionals and has clear advantages [1].

The ObsCare software was created in 2003 to meet the need for an obstetric-specific EHR and is currently in use in the obstetric departments of nine Portuguese Hospitals. It was produced for use as a clinical record for health professionals, allowing the prospective collection of structured data that can be used to facilitate and improve the analysis of the current situation of obstetric interventions in the Portuguese population (e.g. prevalence and reasons for cesarean section) [2,3].

The ObsCare-specific forms were developed by health information experts, based on World Health Organization (WHO) guidelines. These forms were iteratively updated over time, incorporating new knowledge and also the practical needs of obstetrics departments. ObsCare contains forms to record clinical and administrative data from appointments, hospital admissions, labor and abortion, surgical procedures, emergency department visits, and newborn data; it also includes a timeline representing the most relevant timepoints of each patient's care. In 2017, ObsCare was used by obstetricians and obstetric nurses to record data from 14,034 newborns [2].

However, ObsCare and other EHRs have major challenges related to semantic interoperability and data quality. In recent years, several projects exist to address issues of EHR modeling and implementation, focusing on the development of a future-proof EHR system [4,5]. One of the possible approaches is the use of openEHR, a set of open specifications for EHR architecture [5–7] which assumes a two-level framework, Reference Model (RM) and Archetype Model (AM) [8]. These two levels are applied to separate knowledge and information models [9,10]. While RM represents the semantics of storing and processing in the system, the AM is the keystone of openEHR. Archetypes are structured and complete representations of domain-level information concepts [11,12]; in others words, AM contains the knowledge enabling environment by defining domain level structure and constraints on the generic data structure residing in the RM [13] . Clinicians have an important role in the creation and improvement of these archetypes, which empowers them to directly influence EHR functioning and the quality of patient care [11,12]. Archetypes can be classified, regarding their topics, into two groups: 'general medicine' (e.g. drug administration, vital signs, etc) and specialist. Any speciality will routinely generate data of both categories, and therefore has requirements both for specific data points within the general archetypes, as well as completely specialist archetypes.

To date, there is a lack of research evidence on the possible use of openEHR archetypes to represent obstetric clinical EHR information and the available studies focus only on prenatal care data validation and the birth plan [14,15]. This study aimed to describe a summary representation of Obscare workflow and

to validate whether archetypes in the openEHR Clinical Knowledge Manager repository can represent ObsCare clinical concepts.

Methods

This study was developed based on the following steps:

a) **ObsCare form selection**

The authors chose the labor/abortion form from ObsCare, which includes detailed data on labor and abortion occurrences and procedures.

b) Description of the care process workflow

The authors identified the steps of the obstetric care process used to fill the selected ObsCare forms. Each step represents one ObsCare subform, built based on the available literature and integrating expert opinion over the 15 years of ObsCare clinical use. A clinical workflow related to the whole process was modelled, following the openEHR Task Planning Model [16], a recent specification of work plans in healthcare, and designed as a formal extension to the main openEHR EHR information models [16]. We used the Business Process Model and Notation (BPMN) for reasons of tooling availability to express the workflow model [17].

c) Detailed data extraction

The forms selected in step a) were reviewed by the authors to extract all the included variables. This review was performed by healthcare professionals, one of them a gynecology and obstetrics specialist. All the fillable fields available in the selected ObsCare form were included as variables. When the same variable was repeated in more than one ObsCare subform, only one was included in this analysis.

d) Clinical Knowledge Manager (CKM) analysis.

The identified variables and the underlying clinical concepts were searched for in the openEHR International Clinical Knowledge Manager (CKM) repository [18,19].

CKM is a system for collaborative development, management, and publishing of a wide range of clinical information artefacts. To perform the CKM analysis, the authors organized a variable list including all the ObsCare retrieved variables, and the search was conducted using the name of the clinical concept, keywords, and core-data items. When the existing CKM archetype included all the needed information, it was classified as "complete". We classified the existing archetypes as incomplete and considered reformulating them when they could represent the variables, but we considered that there was a need to improve the concept description and/or add additional items to the archetypes. The authors considered proposing new archetypes when the concepts were not available in the CKM repository.

We also analyzed the type, openEHR status, and specialty of the CKM archetypes that can be used to represent ObsCare variables.

Results

The ObsCare labor/abortion forms include eight sections: (1) abortion record, (2) labor data, (3) labor analgesia, (4) external cephalic version, (5) shoulder dystocia, (6) instrumental birth, (7) postpartum bleeding, and (8) complementary information. The use of the selected ObsCare form follows the workflow care process represented in Figure 1.

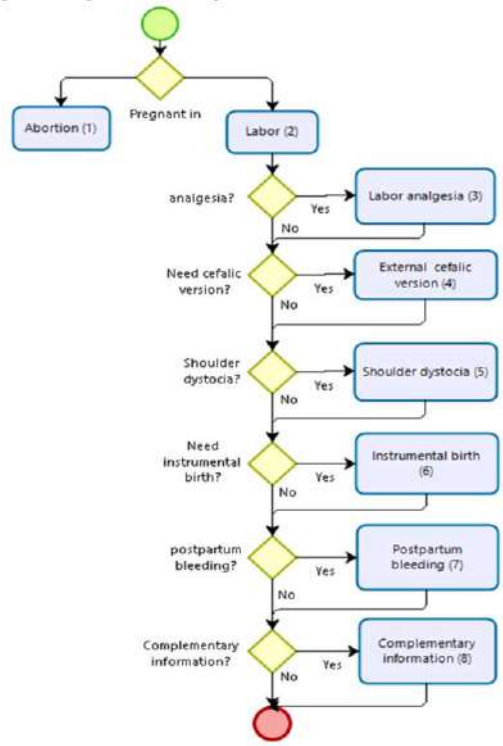

Figure 1 - ObsCare obstetric care process workflow represented in BPMN

We identified 379 variables in the selected ObsCare form. Fifty-eight percent (n=219) of the identified variables can be fully represented by the archetypes available in the CKM. Twenty-six percent (n=99) additional variables were partially represented by the existing archetypes with the need for some adjustment. Only 16% (n=61) were not represented by an existing archetype and a new archetype(s) will need to be created (Figure 2).

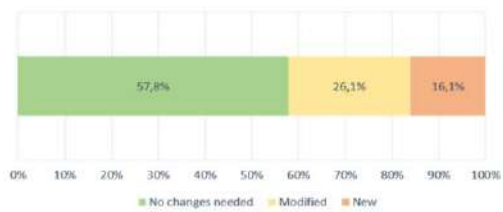

Figure 2 - Summary of openEHR repository status to represent the variables identified in the selected ObsCare form.

a) openEHR Archetypes: complete and requiring adjustment

318 ObsCare variables could be completely or partially represented by the 33 existing openEHR archetypes identified in table 1.

Table 1 - Archetypes used in the ObsCare form. The frequency of use and the need for modification is also provided.

	Total	Need modification	
openEHR archetypes	n	n	(%)
Procedure	68	42	(61.8)
Healthcare provider identifier	51	1	(2.0)
Individual healthcare provider	45	0	(0.0)
Pregnancy Summary	36	36	(100.0)
Problem/diagnosis	23	0	(0.0)
Medication summary	15	0	(0.0)

Fetal Heart Rate	1	1	100.0
Body surface area	1	0	(0.0)
Apgar score	1	0	(0.0)
Total	318	99	(31.1)

The archetype "Procedure" was the most frequently used to represent ObsCare variables (n=68), in relation with the high number of form variables that are used to describe labor-related interventions; nevertheless, it would require modification to adequately represent nearly 62% of those variables. "Healthcare provider identifier" and "Individual Healthcare provider" were the 2nd and 3rd most applied archetypes. These archetypes were used to represent data from the health professionals involved in obstetric care (e.g., the professionals who assisted the labor/birth or that were called for a complication) and would only need update to represent one variable (unknown healthcare provider assisting to labor).

Finally, "Pregnancy summary" and "Problem/diagnosis" archetypes are also frequently needed to represent ObsCare data. These archetypes correspond to records of obstetric information (e.g.: gestational age) and maternal or fetal diagnoses. However, "Pregnancy summary" could not fully represent all of the ObsCare variables.

Table 2 represents the type, speciality and openEHR status of the archetypes. Most of the archetypes used in the ObsCare form were 'Cluster' structures, closely followed by 'Evaluation' and 'Action' archetypes. Although most of the reviewed archetypes were generic, 14% of them were specific to obstetrics. Moreover, although half (50.8%) still have the status of 'Draft' - which makes editing suggestions possible - 44.5% are "Published" i.e. already formally validated by health professionals.

b) Variables not represented by existing openEHR archetypes

The authors found that around 16% of the variables from the selected ObsCare form were not represented in the CKM. These variables are related to several areas of obstetrics, such as placenta, bishop index, number of pulls during instrumental birth, anesthetic blockage space, effectiveness of anesthesia assessed by the doctor and the patient, passage to the operating room (hours) in the context of post-partum bleeding, type of abortion, and fetal position, among others.

Discussion

In this study, we described the status of the openEHR CKM to respond to the needs of a specific obstetric product — ObsCare. We identified 379 variables in the selected form, from which 26% would need the corresponding openEHR-archetypes to be modified and 16% would need new archetypes.

ObsCare has been used for the last 15 years, and the users (obstetricians, nurses, neonatologists, among others) have been validating and suggesting additional data, enriching the content of the form. ObsCare has eight forms (and their subforms) and a timeline, which presents the most relevant information from a particular patient, summarizing and making data visualization much easier. However, ObsCare developers acknowledge that this EHR needs improvements to become a future-proof tool, to strengthen data quality and precision, interoperability, and so on.

The openEHR platform, which supports interoperability and the capture of all clinical knowledge in a structured way separated from the software, provides the formalism and tools to directly link healthcare professionals and developers [5].

Another important point is related to obstetrics procedures. During the labor, birth and abortion care, healthcare professionals perform numerous actions related to diagnosis and treatment. For example, medication administration and blood collection. These diagnostic and treatment workups involve the cooperation of several important health professionals (e.g. nurses, technicians, obstetricians, anesthesiologists and so on) and that is reflected in the high number of variables present in ObsCare that are related to the description of procedures and the identification of the ones that perform them. Because of the complexity of labor and abortion care, a lot of archetype modifications were seen as necessary. In this step, the researchers experienced some challenges to establish the best way to use some particular archetypes.

A general criticism of the CKM and archetype-based modelling is that it is not always easy for healthcare specialists unfamiliar with the formalism or methodology to locate or determine the best concept to use within the 'general medicine' archetypes and specialist ones. Nevertheless, engaging specialists in modelling enables significant improvements in both the general archetypes (by addition or modification of specialist related attributes, e.g. in models like 'medication administration') and the specialist archetypes.

Accordingly, the archetypes relevant to the ObsCare forms include numerous 'general' archetypes, as well as others specific to the obstetric field.

Fortunately, many openEHR archetypes have the "draft" lifecycle status in CKM, meaning that change requests may be submitted in the current development phase.

The small amount of data required for the ObsCare forms not represented in the current openEHR archetypes, reinforces the need for proposals for new archetypes that represent the entire pregnancy cycle until six weeks postpartum, such as gynecological history, labor, birth, placenta, postpartum, newborn and so on [15]. Most of these variables would need obstetric-specific archetypes to be adequately represented. Such variables are indispensable for an obstetric EHR. These results were already found in another study and reinforce the need for more research in obstetric-specific modelling [15]. By these results, obstetric data could be organized and better used by other developers and health professionals.

On the other hand, the presence of variables with incomplete records and variables of doubtful meaning is a standard problem and is well-documented in EHRs [6,7]. ObsCare also exhibits these problems; we found that the selected ObsCare form would benefit from improvements on how the questions are formulated to ensure that all healthcare professionals correctly understand the content to be included in each form field. Consequently, we believe that the openEHR platform can be used to improve ObsCare.

The major contribution of this paper is to describe the relevant data, workflow, and the need for new and modified archetypes related to labor, birth, and abortion. Using agreed structured data expressed as archetypes would achieve semantic interoperability [8,10] between the EHR and other data users.

Governmental institutions, medical associations and other groups that produce clinical knowledge artefacts (e.g. clinical guidelines) could achieve significant benefits by incorporating domain-level information models in the form of archetypes, such as those described here for obstetrics, within their programs. The availability of computable artefacts would express obstetric information structures and needs in a way that can be directly used in the development of EHR and also for clinical decision support systems (CDSS). Using this structured data, the development of EHR could reduce the heterogeneity of similar applications and improve semantic interoperability [20]. openEHR presents the highest level of interoperability (level 4), where the data are electronically interpreted. In this case, the transferred messages are structured and contain standardized and coded data. This is the ideal state where systems exchange information using the same formats and vocabularies. In addition, openEHR improve EHR data quality, which is related to data accuracy, completeness, timeliness, among others [7,21]. ObsCare is a pioneer product in Portugal; neverthless, upgrading it to the openEHR platform is a challenging process and demands many steps, the first being to identify the ObsCare clinical concepts and match them with archetypes that are already available in CKM. Future steps will include proposing modifications to already existing archetypes and the creation of those that are not yet available.

Although the importance of user requirements capture prior to the construction of any computer system is much referenced in the literature, it was observed that there were few such studies available for IT systems in obstetrics [15,20,22].

In a study similar to the one reported here, that aimed to validate the minimum data set needed for a prenatal care EHR using archetypes, similar results were found, i.e. that significant CKM archetype reuse was possible along with a certain amount of modifications and proposed new models [15].

Overall, however, there is a relative paucity of international research studies related to formal modelling for health information systems or the use of the openEHR platform in specialist clinical areas, including in obstetrics in primary care [14,15,20]. Health information systems that use the openEHR platform offer great potential to improve clinical practice in obstetrics, where the same woman is seen many times by different physicians and other health professionals. The complexity of the diagnostic and therapeutic workups leads to a strong need for a higher direct involvement by healthcare professionals in the semantic modelling as well as workflow and usability design, contributing to the improvement, development and greater use of these systems [1,15,20,22]. The archetype formalism, methodology, and tools provide a significant step forward in enabling this involvement.

The current study has some limitations that must be considered. First, it is based on a single form from a wider obstetric-EHR; the labour/abortion form is one of the most commonly used ObsCare forms, nevertheless, it will be important to extend this approach to all other forms. Moreover, although ObsCare has been in clinical use, in Portugal, over the last 15 years, this study did not include an external validation of the extracted variables and they might not adequately represent other settings or countries' practices. Additionally, although this study allowed the identification of important clinical concepts present in ObsCare and matched them with already existing CKM archetypes, it is only an initial development and there is still need of further steps.

Conclusions

The present study showed that the openEHR CKM repository requires further enhancements to be able to fully answer to the needs of an obstetric-specific EHR, the ObsCare software. Our future perspective is modelling the missing obstetric archetypes and modify those that already exist. Following that, we will incorporate these standards into the future evolution of ObsCare.

Abstract

Hyperglycemia associated with pregnancy has been related to several unfavorable perinatal outcomes, as well as to the increase of incidence on future complications. Thus, the diagnosis of hyperglycemia in the pregnancy-puerperal context should be a global health concern. This article presents the development of a mobile application prototype which informs, imparts accurate diagnosis and provides tools for obstetric telemonitoring in women with pregnancy associated diabetes. After detailed analysis of the proposals for a new diagnostic strategy considering possible scarcity of resources, key elements were selected and inserted into the prototype, in order to cater for the most aspects and make it as thorough as possible. The application has been adapted to the Brazilian reality, however, having adjustments in compliance with international protocols, it has the potential to be used worldwide.

Keywords:

Mobile Applications; Diabetes, Gestational; Obstetrics

Introduction

It is known that hyperglycemia is one of the most common medical conditions during pregnancy. Besides that, the obstetric history of Gestational Diabetes Mellitus (GDM) is the main risk factor for the development of type 2 diabetes and metabolic syndrome in post-pregnancy women. Thus, it is feasible to assume that hyperglycemia during the pregnancy-puerperal cycle constitutes a relevant problem nowadays, considering not only the risks of worse perinatal outcomes (increased cesarean deliveries, traumas and distorts at delivery, macrosomia, respiratory distress and neonatal hypoglycemia, among other complications), but also the risk of developing future maternal diseases. This fact can also be extended to the children of these women, thus increasing the risk of the children developing, for example, obesity and type 2 diabetes in the future. Hence, it is evident that the diagnosis of GDM should be considered a global health concern [1-3].

Regarding the diagnosis, when hyperglycemia is detected during pregnancy it is classified as either Gestational Diabetes Mellitus (GDM) or diabetes mellitus in pregnancy (DIP). Women with slightly elevated blood glucose levels are classified as having GDM and women with substantially elevated blood glucose levels are classified as women with DIP. DIP may either have been pre-existing diabetes (type 1 or type 2) antedating pregnancy, or diabetes first diagnosed during pregnancy [3].

The predominance of hyperglycemia during pregnancy may vary depending on the diagnostic criteria used as well as the population studied. The International Diabetes Federation (IDF) estimates that approximately one in six live births (16.2%) in 2017 was related to some form of hyperglycemia in pregnancy. An estimated 86.4% of those cases were due to GDM, 6.2% due to diabetes detected prior to pregnancy, and 7.4% due to other types of diabetes (including type 1 and type 2 diabetes) first detected in pregnancy. Estimates regarding hyperglycemia in gestation in Brazil are inconsistent, but it is estimated that the prevalence of GDM in the Brazilian Health System is of approximately 18% [1,2].

GDM context in Brazil

Hyperglycemia (high blood glucose level) is currently inserted in the context of an actual obesity epidemic that has been observed in several countries. It is estimated that approximately 58% of the female diabetes mellitus (DM) cases in Brazil are attributed to obesity, whose causes are related, among other factors, to poor diet and nowadays' lifestyle [4].

In this context of increased prevalence of obesity, associated with the raising of the maternal age and also the lack of physical activity, especially in the last two decades, there was a progressive escalation in the number of women diagnosed with diabetes at childbearing age and during the pregnancy-puerperal cycle [2].

Considering the prevalence and the various short-term and long-term consequences of GDM for mothers and their children, a discussion forum on the topic was held in São Paulo, Brazil, on August 1, 2016. Participants in this forum were physicians specialized in assisting women with GDM: consultants from the Pan American Health Organization / World Health Organization (PAHO / WHO in Brazil) and technical advisors from the Ministry of Health, obstetricians of the Brazilian Federation of Gynecology and Obstetrics (FEBRASGO) and endocrinologists of the Brazilian Diabetes Society (SBD). The purpose of this gathering was to draw a proposal for the diagnosis of GDM in Brazil, taking into consideration that some countries follow protocols related to the diagnosis and management of hyperglycemia during pregnancy inserted in their respective contexts. The discussion took into account previous general agreements and studies, adding Brazilians particularities. Therefore, two strategies were proposed towards the diagnosis for GDM for the population, especially considering the fact that Brazil is a continental country, and that, consequently, it is subjected to scenarios of scarcity and fragility in the assistance in various places. The two strategies

are based primarily on the availability of the oral glucose tolerance test with 75g of glucose (75-g OGTT) [2].

These two strategies were presented and became part of a document – published by PAHO / WHO in Brazil, Ministry of Health, FEBRASGO and SBD in 2017 – called "Screening and diagnosis of Gestational Diabetes Mellitus in Brazil" (free translation), in which the main points of consensus on the forum were presented taking into account the distinctness in access to health services in Brazil [2]. However, in spite of the fact that these strategies were designed for the Brazilian context, where there is a lack of resources available in some areas, such strategies could be used in a worldwide perspective in places where access to the resources of laboratory tests in pregnancy is not so easy.

The use of mobile technology for gestational telemonitoring

Mobile applications in the context of an increasingly digitized world are inserted in the context of pregnancy, including, among other factors, access to information available as a source of support and advice and the use of several new devices – thus, they are able to change how the pregnancy and maternity are understood and practiced [5].

Diet control and physical activity in pregnancy, for instance, are essential issues in the treatment of hyperglycemia during pregnancy. And, even though health professionals are constantly trying to encourage healthy behaviors based on such issues, verbal information can be easily forgotten, and printed information may be lost as well. In this context, the use of applications in health interventions seems to be more appropriate for a better fidelity to the treatment, considering its various purposes and forms of communication rather than just texts (sounds, images, interactivity) [6].

A recent review involving telemonitoring effectiveness in obstetrics brought about the presence of several telemonitoring applications in this area of medicine. Some of them are related to cervical dilatation or preterm labor, GDM, maternal satisfaction, health care-related costs, birth weight and gestational age. Regarding the management of GDM, the telemedicine application observed in the studies focused mainly on mechanisms of transfer of glucose values from the patient to a provider, which reduced the need for frequent clinical visits and possible maternal, fetal or neonatal adverse outcomes [7].

Thus, in view of the high prevalence of hyperglycemia in the pregnancy-puerperal period and all the complications associated, as well as the fact that follow-ups through applications could generate better adherence to the treatment, we were highly motivated to the development of this work.

This article presents a mobile application prototype to inform, provide a correct diagnosis and supply tools for obstetric telemonitoring involving glycemic control in women with diabetes associated with pregnancy, taking into consideration the probability of a context of scarcity of laboratory resources.

Methods

This is an applied study based on another research (trial), carried out from January to October 2018. The proposed application for glycemic control in women with diabetes associated with pregnancy will be incorporated into an obstetric telemonitoring system for the detection and early intervention in the main gestational intercurrences, this system is being tested in the context of another parallel study by the authors.

The application is aimed at women in the pregnancy-puerperal cycle who have some alteration of glycemic levels and also for the health professionals involved with their care.

The study was conducted in three stages:

1. Detailed analysis of the strategies proposed by the document “Screening and diagnosis of Gestational Diabetes Mellitus in Brazil”;
2. Definition of key elements on what would be available in the application, aiming to provide users with the three pillars proposed by us in order to be as thorough as possible (I-D-F): (1) Information – which includes updated concepts about diabetes during pregnancy, with accessible language; (2) Diagnosis – which must be correct and timely, based on the context in which the patient is inserted and according to the established protocol (in this case, as defined in the document "Screening and diagnosis of Gestational Diabetes Mellitus in Brazil"); and (3) Follow-up – through the evolution of glycemic control, diet and patient weight;
3. For the development and presentation of the prototype, the Balsamiq® tool was used, which allows the construction of graphic interfaces.

Results

Analysis of the document “Screening and diagnosis of Gestational Diabetes Mellitus in Brazil”

The document in question was analyzed at length with the intention of providing a precise perception of the diagnostic process to be inserted in the prototype. The two strategies proposed in the document are basically based on whether the oral glucose tolerance test with 75 g glucose (75-g OGTT) is available for or not in the region where the pregnant / puerpera woman is.

In case of availability of such test, all pregnant women should perform the fasting blood glucose test (up to 20 weeks of gestational age) for diagnosis of GDM and Diabetes first diagnosed during pregnancy. All pregnant women with fasting blood glucose lower than 92 mg/dL should perform 75-g OGTT between 24 and 28 weeks. If the onset of prenatal care is delayed (after 20 weeks of gestational age), the OGTT should be performed as soon as possible. In this way it is estimated that 100% of cases of GDM should be detected [2].

In cases where just the fasting glucose is available, all pregnant women should perform fasting glucose at the beginning of prenatal care for the diagnosis of GDM and Diabetes first diagnosed during pregnancy. If the test results are below 92 mg/dL, before 24 weeks of gestational age, fasting glucose should be repeated for 24 to 28 weeks. It is estimated that in this way that 86% of cases of GDM are detected [2].

The diagnosis in the puerperal period also follows the strategies based on the availability of 75-g OGTT. Thus, in case of availability, the 75-g OGTT six weeks postpartum sets the gold standard for diagnosing diabetes after pregnancy (100% detection). If only fasting glucose is available, it is estimated that only 66% of the cases of changes in glucose metabolism, including DM [2], might be diagnosed.

Application of the key points in the development of the prototype

Taking as a starting point the recommendations of the document in question, a list of key elements which should be included in the prototype was made. This inclusion was done by using Balsamiq®, a medium-fidelity prototyping software, which

allows the creation of functional interfaces, giving the user an initial impression of the operation of the application.

The proposal to create a login for the access of to the application was raised due to the fact that the patients' information should be only accessed by them, and made it available to third parties, including health professionals, solely under their authorization.

As for the login, personal identification data is filled in, whether the user is a health professional, pregnant or puerpera, the gestational age or postpartum time, as well as a valid personal email and a password. The application user must agree to the terms of use of the application in order to obtain access (Figure 1).

Figure 1 – Screen in which there are fields for insertion of information that will compose the profile of the user

The application menu has been designed to be presented in a simple way, either on the home screen or based on a quick access (Figure 2), which enables the migration between topics without necessarily returning to the home screen. The topics were distributed as follows: My Profile; About Diabetes in Pregnancy; Diagnosis of Diabetes in Pregnancy; My glycemic control; Alerts; Settings; About; Logoff.

Regarding the Information pillar, we are concerned to inform patients, in clear and accessible language, of common questions (Figure 3) about diabetes, whether gestational or not. For this pillar, the "About Diabetes in Gestation" section has been targeted in the application, and the questions are: "What is Diabetes?", "What is Gestational Diabetes?", "Why Gestational Diabetes Happens?", "What are the risk factors for having Diabetes in pregnancy?", "How to diagnose Diabetes in pregnancy?" and "How to know if after pregnancy Diabetes will continue?".

Figure 2 – Proposed Start Menu and Quick Access Menu Screens

Figure 3 – Questions from the section "About Diabetes in Gestation"

As for the Diagnosis pillar, it will be correctly done through a series of simple questions, in which the patient or health professional should only answer "yes" or "no" (Figure 4) and choose the values of blood glucose and/or 75-g OGTT obtained during the diagnostic investigation. All the decision making and answers presented by the prototype follow the protocol previously established, be it in the context of pregnancy or puerperium.

Figure 4 – Question 1 that initiates the flow of questions for the correct diagnosis: "At the place of prenatal care is there 75-g OGTT available for the realization?" / Question requiring the value of the first fasting glycemia to set or not immediately the diagnosis: "What was the value of the first fasting glycemia obtained in this gestation?"

As for the Follow-up pillar, in view of the glycemic control, we devised a table synchronized with a chart - this table can be filled with the values of capillary blood glucose, and that will allow to follow the evolution (during a day and to the over several days) and the consequent need for glycemia correction (Figure 5).

In addition to the glycemic control, the Follow-up pillar also involves "Physical exercise, diet, and the weight control" section in which the patients receive information about the types of exercise and diet according to their contexts. Based on the calendar, the patient can enter the days on which she performed physical activity (as well as the nature of the activity and how long it lasted), and her daily diet, as well as the evolution of her weight throughout the days (Figure 5). This information would be saved and would enable a simple and practical analysis, later, by health professionals.

Figure 5 - Screens representing the graph of the section "My glycemic control - Glycemic curve" and "My glycemic control - Physical exercises, diet and weight control"

In this prototype, there is still the possibility of certain patients' profiles to be connected to monitoring by the responsible physician. In this way, the health professionals can have in their device the list of pregnant/puerperal women whom they accompany and can monitor how their blood glucose curve progress in real time. In this way these professionals could contact the user if necessary, advising her, for instance, to an early return to prenatal care.

The "Alerts" section has emerged as a proposal for the pregnant/puerperal women to control functionalities that will serve as true guidelines for their diet, physical exercises and medication (in case of using oral hypoglycemic agents and/or insulin) and for measuring capillary blood glucose. When activating these functionalities, they will be synchronized with the device, which will allow the user to receive, at the scheduled times, notifications that will act as real reminders to carry out those activities throughout the day. In addition, the user can activate features that begin a countdown to the beginning of the period of the laboratory tests of fasting glycemia and 75-g OGTT, when applicable.

Discussion

The recent proposal for the screening and diagnosis of GDM in Brazil has emerged taking into account different contexts of availability of resources (technical and financial), and proposals such as this should be encouraged, especially as they seek greater attention to prevailing conditions and with significant morbidity and mortality if not correctly diagnosed/managed.

In this context, consideration was also given to the fact that caring for hyperglycemia is not confined to pregnancy alone – because even if glucose tolerance normalizes rapidly postpartum in most women who have developed GDM, the risk of developing of type 2 DM or of glucose intolerance is significant. It is for this reason that the monitoring of women with GDM after childbirth is fundamental [2]. Our application proposal, therefore, also seeks to encompass the postpartum context, guaranteeing to inform, correctly diagnose and follow up these women throughout the pregnancy-puerperal cycle.

The control through the glycemic curve proposed by the application can be performed in the ward or at the ambulatory. In these contexts, it is important that the setting of the times and days when the capillary blood glucose dosage should be performed and the analysis of this curve should only be made by a trained physician, as well as possible corrections with drug therapies.

It is well known that mobile applications for self-management of diseases such as diabetes and general well-being (including diet and exercise monitoring) are widely available. However, users are faced with an enormous amount of new applications, which often do not use scientific evidence for their development and do not take into consideration the context in which the user is inserted in. In addition, users often do not seek or receive guidance from health care professionals about choosing the appropriate application [8]. Thus, the application in question appears to change this scenario, because it is a reliable tool, based on evidence and that will be used with the guidance provided by health professionals.

On top of that, the application presented here seeks to improve the relationship between women and health professionals, as well as their relationship to their health condition. Mobile applications of this nature allow patients to become more involved in self-management of their health. This type of follow-up increases confidence, adherence to treatment and participation by patients, giving them the knowledge to act and adopt behaviors to maintain and improve their health by taking actions, asking questions to health professionals and participating in the decision-making process related to their treatment [9]. Hence, it is well known that there is evidence of better health outcomes when patients are involved in self-management of their own diseases [8].

Literature surveys point to the growing number of applications available that are likely to be distributed between the two most popular mobile platforms, iOS (Apple Computer Inc.) and Android (Google Inc.) [10]. Thus, we expect the application to be available on both platforms in the future after its validation, aiming for free access and if possible, encouraged by public government policies.

Some specific potential impacts, such as the declining of morbidity and mortality due to diabetes in the gestation after the correct use of the application, might undoubtedly be observed if the information of this tool is used and followed in the right and early manner, along with the guidelines of health professionals. Nevertheless, they might be difficult to quantify in the future, having as a direct causal relation to the insertion of this application.

It is expected that, starting with the clinical trials with this application, it will be possible to measure the impacts of monitoring glycemic levels during pregnancy. Despite being based on gestational diabetes follow-up protocols advocated by the WHO, the Brazilian Society of Diabetes and the Brazilian Federation of Gynecology and Obstetrics, the use of computational protocols for the development of this prototype allows the parameterization of other protocols in their development. Thus, this application can be applied not only in Brazil but in other countries where the shortage of professionals and laboratory tests are a reality. In addition, from new and fast configurations, it is possible to use this application in other health contexts worldwide.

Conclusions

In the present work, a prototype was presented whose development was based on guidelines and scientific evidence for the monitoring of the glycemic changes during pregnancy, following the three pillars recommended by the authors: Information, Diagnosis and Follow-up (I-D-F), aimed at the early detection, timely treatment and follow-up in order to

reduce maternal and neonatal morbidity and mortality. It can also be used as self-management and a better adherence to treatment and follow-up by the pregnant / puerperal woman. The use of this application is expected to improve potential limitations on the scarcity of exams and professionals, which make it difficult to properly monitor these women and fetuses.

The use of mobile technologies and gestational monitoring applications has proven to be an important strategy to achieve better results in gestational follow-up. This application has great potential for development and application in future studies, assisting on the diagnostic process in the individual context of each patient, raising awareness on the general population about hyperglycemia in pregnancy and subsequent glycemic control in patients with this condition. Future application work in clinical practice will be carried out to evaluate the implementation of this application, analyzing users' opinions (patients and health professionals) and possible limitations or difficulties found in the use of this tool.

Abstract

The purpose of this study was to assess the project management of a national health information technology project focused on developing digital health care services. An e-questionnaire was sent at the end of the development project, and 93 experts (18%) from five university hospitals responded. The questionnaire was based on the Common Assessment Framework (CAF) to identify management success and also to get an overview of the project's performance. The questionnaire contained 11 background variables and 17 Likert scale items in five themes on leadership, strategy and planning, people, partnerships and resources, and processes, and one open-ended question. After analysis using descriptive statistical methods, the results showed that, overall, participants felt confident about management of the project. Criticism focused on the distribution of resources and lack of knowledge about the status of development activities in other hospitals. The CAF enablers criteria revealed subjects for further development.

Keywords:

Information technology; patient care management; systems analysis

Introduction

Deployment of digitalization is creating a variety of opportunities for the development of new ways to provide health care services. Digital services, meaning encounters with patients through virtual online appointments or electronic communication using various tools and technologies, is a growing means of providing health services [1]. One comprehensive platform for offering digital health services is patient portals, which nowadays have technical functionalities to support national interoperability at the levels of information technology (IT) infrastructure, applications, data, services, procedures, and policies, in addition to security [1–3]. Patient portals are comprehensive gateways providing health information, access to personal health records, the ability for patients to send secure messages to health professionals and manage appointments, decision support tools for self-care and diagnosis, and discussion forums [3–4]. While personal health records are managed by patients, patient portals are managed by health care organizations [4]. Results from many studies show that the change from face-to-face to online encounters through technology has already been accepted by both patients [5–6] and professionals [7–11], and effective treatment outcomes have been achieved [12].

Overall, the development of digital services is an international challenge [1–2] and, obviously, requires strategic goals at a national level. In Finland, the objective of the National eHealth and eSocial Strategy 2020 is to support the active role of citizens in promoting their own well-being by improving information management and implementing self-management and online services [13]. Strategic statements are crucial because they usually include a promise of allocation of resources.

Involvement of multidisciplinary team (physicians, nurses, and other experts in clinical areas as well as IT experts) is key for the development of digital health services [14–15]. The development process in regard to digital services encompasses a variety of actions for defining, procuring, planning, implementing, and providing new services; thus, it is prone to the risk of deterioration of processes and outcomes. According to the International Project Management Association (2006), project management is seen as an umbrella term encompassing planning, organization, monitoring, and control of all aspects of a project, along with motivations for all included to achieve the project objectives in a safe manner, on time, within the budget, and meeting performance criteria [16].

The implementation of health information technology (HIT) is executed as a project that often includes multiple subprojects. The success of HIT implementation has been widely evaluated, covering areas such as HIT adoption, acceptance of technology, and clinical quality, but there has been a lack of focus on or acknowledgment of the organizational context or human factors that could impact HIT implementation [17].

Due to the steadily growing number of projects in health service systems, the need for evaluation frameworks to assess project outcomes is obvious. The concept of project success is based on multiple assumptions regarding structures, processes, and outcomes as parts of a project [17–18]. As a result, many studies have emphasized splitting the concept of project success into two parts: project success, meaning the outcomes, and project *management* success, meaning structures and processes [17]. In particular, de Wit (1988) argued that product success should be assessed separately from the success of project management activities [19]. Radujković and Sjekavica (2017) analyzed various factors affecting project success and classified them into three categories: elements of project management competence, elements of organization, and elements of project management methodologies, methods, tools, and techniques [20]. Roberts (2018) used a framework that included technological, organizational, project-specific, and external factors to assess public health project success [21].

The European Public Administration Network launched the Common Assessment Framework (CAF) in May 2000 as the first European quality management instrument specifically tailored for and developed by the public sector itself. It is a common, basic, accessible, and easy-to-use model for all public

sector organizations across Europe and deals with all aspects of organizational excellence [22]. The CAF is designed to be used by public sector organizations, which distinguishes it from the European Foundation for Quality Management (EFQM) framework, which was founded within industry[23]. The CAF instrument is in the public domain, with the manual available online. Figure 1 presents the CAF framework with criteria [22].

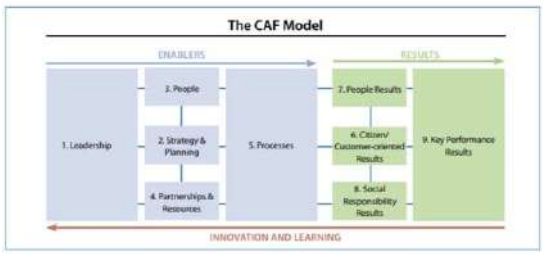

Figure 1. The CAF Framework [22]

The CAF framework is based on the premise that excellent results in organizational performance for citizens/customers and society in general are achieved through the leadership that drives people, partnerships, resources, processes, and strategy and planning. The nine criteria of the CAF represent the main factors that should be considered in evaluations looked at from two perspectives: Enablers and Results. Referring to de Wit's (1988) suggestion, the Enablers cover management success, and the Results cover project success [19]. There are five Enabler criteria (leadership, strategy and planning, people, partnerships and resources, and processes) and four Results criteria (citizen/customer-oriented results, people results, society results, and key performance results) [22].

In earlier studies, the CAF framework proved to be helpful for assessing the managerial practices of an organization based on the Enablers criteria and for the trends in results based on the Results criteria. The CAF self-assessment tools have proved to be helpful for finding areas in need of improvement [23–24].

The purpose of this study was to assess the project management success of a national HIT project focused on developing digital services in health care. There was particular interest in finding out how participants experienced the development project management from the perspective of the CAF criteria.

Methods

Study Context

This study was one part of a larger study evaluating a three-year national development project called Virtual Hospital 2.0. Funded by the Ministry of Social Affairs and Health, Virtual Hospital 2.0 was one of the main projects necessary to achieve the strategic goals of the national eHealth Strategy [13]. In particular, the project aimed to build Healthvillage.fi, a digital health service system comprising various digital portals that was developed through a collaboration among five university hospital districts and patient associations in Finland. Each university hospital was involved in the development work by either being responsible for creating a hub with certain care pathways or giving their expertise to other hospitals in their hubs. The first hub in Finland, informing and caring for mental health patients, was launched in 2009, and the second hub, for weight management, was launched in 2015. The success of the first two hubs was the guiding principle with the Virtual Hospital 2.0 project. To date, a total of 30 hubs and 86 pathways have been constructed in the project. Healthvillage.fi delivered three distinct types of services through hubs: 1) public health services available for all citizens, 2) digital care pathways for patients with a diagnosis and a care relationship, and 3) eLearning tools for healthcare professionals aimed at changing working practices.

The sociotechnical approach [15] guided the multidisciplinary teamwork in the development of portals and hub materials for patients with various diseases. The sociotechnical model helped to realize various dimensions of the development project: (1) computing hardware and software infrastructure; (2) clinical content; (3) human–computer interface; (4) people; (5) workflow and communication; (6) internal organizational policies, procedures, and culture; (7) external rules, regulations, and pressures; and (8) system measurement and monitoring [14–15]. Figure 2 illustrates the modified sociotechnical model adopted in the development of the work.

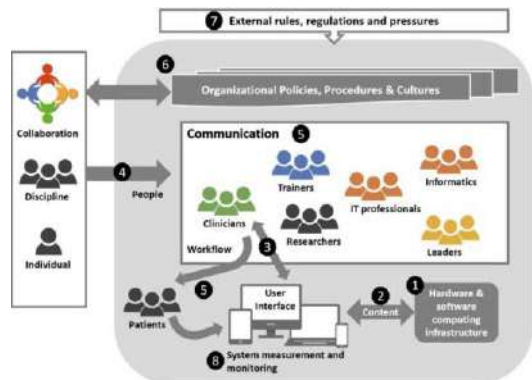

Figure 2. The Sociotechnical Model

In this study, patients were not informants because they have been involved in other studies [5].

Data Collection and Analysis

The data for three distinct studies were gathered with an e-questionnaire containing 11 background variables, 1 open-ended question, and 50 statements using a five-point Likert scale where 5 denoted strong agreement and 1 denoted strong disagreement. The participants (physicians, nurses, and other health care professionals, as well as IT designers [n=501]) were employed in the Virtual Hospital 2.0 project in the autumn of 2018. The concept of Enabler within CAF was applied to measure the management success of the project. The questionnaire contained five themes describing the CAF Enabler criteria: leadership, strategy and planning, people, partnerships and resources, and processes. The 17 items in total were operationalized based on the criteria and dimensions of the sociotechnical model used in the development project [14–15; 22]. The number and format of variables were decided by the evaluation team.

Research permission and ethical approval were received from project management. All questions (n=50) were validated by reference to earlier studies. Finally, the content validity of the questions was assessed by an external expert group, and minor changes were made based on their assessment. The link to the e-questionnaire was sent to each participant in the project (n=501) by their own organizational representatives. Two reminder messages were also sent by each organization.

The results were analyzed using descriptive statistical methods. The Likert scales were taken from the initial answer format of 1=totally disagree to 5=totally agree and modified by combining 1 and 2 to 1=weak, 3 to 2=undecided, and 4 and 5 to 3=strong agreement. The answers to open-ended question

were analyzed with content analysis. Narratives from answers to the open-ended question regarding the primary needs for development were used to confirm the opinions of the respondents.

This study was conducted in an ethical manner and in accord with best ethical research practice. Confidentiality and informed consent of the respondents were maintained so that none of the respondents could be recognized. The research data was stored electronically in secured servers at the University of Eastern Finland where only authorized persons in the research group had access . The data maintenance life cycle followed the principles of UEF, and the data will be destroyed when it is no longer needed.

Results

A total of 91 (18%) participants responded to the e-questionnaire. The majority of respondents were women (88%). Healthcare professions that were represented included nurses (48%), physicians (17%), or other clinicians (16%), and 19% represented various other types of expertise. Among the respondents, 80% had an academic degree. Half of the respondents to the survey represented two of the five university hospitals involved in the project. More than 60% of the respondents had worked in their organization for over 10 years, and 23% worked full-time, 21% part-time, and 56% worked on the project alongside the regular daily duties of their jobs. The participants represented development teams in a total of 14 different hubs. The three most frequently mentioned hubs were rehabilitation, childhood diseases, and heart diseases. Half of the respondents (n=41) replied to the open-ended question, out of which 30 focused on project management.

The project management success is described in the graphics of Figures 3 through 7, with the narrative in italics below the graphics being respondent comments used to support the results. In terms of leadership, the respondents were confident about the atmosphere, but there was some hesitation about the fluency of communication and managerial support (see Figure 3).

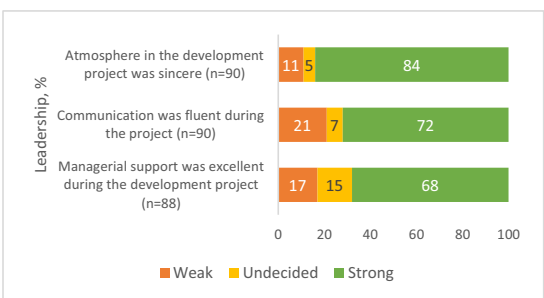

Figure 3. Leadership

The outcomes of the project should not stay inside the university hospitals.

The project management should focus on equal use of resources, both financial and competency-related, in the hospitals.

The respondents could not assess how the project was related to other digitalization projects in the country (Figure 4). They were also unaware of factors regarding the relationship with the development work in primary care.

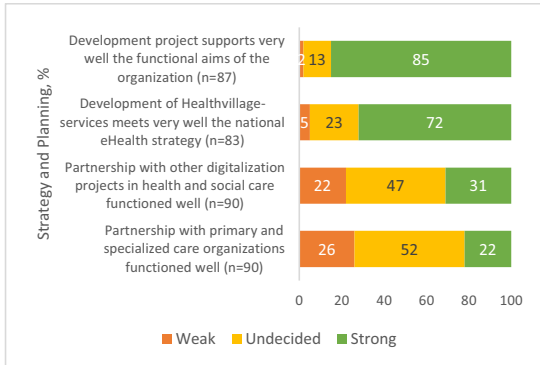

Figure 4. Strategy and Planning

The development work occurring in primary care and specialized care must be integrated.

The development work has produced a variety of material in digital format to support patients and professionals. Now is the time to really focus on dissemination of outcomes over the whole country.

The participants felt very positive about working on the project. Only a small minority had some criticisms (Figure 5).

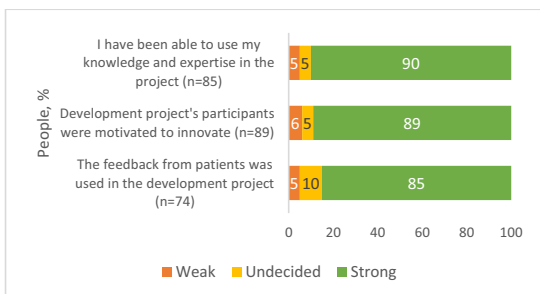

Figure 5. People

Working on this along with my daily duties has been sometimes overwhelming.

We as developers have worked hard on the project. Now I am worried about the rest of the clinicians, how to get them on board.

The development teams are not established based on the need of knowledge; pure enthusiasm is not enough.

Cooperation among various levels of the project seemed satisfactory. Some critical opinions were expressed in terms of working together with other participating university hospitals and the IT experts (see Figure 6).

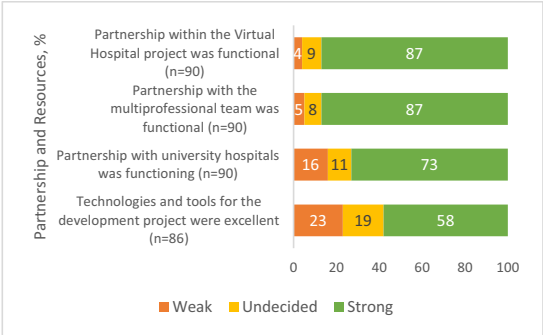

Figure 6. Partnership and Resources

In this project, resources have not been shared equally in terms of workload.

The model to create the hubs has now been tested and implemented many times. So, how to disseminate the knowledge further?

The opinions about the development process varied among the respondents. More than half were satisfied, with an almost equal distribution of those unsure about or against each item (see Figure 7).

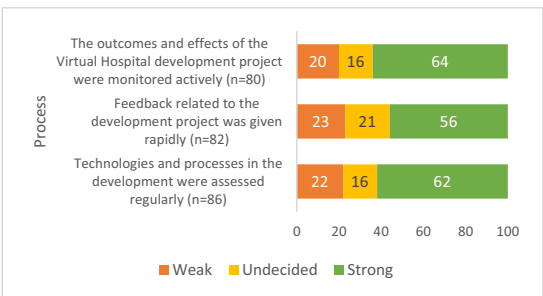

Figure 7. Processes

Too many important decisions have been made inside one university hospital. A national project involves shared and timely decision-making.

The support from IT departments has not functioned well; especially, we have been forced to wait for responses to our feedback.

Funding has not been followed during the project based on the knowledge and competencies in each university hospital due to a different situation in the development.

The use of the CAF's Enabler criteria in the assessment gave new insight for project management. In this case, the CAF was used for assessment at the end of the project, but as the digitalization of services continues, the procedures and policies assessed can be used to guide further development.

Discussion

The purpose of this study was to assess the project management success of a national HIT project focused on developing digital health care services. The specific interest was to assess the experiences of participants with regard to the project management. The data were gathered at the end of the development project, in August 2018. The data collection was organized through development managers so that the respondents had no contact with the researchers, and emails could be used for disseminating the link to the e-questionnaire. The low response rate (18%) may have been caused by the timing of data collection, given that late August is still a holiday season in Finland. Further, the link was sent by the development managers at the university hospitals, and the data collection occurred as the project was ending, so potential participants may have been receiving an excess of other emails. The link was opened a total of 229 times, but we do not fully know the reason why the questionnaire was left unanswered. In addition, because the national development project had also been a key focus among other researchers and stakeholders, some participation fatigue may have existed, particularly given that the project was ending in two months and an extensive amount of material on project outcomes was being collected at this time. What was learned by this could be applied in the future, particularly the involvement of researchers interested in national development projects should be planned at the beginning of a project, especially when pre- and post-project interventions are of interest [1].

While the project manager, team, organizational structure, culture, and atmosphere are still regarded as key components enabling a project's success, it is important to recognize all the factors influencing success [15, 20]. Although the CAF primarily focuses on the evaluation of management performance and the identification of organizational goals to make improvement possible, the ultimate goal is to contribute to good governance [22]. Roberts (2018) found in his study that leadership was the most important project success factor. He suggested that investing in the leadership and project management skills of project participants could improve the success of future projects [21]. In terms of leadership, this kind of multisite project can be challenging for supporting and guiding participants from different organizational cultures. Variations in the level of commitment to project aims may be difficult to monitor, and we found commitment especially challenging given that the project spanned approximately two-years. The strategies and planning we identified in this study referred mostly to national development initiatives in health care, as this project was one of the main development projects funded by the Ministry. Thus, we were surprised to discover that participants had limited knowledge about other national digitalization projects in health care. However, as the sociotechnical model highlights external rules and regulations should be taken into consideration for their influence on organizational policies [14–15].

Many studies have noted health care professionals' hesitation and fear about the implementation of new IT tools in daily practice [10–12]. In this study, half of the respondents were nurses, and they were enthusiastic about being involved in this development work. Participants expressed concerns regarding the rest of the clinicians and patients, and specifically how to ensure their voices were also represented. Further, opinions on partnership and cooperation were mainly very positive, which reflected on the multidisciplinary team's involvement as a part of the adopted sociotechnical model [14–15]. However, we found that while partnership between the university hospitals was satisfied, there were some criticisms around the technologies and tools. To address this, communication and collaboration between IT experts and end users should be of high importance, and considered in all IT projects [25].

Being a national development project, one aim was to create a model to develop digital services [4]. Thus, the processes during development were monitored and assessed. However, the participants wanted to know more regarding the progress, and criticized that the speed of feedback was unacceptable. Participants also stressed that their extensive work should be used for future implementation of digital care pathways.

Conclusions

Based on the project participants' opinions, we applied the CAF to reveal areas for development in project management. The five Enabler criteria of leadership, strategy and planning, people, partnerships and resources, and processes linked well with the sociotechnical model adopted in this development project. It can be argued based on the results that the length of the project is the basis of project management success, as it affects all criteria. However, more emphasis should be placed on communication as culture, leadership, resources, and competencies often vary between health care organizations.

Acknowledgments

The authors want to express gratitude to the Virtual Hospital 2.0 management for funding this external evaluation.

Abstract

Identification of risk patients in emergency departments is a complex interplay between clinicians, patients, working procedures, and information systems. Through a mixed methods approach, we have developed an novel patient monitoring dashboard that couples clinical data streams to convey the state and trajectory of patients admitted to the emergency d epartment. In this paper, we describe the design and implementation of the novel system by providing a description of how the project was conceived, divided into subsequent phases, and is currently being executed. Experience from this work highlights the importance of carefully assessing each on-site installation point, interdisciplinary partnerships through embedded presence, and continuous emphasis on the purpose and aim as a mean to greatly improve project momentum and buy-in.

Introduction

Identifying patients at risk of unforeseen deterioration in emergency departments (ED) remains an ongoing challenge despite numerous initiatives to formalize and systematize observations, tracking the state and trajectory of patients, and responding to changes to avoid complications.

In this paper, we provide a description of how this challenging clinical problem sparked a collaboration between engineers and clinicians resulting in the design, implementation, and evaluation of a novel patient monitoring dashboard. As we describe the prototype, process, and inter-disciplinary collaboration, we aim to provide a set of recommendations for similar attempts in assessing the impact of new health information systems. In doing so, we seek to extrapolate key findings that are decoupled from the initiating problem of detecting deterioration, and which instead point to more general challenges in systems design and implementation within secondary healthcare.

The inception of this project, originates from the work of Henriksen et al. who found that as many as one in three patients whose vital signs are within normality at admission, have an abnormal vital sign registration within the first 24 hours [1]. These patients have a higher risk of being transferred to the intensive care unit, experience heart or respiratory failure during admission, and a higher 7-day mortality. Identifying patients at risk in EDs spurred a research project collaboration between software engineers and clinical researchers to leverage their joint knowledge for proposing a way to alleviate the risk of unforeseen deterioration.

Related Work

A multitude of protocols and observation regimens have been introduced, evaluated, and often implemented in the last 20 years. Still, it is hard to come by evidence that undisputedly points to significant changes in patient outcomes due to the implementation of an Early Warning Score (or similar). The hospitals involved in this study relied on the DEPT triaging system for assessing the severity of patients [2]. DEPT deploys a mixture of objective (e.g., blood pressure) and subjective observations (e.g. pain), see Figure 1. The most severe observation determines the overall severity and priority of the patient.

Figure 1 - The DEPT Triage System

Part of the challenge relating to the utility of these systems, is not only due to the heterogeneity of patients, but also the variety in experience, background, and profession of attending clinicians [3]. Another major factor is the socio-technical complexities that come into play when mixing this variability with information technology.

Several sophisticated novelty detection systems have been proposed over the years. Clifton et al. published several studies on the application of Gaussian process regression for dealing with missing values and forecasting of trajectories [4], and also investigated extreme value theory as an mean to perform online learning of patient-specific models [5]. Clifton et al. are also one of the few groups that succeeded in advancing a system beyond the pilot evaluation stage, and actually tested their system in realistic settings [6]. Another substantial line of work originates from Edelson & Churpek who developed the CART score to predict cardiac arrest [7]. Perpendicular to the issue of modelling and prediction, we found a need to assess how to best visualize the system state.

Although there has been slow progress on systems designed for patients to monitor themselves, clinical dashboards and data aggregation have been subject to much work [8]. Generally, there seems to be less focus on taking a pragmatic stance to improve utilization and integration of existing streams of data, and integration of these into information systems in ways that improve the clinical perception of multiple patients simultaneously.

Methods

As the project has been ongoing since early 2013, we have split the methodology description into several stages. First, an initial stage from 2013-2015 focused on early scoping that took place at the ED of Odense University Hospital, and resulted in a prototype of a patient monitoring dashboard. The second stage from 2016-2017, was the system prototype maturation and integratation into additional information systems. The third stage ran from 2018-2019, and focused on a multidimensional effect evaluation.

From the very beginning of the project, it quickly became apparent that clinical epidemiologists and engineering researchers had substantially different approaches to designing and conducting research. As software engineers, we did not have any prior experience with the clinical, technical, and operational aspects of EDs. Consequently, we needed to design our study approach in a manner that embedded us within the context.

To achieve this, we designed the project using a mixed methods approach where we could explore several pathways to illuminate potential solutions to the problem of identifying patients at risk. This lead us down three distinct paths as illustrated in Figure 2, each path highlights a number of related activities.

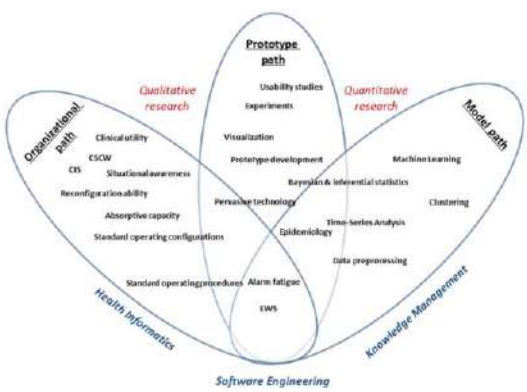

Figure 2 Methodological Project Paths

Firstly, as outsiders familiarizing ourselves with the context of our problem proved to be indispensable. To begin we mapped out an 'organizational path', which sought to clarify how clinicians dealt with the matter of patient processing, monitoring, and treatment. To do this, we deployed a number of tools, some were methodological by nature, and others were frameworks or research fields that helped us to understand the domain. The understanding of how clinicians worked with patients and the systems they utilizeed was then paired with data from actual patients. This data was the cornerstone of the 'modelling path', where we sought to understand patients and patient monitoring systems using a number of quantitative techniques, with the intention of deriving novel features and new ways of representing and understanding patients and monitoring systems. The 'organizational' and 'modelling' paths came together in the 'prototype' path where we attempted to validate assumptions from both of these paths. This was achieved via different prototype modalities, supported by usability studies.

Initial Stage – Early Scoping

Our first major effort was conducting a field study of the context. The first author of this paper followed physicians, nurses and nurse assistants on full work shifts at all times of the day and took note of how patients were attended to, how clinicians registered observations personally and collaboratively, and how information technology was used during the admission [9].

In parallel with this, we needed to establish a foundation for building better deterioration detection models with predictive analytic models. During the field study, we had observed several occasions where patients expressed individual normality that was not captured by the existing population-based threshold models. However, acquisition of vital signs from patients was not something the existing information communication (IT) configurations supported. Vital sign observations were registered in the department's electronic healthcare record according to protocol, but the registration frequency were low, and automated data extraction was not an option.

Coincidentally, a network diagram of the patient monitoring platform emerged while discussing other integration options with the local medical device engineers. This revealed that the ED had purchased a Philips IntelliVue™ solution that included a database server that automatically buffered all registrations from connected monitors. Thus enabling the HL7 Parameter Data Interface (PDI) allowed us to export vital sign readings at a configurable interval from the Philips database.

The Data Collection

Each bed at the department was equipped with a Philips IntelliVue MP30/50™ monitor. Each monitor had a Philips X2 Measurement ™ module, which could follow the patient during transfers. Each monitor had capacity to monitor heart and respiration rate through 3-lead electrocardiography, peripheral oxygen saturation (spO2) and pulse rate using pulse oximetry, and systolic/diastolic blood pressure (SBP/DBP) using non-invasive cuffs. To retrieve data we built a registration server that acquired registrations from all active monitors every minute using the HL7 PDI interface. The attending nurses were asked to register patients on the Philips monitors by name and social security number to enable later coupling with external health registries.

Prototype Design

The final phases of the initial stage focused on distilling the findings from all activities into a prototype system of a patient monitoring dashboard. Through incremental collaboration with clinicians, a functional prototype was implemented and evaluated in a pilot study involving 18 nurses and 50 patients [10]. The participating nurses were also asked to assess the system using the System Usability Scale [11], and results indicated that the overall design philosophy of the system made it easy to understand and use.

Second Stage - Refinement

After having successfully evaluated the prototype, we went on to acquire funding for further development of the system. This was achieved by funding from the Strategic Initiatives Program by the University of Southern Denmark through a 2M DKK grant. This gave us the opportunity to rewrite the entire prototype and explore new ways to deal with the

challenges of coupling registrations from the patient monitors with the department's clinical logistics system. The new system was dubbed the Patient Deterioration Warning System (PDWS). During this stage, the project grew in organizational complexity as an additional site was included, and the newly enforced General Data Protection Regulation had incentivized the IT departments across the region to impose stricter control with installation and evaluation of information technology for research purposes.

Third Stage – Effect Evaluation

Having rewritten the entire PDWS system, and tested deployment and operational stability of the system, the third stage of the project focused on conducting an effect evaluation. The intention of this larger trial was threefold:

1. To assess if deploying the PDWS into EDs would help clinicians identify patients who deteriorated unexpectedly.
2. To investigate if the design philosophy of the PDWS fitted well within clinical work.
3. To evaluate if utilizing the PDWS could help the departments in improving efficiency and quality.

Cluster Randomized Trial

The evaluation has been designed as a cluster randomized trial (CRT) consisting of three intervention and three control periods interleaved at each study site. Each period, lasting five weeks, has been separated by a one-week washout buffer. The study aims to include 10.500 patients, which will yield sufficiently material for evaluating the clinical hypothesis that the PDWS can reduce unexpected deterioration by 50%. The primary clinical outcome has been defined as patients who are transferred to the Intensive Care Unit, suffer from heart/respiratory failure, or die during admission. The evaluation stage will be assessed by journal review by clinical experts.

The CRT was initiated May 2018 and is scheduled to run until early 2019. During the period, project nurses and assistants will include patients at each site. Following the CRT period, data from all consenting patients will be transferred to a research repository and used for further research.

Study Sites

The first part of the study (field study, initial vital sign registration, and prototype pilot evaluation) was conducted at the Emergency Department of Odense University Hospital (OUH). OUH has an uptake population of 430,000 citizens and its ED has an capacity of 44 beds. The second part of the study expanded the participating sites to include also the ED of Hospital of South Western Jutland (HSWJ). HSWJ has an uptake population of 220.000 citizens and its ED operate 51 beds.

Although both EDs are situated in the Region of Southern Denmark, and are part of the same healthcare system, each ED organizes the patient admissions very differently. For example, at the ED of HSWJ, a patient is usually never transferred internally once admitted. Whereas in OUH, patients are seen and treated in a short term Acute Treatment Center for the first eight hours of admission, and then later transferred to the Center for Accellerated Patient flows for the remaining part of their admission.

Approvals

The project has been presented to the Scientific Ethics Committee of Southern Denmark, but does not need approval according to Danish legislation. The Danish Data Protection agency has accepted that we store data (J. nr. 17 14630). Research data are managed by OPEN (http://Open.rsyd.dk). Data from patients who provide informed consent will be used for the effect evaluation stage, and for future work in predictive analysis.

Results

As the project is still ongoing, and parts of it has already been described in other work, for the paper, we
seek to draw out some of the lesser known aspects – while still combining the entirety of the project to convey the key lines of results.

Data Acquisition

During the first part of the project, we acquired all registered vital signs over a two-year period as part of the initial prototype implementation. Although only a subset of these vital signs could be distinctly linked to specific admissions, the dataset in its entirety gave us a unique insight into the utilization of patient monitoring in the ED at Odense University Hospital. Table 1 lists the summary of all registrations. The number of registrations in relation to sensor type was evident, as we observed a decreasing number of registrations due to sensor nuisance.

Table 1- Vital Signs Registered During the Initial Stage

Vital Sign	#Registrations	Mean	Std.Dev
Heart rate	4,668,890	88 bpm	21 bpm
Respiration rate	4,491,545	20.4 rpm	5.7 rpm
Pulse rate	7,277,427	84.4 bpm	19.3 bpm
spO2	7,181,895	95%	3.8%
SBP	232,895	124 mmHg	26.4 mmHg
DBP	232,895	68.4 mmHg	17.9 mmHg

We evaluated the distributions of each vital sign type, and interestingly found distinct differences to what is considered normal vs. alarming thresholds according to the NEWS system [12]. Heart and pulse rate readings only exceeded the upper limit of 131 bpm in 3% of all cases, and just 0.2% of all readings were below 42 bpm. These numbers were much higher for respiration rate registrations where 16% surpass 25 rpm, and just 0.4% are lower than 8 rpm. 10% of spO2 registrations were lower than 91% oxygen saturation, and this was even without factoring in patients being administered additional oxygen. For systolic blood pressure, 7.5% of readings were lower than 90 mmHg which was quite substantial given the risk of low blood pressure [13].

Deriving Novel Metrics for Monitoring

Another line of work attempted to identify different models of normality for a range of clinical and patient specific factors [14]. Although we did not find support for the presence of such normality ranges, we instead identified clusters of patients who generally had vital signs within non-alarming thresholds, but with a distinctly higher mortality ratio. The main difference to similar clusters was a higher standard deviation. Thus, we identified a group of patients who seldom triggered any alarms, but still expressed high variability. This lead to the inclusion of the metric '*Relative severity*', which was implemented as an aggregated sum of shifts between states. Clinician could thus order patients by highest severity as prescribed by the attending physician, or by variability.

The degree of monitoring a patient was exposed to during admission was formalized in both departments by observation regimens. For example, a patient who was classified as

Figure 3 The Patient Deterioration Warning System - Client System

Orange was to be continuously monitored, and have vital signs registered in their electronic health record hourly. However, from our exploratory analysis of the vital sign dataset, we found that several factors, both patient and department specific, influenced the extent to which patients were monitored [15]. The findings of this work were utilized in the PDWS, as abnormal device utilization could be used as a marker for clinical concern.

The Patient Deterioration Warning System

The PDWS consists of a backend system implemented in Java™ using Spring v.4 with Hibernate for persistency and Envers for entity auditing, and a front-end implemented in AngularJs v.5. The PDWS interface is shown in Figure 3, and has been described in other work [10]. The system conveyed the state and trajectory of all admitted patients who at some point in time had been monitored using any of the department's vital sign monitors. All registered readings were scored using the DEPT system and aggregated into configurable periods of time with respect to the expected length of stay for a given ward. As the system automatically stored all vital signs from monitored patients every minute during their entire stay, and linked these with admission information, we were able to gradually establish a very detailed dataset of all patients admitted to the participating EDs.

The project as a whole made a giant leap forward when we figured out how to couple data from the monitors with data from the logistics system. The latter was essential for the daily operation of the department, and any changes in the admission flow of patients was instantaneously updated in the logistics system.

As portrayed by Figure 3, the PDWS was made available to clinicians using 24" all-in-one computers running Chrome OS. Nine of these were installed in offices at the ED of OUH, and six at the ED of HSWJ. Each computer was installed in the vicinity of the existing patient monitoring overview screen, and the clinical logistics system.

Discussion

As clinicians become increasingly reliant on computers to filter and present data, a sensible balance of work shared between information systems and clinicians must be sought. In this project, we sought to do so by simplifying a few of the streams of data that demanded the attention of clinicians, thereby aiming to mitigate the risk of information processing overload. The CRT is currently ongoing, and some preliminary observations are worth discussing.

Workflow Integration and Information Habits

Several aspects of the PDWS design philosophy, especially non-intrusiveness, and the assumption that clinicians will automatically utilize a novel system tailored to specifically address a problem most are familiar with in the settings, appeared to be challenged in the CRT. Self-evident as it may be, it became strikingly clear that installing yet another computer screen in the cramped work spaces of most clinicians did not offer much of a head start for evaluation of a new health information system. In most of the ED offices, the PDWS screen mentally disappeared in the clinicians information landscape. Futhermore, evaluation of new systems that aimed to enhance or replace existing systems, which were already highly embedded in current practice, was complicated. Old habits die hard, as was also evident by information acquisition. Essentially, the aim should be to make information acquisition easier with new system, rather than the old one. Deciding to obstruct access to systems already in use is seldom feasible, rather the alternative is to make the new noticeably easier to use. Several participants proposed embedding the PDWS components into existing IT solutions. This would however make it considerably more complex to conduct a targeted effect evaluation review.

Integration with Existing Information Systems

The real-time utilization of information from other hospital information systems, raised some concern amongst the organization. Legitimate concerns regarding unknown side effects were raised based on the new approach in utilizing existing systems. The solution was to conduct a PDWS code and performance audit on the supplier side to ensure that the PDWS did not strain existing resources or add risk.

Continuous Emphasis on Purpose and Aim

Two other crucial aspects we strived to address, which also relate to the issues above, were training in system use and awareness of intent and purpose. Prior to the CRT, the project and system was introduced to clinicians through newsletters, employee meeting presentations, and posters adjacent to each

screen. During the intervention periods we conducted several walkthroughs of the system. Still, we found that a major percentage of clinicians refrained from relating to the system. Project staff (nurses and nurse assistants), despite extra traning and expressed enthusiasm in the objective of the PDWS, were generally hesitant to act as system ambassadors in relation to coworkers. This points to the need for continous emphasis on the purpose of systems research in the settings, and awareness of the implications of employee turnover.

Future Directions

In several of the Danish Regions, work has been initiated to integrate data from medical devices faster and more seamlessly into decision making. Medical device data are to be enriched with data from other information sources (e.g., atttendending clinician, ordering speciality, patient info) to improve clinical, managerial, and operational services. The application of device utilization in the PDWS project, may serve as inspiration for new abnormality metrics. For example, raising flags when an abdominal ultrasound is ordered for a patient when it is not a part of the expected treatment plan.

Conclusion

Organizational, cultural, and technical aspects influence the detection of patients at risk of deterioration. Current patient monitoring solutions have shortcomings regarding incorporating the temporal and spatial organization of clinical work. A substantial ratio of automatically registered vital signs should be triggering more clinical concern than what is being observed. Coupling this with the fact that monitoring of patients in an ED is highly skewed, and that temporal trends are hard to derive from existing monitoring solutions, points to the need for better visualization tools.

Based on experiences from this work, we recommend that similar initiatives seek to: 1) *Carefully assess the settings of each installation point* to increase integration with existing workflows and information habits. 2) *Strive to establish interdisciplinary partnerships through embedded presence* to greatly improve the project momentum. Similarly, performance, load analysis, and openness regarding code reviews of integration points with external hospital information systems should be leveraged with stakeholder concerns. 3) *Continuously emphasize purpose and aim of a project and system,* as the typically high employee turnover in hospital departments, challenges long-term projects driven by user involvement. Consequently, a continuous effort is required to imprint the purpose of both research aim and the purpose of the evaluated information system.

Acknowledgements

This project was originally funded as a part of the Patient@home project, and subsquently by the Strategic Initiatives Program by University of Southern Denmark and Odense University Hospital. Additionally, this project would not have been possible without the support of the leadership and enthusiasm of both participating emergency departments.

Abstract

Potentially inappropriate prescribing of direct oral anticoagulants is frequent with the most common errors being dosage, administration, and duration of therapy. We developed RecosDoc-MTeV, a documentary-based clinical decision support system (CDSS) for the management of direct oral anticoagulant prescription to prevent and treat venous thromboembolism. Simultaneously, the network of Parisian public hospitals (AP-HP, France) developed narrative clinical practice guidelines (CPGs) and a companion smartphone application to enhance medication and patient safety related to direct oral anticoagulant prescription. To assess the effectiveness of these CDS tools, we performed a retrospective review of 274 random patients hospitalized in 2017, which were either at risk of venous thromboembolism or actually treated for the disease. Consistency between the two CDS tools was measured at 96.7%. Administered treatments were compliant in 67.2% and 72.3% of the cases, with AP-HP CPGs and RecosDoc-MTeV, respectively. These results support that implementing CDSSs for the prescription of direct oral anticoagulants may ensure safe prescribing of high-risk medications.

Introduction

Anticoagulants are the mainstay of therapy for the acute and long-term prevention and treatment of numerous types of thromboembolic disorders. The prevention of thromboembolic stroke among patients with chronic atrial fibrilation is one of the primary indications for anticoagulation therapy. In addition, anticoagulants are indicated in, and increasingly prescribed for, the prevention and treatment of venous thromboembolic disease including deep vein thrombosis and pulmonary embolism. Until recently, anticoagulation therapy was dominated by parenteral anticoagulants and vitamin K agonists, e.g. warfarin. Since 2009, a new therapeutic alternative has appeared with direct oral anticoagulants. They have revolutionized the management of patients undergoing anticoagulant therapy due to their rapid onset of action, fixed dosage, and non-necessity of biological monitoring for their therapeutic effectiveness [1], becoming the first-line choice for treatment of venous thromboembolic disease and atrial fibrillation.

However, antithrombotic drugs and especially oral anticoagulants belong to the class of drugs causing the primary cause of serious adverse reactions and the primary cause of hospitalizations for adverse reactions [2]. It is estimated that more than 900,000 incidents of recurrent, fatal and non-fatal venous thromboembolic events occur in the United States annually [3]. In France, the annual incidence of venous thromboembolic disease is in the order of 50,000 to 100,000 cases responsible for 5,000 to 10,000 deaths. These situations could be avoided if clinical practice guidelines (CPGs) establishing the proper use of antithrombotic drugs were correctly implemented.

Numerous CPGs for the management of anticoagulation, like CPGs from the American College of Cardiology [4], have been published recently. However, the implementation of such narrative guidelines is complex: direct oral anticoagulants are contraindicated for patients with mechanical valve replacement, or with severe renal insufficiency. Clinical situations may sway patients and clinicians to favor one oral anticoagulant over another. Patients who prefer once-daily dosing will find both edoxaban and rivaroxaban to be more convenient than the twice-daily regimens for apixaban and dabigatran. Patients looking for single-drug treatment (especially outpatient treatment) will favor the use of apixaban or rivaroxaban, which do not require 5–10 days of pre-treatment with low molecular weight heparin as it is required for dabigatran and edoxaban. Besides, dosage, administration, and duration of therapy are quite different according to the situation (prevention vs. treatment), the patient, and the prescribed direct oral anticoagulants. As a consequence, the dissemination of narrative CPGs has had a limited effect in changing physician behavior and direct oral anticoagulant treatment remains underutilized in current clinical practice [5].

Clinical decision support systems (CDSSs) are receiving increased attention as tools to reduce costs and improve care. CDSSs embedding CPGs in their knowledge base have shown to be efficient tools to promote the adoption of CPGs by physicians [6], especially for the prescription of direct oral anticoagulants [7]. For instance, Karlsson et al. [8] demonstrated that a CDSS could increase guideline adherence with anticoagulant therapy in patients with atrial fibrillation.

This CDSS, integrated into the regular electronic health record (EHR), used medical record data to identify patients with a diagnosis of atrial fibrillation and at least one risk factor for stroke with no anticoagulant therapy and displayed a pop-up screen warning. In the same way, Borab et al. [9] evidenced that using CDSSs increased the proportion of surgical patients who were prescribed adequate prophylaxis for venous thromboembolic disease, correlated with a reduction in venous thromboembolic events. In most of the cases, when CDSSs are embedded into the EHR, decision support is implemented as the display of alerts triggered when discrepencies exist between physician prescription and guidelines. However, it has been reported that alert-based CDSSs may be counter-productive since healthcare professionals suffering from "alert fatigue" may ignore most of them [10].

We have developed a guideline-based CDSS called RecosDoc-MTeV to assist decision-making for anticoagulation therapy based on state-of-the-art knowledge combined with local CPGs as elaborated by Saint-Antoine and Tenon hospitals, two hospitals of the Parisian network of public hospitals, Assistance Publique – Hôpitaux de Paris (AP-HP, France). At the same time, because there were no national guidelines to support the managament of anticoagulation, the Assistance Publique – Hôpitaux de Paris published narrative CPGs to improve the quality of antithrombotic prescription within its 39 hospitals.

We conducted an analysis to assess the consistency of the propositions provided by RecosDoc-MTeV and AP-HP CPGs. Another objective was to evaluate the conformity to RecosDoc-MTeV and AP-HP CPGs of actual anticoagulation therapy prescriptions. The analysis has been performed on a sample of clinical cases randomly selected from patients hospitalized in 2017 in both Saint-Antoine and Tenon hospitals.

Materials and Methods

Description of RecosDoc-MTeV

RecosDoc-MTeV is a guideline-based CDSS applied to the management of anticoagulation therapy and the prescription of direct oral anticoagulants. The system relies on a knowledge base that models current state-of-the-art CPGs completed by the expertise of the hematologists of Tenon hospital (IE, GG) and the practice of the head of Tenon hospital pharmacy (ID).

The knowledge base of the CDSS is structured as a decision tree essentially made of two subtrees to represent the management of venous thromboembolic disease prevention and treatment (see figure 1). The prevention subtree explores various surgical situations, making the difference between orthopaedics surgery, cancer surgery, bariatric surgery, and other surgeries which have different risks of venous thromboembolic disease. In the same way, the different orthopaedics surgeries associated with different length of treatment are considered, e.g., hip replacement, knee replacement, hip fracture, and femoral neck fracture. For cancer surgery, a difference is made between the management of breast cancer, abdominopelvic cancers (either digestive, gynaecologic, or urologic cancers), and non-abdominopelvic cancers (either thoracic, otorhinolaryngologic, or brain cancers). In non-surgical situations, a pharmacological preventive treatment is recommended for hospitalized patients with high risk of venous thromboembolic disease. The treatment subtree is built in a similar way. It explores the special case of heparin-induced thrombocytopenia and some specific clinical conditions such as the co-occurrence of venous thromboembolic disease with an active cancer, a pregnancy, or any other clinical situations with acute organ failure.

At different points of the decision tree, it happens that evidence is missing to assess the risk of venous thromboembolic disease and guide the therapeutic strategy. In these cases, the risk is computed according to specific external scores provided by the literature and accessible on the Internet by external links (scores of Caprini [11], Padua [12], and Compass in the prevention subtree; scores of Wells and 4T in the treatment subtree).

In all cases, the recommended treatment varies with the value of creatinine clearance to assess the renal function, the value of the Body Mass Index (BMI) to assess overweight and obesity, and the existence of an antecedent of heparin-induced thrombocytopenia.

RecosDoc-MTeV has been developed according to the documentary paradigm of decision support [13] which allows for contextual interpretation of patient data and guidelines knowledge. Once the knowledge base is built, it can be used as an autonomous application and browsed by the physician user. At each depth level, a question is displayed in a closed-ended form to document a clinical criterion that may either concern patient information (renal failure, obesity, pregnancy, cancer), therapeutic history (prior heparin-based treatment) or one of the scores used to assess the risk of venous thromboembolic disease.

Starting from the root of the decision tree, the physician user navigates through the knowledge base while answering questions and thus instantiates the relevant patient criteria to establish the recommended treatment. Guideline-based patient-centered therapeutic recommendations are then provided when the navigation is completed, i.e. when a leaf of the decision tree is reached.

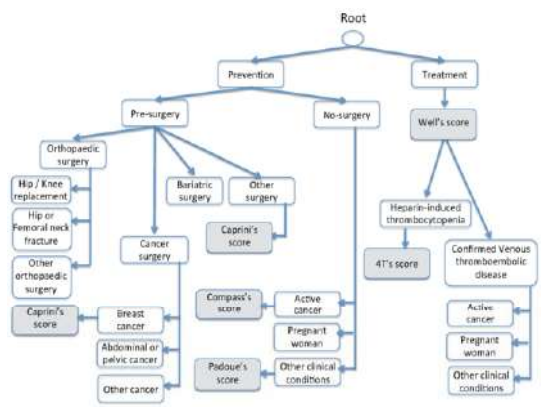

Figure 1– Excerpt of the top of the decision tree.

Description of AP-HP CPGs

AP-HP CPGs [14] have been developed in 2014 at the initiative of the Thrombosis working group of Assistance Publique – Hôpitaux de Paris to support the proper use of antithrombotics by residents and practitioners. AP-HP CPGs are described in a 55-page long document. The first part of the document is dedicated to the description of clinical conditions associated with

Figure 2 – Screenshots of RecosDoc-MTeV (left), and of the AP-HP app (middle) and narrative CPGs (right).

low, moderate, and high risk of thrombosis. Then, therapeutic protocols recommended for the different levels of risk are presented along with the recommended surveillance. In order to facilitate the availability of these recommendations and make healthcare professionals able to have at hand the essential information about anticoagulant drugs, AP-HP developed a smartphone application (app) named "Recos Thromboses" based on AP-HP CPGs.

Figure 2 displays the three types of interfaces: the structured patient-centered description of the patient profile as offered by RecosDoc-MTeV, the semi-structured organization of the information as provided by the AP-HP app, and tables as given by narrative AP-HP CPGs.

Selection of the population

In order to assess the consistency of the propositions provided by RecosDoc-MTeV and AP-HP CPGs, we randomly selected a sample of patients hospitalized for more than 48 hours in 2017, either in Saint-Antoine hospital or in Tenon hospital, stratified to cover the different clinical situations in the groups for prevention of, and treatment for, venous thromboembolic disease. We used ICD10 codes and CCAM codes (a French terminology to code medical acts) to identify relevant patients for the prevention group, e.g. patients undergoing orthopaedic surgery, cancer surgery, or bariatric surgery, and patients hospitalized for medical conditions at risk, such as acute renal failure, cardiac failure, respiratory failure, infection or sepsis, and pregnancy. We proceeded the same way for the treatment group to select patients diagnosed with venous thromboembolic disease according to ICD-10 codes (either deep vein thrombosis (I80, I81, or I82) or pulmonary embolism (I26)).

Quantitative analysis

We considered that the recommendations provided by AP-HP CPGs were the gold standard. We evaluated RecosDoc-MTeV by comparing the set of propositions issued by RecosDoc-MTeV, denoted $\{\text{RecosDoc-MTeV}\}_i$ to those generated by AP-HP CPGs, denoted $\{\text{CPG\_AP-HP}\}_i$ on each patient P_i of the randomized sample of clinical cases. We defined that AP-HP- and RecosDoc-MTeV-generated proposition sets were:

- *Identical* when $\{\text{RecosDoc-MTeV}\}_i = \{\text{CPG\_AP-HP}\}_i$
- *Consistent* when $\{\text{RecosDoc-MTeV}\}_i \neq \{\text{CPG\_AP-HP}\}_i$ and $\{\text{RecosDoc-MTeV}\}_i \cap \{\text{CPG\_AP-HP}\}_i \neq \varnothing$
- *Different* when $\{\text{RecosDoc-MTeV}\}_i \cap \{\text{CPG\_AP-HP}\}_i = \varnothing$

We assessed the quality of RecosDoc-MTeV by computing the frequency of identical and consistent propositions of both systems on the population sample. We also evaluated the clinical practices at Saint-Antoine and Tenon hospitals by computing the frequency the treatment actually received by a patient Pi was compliant with RecosDoc-MTeV (when included into $\{\text{RecosDoc-MTeV}\}_i$) and compliant with AP-HP CPGs (when included into $\{\text{CPG\_AP-HP}\}_i$). Computations have been made in the prevention and treatment groups.

Although hospitalized patients gave their consent for the re-use of their clinical data for research purposes at the time of admission, we asked for the authorization of the heads of the departments concerned with the patient cases we used in this study before proceeding with the collection and use of data.

Results

Study population

The target population for ICD-10 queries on Saint-Antoine and Tenon hospitals for the year 2017 was made of 6,881 patients. 355 were randomly selected, from which 81 were excluded (42 clinical cases were out of the scope, 10 medical records were unavailable, and 29 clinical cases had too many missing data) leading to a study population of 274 cases, 182 and 92 dispatched in the prevention and treatment groups, respectively. Patient characteristics are reported for the two groups in Table 1.

Comparison of RecosDoc-MTeV and AP-HP CPGs

For each clinical situation corresponding to each patient, the propositions of RecosDoc-MTeV were compared to the recommendations of AP-HP CPGs. The numbers for each configuration, either identical, consistent, or different are reported in Table 2.

Table 1– Main characteristics of the study population

		Prevention (n=182)		Treatment (n=92)	
		n	%	n	%
Sex					
	Female	118	64.8	46	50.0

Table 2– Consistency of RecosDoc-MTeV with respect to AP-HP CPGs

	Prevention	Treatment	Total
Identical	120 (65.9%)	50 (54.3%)	170 (62.0%)
Consistent	55 (30.2%)	40 (43.5%)	95 (34.7%)
Different	7 (3.8%)	2 (2.2%)	9 (3.3%)

On the whole, CDSS propositions differed from AP-HP recommendations in 3.3% of the cases (CI 95%: [1.5%–6.1%]). The nine clinical situations where the propositions of RecoDoc-MTeV were different of those provided by AP-HP CPGs are displayed in Table 3.

Table 3– Inconsistencies between RecosDoc-MTeV and AP-HP CPGs

Clinical situations	N	RecosDoc-MTeV	AP-HP CPGs
Hallux Valgus in obese patients	2	Pharmacological prevention	No prophylaxis
Hospitalized patients with a low risk of **venous thromboembolic disease**	4	Non-pharmacological prevention	No prophylaxis
V**enous thromboembolic disease** with cancer	2	Unfractionated Heparin	Unfractionated Heparin relayed by Vitamin K Agonists

Compliance of clinical practices with state of the art recommendations

For each patient, the administered treatment, both in the prevention and treatment groups, was compared to each of the propositions provided by RecosDoc-MTeV and AP-HP CPGs. Table 4 reports for each group the compliance level with each decision support resource.

The global compliance of administered treatments with AP-HP CPGs was measured at 67.2% (CI 95% : [61.2%-72.7%]). This compliance was significantly higher in the prevention group than in the treatment group (72.0% vs 57.6%, p = 0.024).

When administered treatments were compared to RecosDoc-MTeV propositions, the compliance level was 72.3% (CI 95%: [66.6%-77.5%]). No significant difference was observed between the prevention and treatment groups (73.6% vs 69.6%).

Table 4– Compliance of administered treatments with RecosDoc-MTeV and AP-HP CPGs

	N	Compliance / AP-HP CPGs		Compliance / RecosDoc-MTeV	
		n	%	n	%
Prevention	182	131	72.0	134	73.6
Treatment	92	53	57.6	64	69.6
Total	274	184	67.2	198	72.3

When compared, the two compliance measures are not significantly different. The contingency tables of the two compliance variables were built for each subgroup, prevention and treatment, to measure the agreement between the two decision support resources, RecosDoc-MTeV and AP-HP CPGs (Table 5).

Table 5– Contingency tables for the compliance variables with respect to RecosDoc-MTeV (RM) and to AP-HP CPGs (AP) in both prevention and treatment groups

	Prevention			Treatment		
	AP+	AP-	Total	AP+	AP-	Total
RM+	129	5	134	52	12	64
RM-	2	46	48	1	27	28
Total	131	51	182	53	39	92

For the prevention and treatment groups, the unweighted Kappa measures were 0.903 and 0.700, respectively, considered as “almost perfect agreement” and “substantial agreement”. However, in 26% of the study population, the administered treatment was neither compliant with RecosDoc-MTeV nor compliant with AP-HP CPGs. These non-compliant treatments represented 33% of the decisions in the treatment group with the use of drugs not mentioned in the resources. In the prevention group, the combined non-compliance reached 25% (46 cases), distributed in 15% of decisions where the therapeutic scheme was different than the one recommended, 7% of non-pharmacological prophylaxis, and 3% of decisions based on drugs not mentioned in the resources.

Discussion and conclusion

RecosDoc-MTeV is a guideline-based patient-centered decision support system applied to the prescription of direct oral anticoagulants for the management of venous thromboembolic disease. The system is developed according to the documentary paradigm of decision support [13] which allows the user to interactively navigate through the knowledge base to describe a given patient case and get the patient-specific recommendations. Compared to AP-HP CPGs considered as the gold standard in this study, we found on a randomized sample of 274 patient cases that 62.0% of the propositions were identical, 34.7% were similar and 3.3% were different. It should be noticed that most discrepancies were observed in the prevention group. The nine situations

where inconsistencies were observed concerned the management of the venous thromboembolic disease risk with propositions of pharmacological and non-pharmacological prevention by RecosDoc-MTeV in medium and low risk clinical situations respectively, whereas AP-HP CPGs recommended no prophylaxis at all. When comparing the treatments actually received by the patients to the propositions provided by both resources, we observed that clinical practices were compliant with AP-HP CPGs in 67.2% of the cases, and compliant with RecosDoc-MTeV propositions in 72.3% of the cases (no significant difference). It is interesting to notice that 46 therapeutic decisions in the prevention group and 27 therapeutic decisions of the treatment group were neither compliant with AP-HP CPGs nor compliant with RecosDoc-MTeV propositions. For these 73 decisions, RecosDoc-MTeV propositions and AP-HP CPGs were identical in 100% of the cases. This tends to evidence that in these specific situations, clinical practices are suboptimal and would be improved by the use of a CDSS such as RecosDoc-MTeV.

This study has various limitations. We have chosen AP-HP CPGs as the gold standard which could be questioned since AP-HP CPGs, published in 2014, are older than RecoDoc-MTeV, elaborated in 2016. In addition, the randomized sample incompletely covered the set of possible clinical cases since, for instance, we didn't find any medical record with a history of heparin-induced thrombocytopenia. Indeed there is no ICD-10 code for this disease, and all the ICD-10 codes that we used to target the disease didn't retrieve appropriate clinical cases. The study was also conducted on a small sample of clinical cases and on only two hospitals. Finally, compliance rates are probably overstated since we only took into account the class of anticoagulant drugs for the comparison of medical decisions with RecosDoc-MTeV and AP-HP CPG propositions, while dosage and duration of prescriptions were not considered (data were often missing).

We performed a retrospective review of 274 patients hospitalized in 2017 at Tenon and Saint-Antoine hospitals (Paris, France) who were candidates for direct oral anticoagulant treatment either to prevent or treat venous thromboembolic disease. We assessed the prescription of direct oral anticoagulants according to both RecosDoc-MTeV and AP-HP CPGs. Compliance with the CDSS was 72.3% when only taking into accont the drugs used. These results support that implementing CDSS for venous thromboembolic disease prevention and treatment in routine practice should improve the quality of care ensuring safe prescribing of high-risk medications. Further work needs to be carried on to assess in a prospective study whether the use of RecosDoc-MTeV upon order entry would increase the compliance rate of therapeutic decisions and thus improve the quality of care.

Availability and Quality of Information Used by Nurses While Admitting Patients to a Rural Home Health Care Agency

Abstract

Home health care admission nurses need high quality patient information but that information is not uniformly available. Despite this challenge, these nurses must make four critical decisions at patient admission to construct the plan of care: (1) patient problems to address in the home health care episode; (2) patient medication management; (3) services in addition to skilled nursing; and (4) skilled nursing visit pattern. We observed 12 in-home admissions at a rural home health care agency and interviewed nurses before and after about these decisions. We analyzed content and quality of documents. To evaluate quality, for each decision we assessed concordance between documents. Interview responses provided context in the analysis. Across all admissions, documents and their contents were not uniformly present. Nurses rarely received visit pattern or medication management information. There was discordance in the number of patient problems among and between available documents and the plan of care. Electronic health record design recommendations include interoperability and structured, consistent, actionable information.

Introduction

Home health care (HHC), skilled nursing care in the patient home, is a large and growing sector of the United States health care system. A smooth transition from hospital to HHC is critical to quality healthcare and to reducing hospital readmissions [1; 2]. However, HHC nurses often receive only half of the recommended information relevant to developing the plan of care (POC) [3]. The POC includes orders for: performing procedures and treatments; ongoing assessment; case management; and patient and caregiver education. Missing, incomplete or incorrect information is likely to lead to care delivery inefficiencies where care is missed or more care is delivered than is necessary [4], which in turn may effect patient outcomes and cost. Despite these challenges, HHC nurses must make four critical decisions when constructing the POC during the time-constrained admission:

1. *Problems* to be addressed in the plan of care;
2. *Medication* accuracy and medication self-management capability;
3. The *services* to be consulted (e.g., the disciplines involved in addition to skilled nursing such as physical therapy); and
4. *Visit pattern* (when and how often to visit the patient).

While each of these decisions could impact hospital readmission, nurses' information needs and how nurses use the information for decision making during the HHC admission are currently poorly understood.

Below we describe the information flow and processes related to the HHC admission from referring facility to admitting nurse documentation in the EHR for one rural HHC agency. As part of the reported intake process, the intake nurse at the HHC agency completes a standardized paper *intake form* containing information obtained from a telephone call with the referral facility such as a hospital, physician's office, or skilled nursing facility-(SNF) (a SNF provides skilled clinical services in a temporary residential setting). The referral facility faxes specific referral information from an ordering physician in a *referral document*. On the intake form, the intake nurse documents patient characteristics and clinical information such as orders, problems, activity level/weight bearing status, disciplines requested [5]. The hard copy intake form along with the referral documents are placed in the patient's paper chart.

After intake, the observed admission process continues when the admission nurse, with the paper patient chart, visits the patient at the patient's home. While in the patient's home, the nurse optionally requests the patient or caregiver for the discharge summary (also referred to as discharge instructions) or progress note (hereafter both are referred to as *transition documents*) which originated from the hospital, physician office or SNF. Such a transition document contains care instructions sent home with the patient for reference.

The admission nurse documents patient clinical information in the electronic health record (EHR). He/she records current health status in the mandated Outcome and Assessment Information Set (OASIS [6], a standardized data collection instrument). The EHR includes a free text POC with problems and patient health goals [5]. If not completed in the home, the nurse later completes the EHR admission documentation outside of the patient home [7].

This paper describes findings from a mixed methods observational study examining the availability and quality information that HHC admission nurses use to make the four critical decisions. The investigation detailed in this paper is part of a more extensive study that chronicles nurses' information and decision practices at the point of care. We intend to design health information technology (HIT) recommendations to enhance the activities involved in the HHC admission process and improve HIT standards for home health agency EHR systems.

Methods

The study was approved by the Drexel University Institutional Review Board. We reimbursed the agency for nurses' time.

Setting. The small, rural Pennsylvania HHC agency served a majority white, lower socio-economic population. Nurses used a commercial laptop-based point-of-care EHR from Allegheny Software Publisher.

Data Collection. Six nurses who admit patients consented to participate. Each nurse was observed admitting two patients for a total of 12 admissions. The sample size of 12 was expected to achieve saturation with respect to making decisions. Nurses were observed as they prepared to visit the patient (pre-home: Phase 1), in the patient home (in-home: Phase 2), and after (in-agency, when they completed the documentation: Phase 3). Two researchers (PS and EB) accompanied the nurse to observe each admission. A third observer sometimes accompanied. All three phases lasted 2 to 4 hours in total per admission.

At the end of each phase, researchers interviewed the nurses to determine after having reviewed the documents, what conclusions were made regarding each of the four critical decisions noted above. The interview was intended to assess the status of the nurse's ability to make these decisions given the information up until that phase. Interviews were audio-recorded and later transcribed. In the patient's home, researchers took field notes, audio-recorded, and photographed the EHR screens and transition documents (if accessed). The nurses completed the documentation in Phase 3 using a video recorded, think aloud protocol.[8] Researchers collected photocopies of patient paperwork and copies of relevant emails (input) and nurse generated documentation including the POC (output). During the data analyses, the research team met with the observed nurses and separately with intake nurses to clarify information and findings (member-checking) by asking the following questions:

1. To analyze medication accuracy and medication self management information (medication management): How is patient medication information communicated to the nurse?
2. With regard to the intake form, referral document, and transition documents, which do you consider:
   - the most important source of any patient information?
   - the most accurate source of information?
3. How do nurses prioritize these different sources of information?

Data Analysis.

Content of Documents and Interviews. Two authors independently searched the intake, referral, and transition documents for terms and phrases associated with the four decisions. They compared coding, came to concensus, and transcribed the terms and phrases onto a Microsoft® Excel spreadsheet for each admission. To identify nurse statements in the interview transcripts and audio recordings across the three different phases, two authors independently conducted top-down (a priori) thematic analysis sensitized to the four decisions. The researchers documented the quotations in the spreadsheet. Team members, including a HHC nursing expert (KB), reviewed the coding and made changes based on discussion. Consensus was reached.

Quality of Documents and Interviews. For each of the four decisions, we assessed, documented, and reviewed concordance of the availability and content of the information in each document and nurse interview. We calculated the proportion of matched information in each document and interview dyad if information was available. For *problems* and *services*, the comparison was to find missing or added patient problems or services. For example, at least one service listed on the intake form was not specified in the interview. For *medication self-management capability*, the content was analyzed using qualitative analysis and then compared to determine whether the assessment of medication management capability had changed across the phases. For *visit pattern*, content was compared to evaluate whether the number of visits in a comparable week had increased or decreased.

To provide more data in the quantitative analysis for decisions in which information was missing, interview responses were incorporated. Phase 1 interviews were included as input. Phase 2 interviews were grouped with output (electronic artifacts produced when documentation was completed-POC), as the interview took place following patient assessment. Phase 3 interviews were grouped with output.

Last, we compared the information that the nurse had before making a decision (input – intake, referral, transition document) and the decision the nurse documented (output – POC).

Concordance was analyzed based on the type of information. For decisions for which we compared presence or absence of information (i.e., visit pattern, medication management), we used 2 by 2 tables. For decisions for which we compared contents of lists (i.e., problems, services) we used 3 by 3 tables: We compared item presence\absence across sources.

Interview and member checking responses were qualitatively analyzed by two authors and compared. Quotations relevant to the documents and information available to the nurse in his/her decision-making were selected.

The mixed methods analysis intertwined the quantitative findings (counts of availability), which were primary, with the qualitative results. The latter provided context for interpretation of the quantitative findings. For example, discordance between phases for information availability was matched to relevant quotes.

Results

Across all admissions, the availability and contents of documents and interviews were variable.

Availability of Documents and Interviews. Across the 12 admissions, intake and referral documents were universally available and the POC was consistently produced. Seven transition documents were available before the visit (as part of the referral documents): Five of which were also available during the visit (requested in the home). Transition documents were available for 7 of the 12 observations. Eleven interviews were conducted. Not all nurses answered all interview questions, often because they did not yet have a decision. During interviews, one or more decisions were addressed in each phase in 11 observations.

Content of Documents and Interviews. Referral documents lacked uniformity across the various referral sources but generally contained diagnoses, medications, and the POC. The actual documents, the information contained within them, the location of the information, and the number of pages varied. Transition documents tended to be one page in length, and were not standardized across referral sources. Information could be illegible, variable, or missing.

Qualitative analysis of nurse interview responses reached saturation with 11 interviews (no new patterns being identified). In Phase 1, a prevailing theme among interviews was the lack of information available for making decisions. This theme applied to the decision about the *visit pattern* decision for which data were not available on any document. Nurses anticipated acquiring needed information from the

assessment and talking to the patient during the first visit: "*I have no idea how often I'm going to see the patient for until after I assess them.*" (Nurse 3).

Problems. Across the 12 admissions, all *intake* and *referral* documents contained patient problems. The 5 *transition documents* viewed in the home listed the problem(s). Two plans of care did not contain *problems*. Nurses replied to interview questions asking about the patient *problem* for 10 admissions in Phases 1 and 2, and for 7 admissions in Phase 3. Although *intake* and *referral* documents contained *problems*, nurses did not solely rely on these documents to identify problems to include in the POC. They also relied on the admission assessment at the first visit:

> *We didn't get any information yet and they just faxed that to me…so I only have like, 8 pages total on this patient and her history at all…We'll just find out when we get there.* (Nurse 6)

Medication list/management. Related to medication accuracy, *medication lists* were not uniformly present in the documents available to nurses; *medication management* information was scarce. A medication list was not present in any *intake* document. It was in 8 of 12 *referral* documents and in 4 of the 5 available *transition documents* viewed in the home. Nurses reported during member checking that they relied on the *transition document* because that medication list was more current. However only 5 patients had the transition documents available for the nurse. The POC did not contain a medication list. The list was documented in the medication reconciliation which appeared elsewhere in the EHR.

Regarding *medication management*, data appeared in 1 of 12 *referral* documents, 3 of 5 *transition documents*, and 3 of 12 POCs. An OASIS question (M2020) about patient medication management was universally answered. Nurse responses related to medication management were present for 4 interviews in Phase 1, 7 interviews in Phase 2, and 8 interviews in Phase 3. Nurses explained that they determined if a patient could manage medications if a patient demonstrated understanding the medications and when to take them, and had an organized pill box:

> *I think he certainly is fine. He had that list printed out, his pill boxes were all filled for the week already. He's definitely sufficient in monitoring that or managing that.* (Nurse 1)

Services. *Intake* forms universally contained *services* information whereas services information was contained in only 4 of 12 *referral* forms, 1 of 5 *transition documents*, and all POCs. Nurses replied to the *services* interview question for 11 of 12 admissions in Phase 1, 9 admissions in Phase 2, and 5 admissions in Phase 3. Nurses reported that skilled nursing was likely to be ordered for those referred from a SNF. Physical therapy was ordered if the patient needed to build strength. Occupational therapy was ordered for conditioning:

> "*OT can teach…measures to conserve energy as far as when they're getting dressed."* (Nurse 1).

Social work was ordered for reasons including advanced directives, long term planning, alcoholism, and the need for community resources to provide more help in the home. A home health aide was ordered to provide assistance with activities of daily living due to the patient's restrictions:

> *Normally if the only diagnoses marked on here are orthopedic- like … the hip fracture- then typically the main service going in would be therapy…Home health aide, that's kind of typical sometimes for that, just because of restrictions.* (Nurse 1)

Visit pattern. *Visit pattern* information was scarce on the documents nurses had access to in the patient home, yet it was universally documented in the POC. No *intake* forms contained visit pattern data. Visit information appeared on 2 of 12 *referral* documents. No *transition document* documented skilled nursing visit pattern, although one transition document did include visit pattern for other services. Nurses replied to the visit questions in 10 of 12 interviews in Phase 1, 9 interviews in Phase 2, and 7 interviews in Phase 3.

In their *visit pattern* decisions, nurses reported that they considered a number of factors. One consideration was insurance constraints, as Nurse 6 stated:

> "*Insurance will pay for us to go out every day, but if there's someone else in home able to do it, they won't pay for us to come out every day*."

A second consideration was laboratory draw orders, according to Nurse 1, "*It'll impact our next visit if they want us to draw the labs in the home*." Nurses also incorporated wound care concerns in their decision making.

> Nurse 3: "*I would say if she had a wound. Or a diabetic foot ulcer. Where we were coming out and we were treating that. Especially for the first couple weeks, I would want to see her three times a week, or even every day*."

Nurses also thought about patient fragility. Nurse 4 said, "*He looks like he's pretty fragile so I think we'll come out more to see him.*" Nurses also considered visit patterns of other services. For example, Nurse 3 said:

> *Physical therapy is coming out to see her. Occupational therapy is coming out to see her. We're almost seeing her every day, but different disciplines. So I like to adjust my time so I'm not running into physical therapy all the time… so we keep our eyes on you, evaluating how well you're progressing.*

Nurses rarely had visit pattern information in their documentation. After assessing the patient in the home, the nurse always documented the information in the POC.

During member checking, nurses stated that their prioritized list of documents in terms of accurate and trusted patient data was: 1) transition document, 2) intake, and 3) referral. Although the transition document was available less than half of the time, it was the nurses' preferred source for the medication list.

Quality of Documents and Interviews. Comparison of input and output for *problem* and *services* decisions involved documents and not interviews, as there were sufficient admission documents for analysis. However, *medication management* and *visit pattern* decisions were not available in documents: Inclusion of interview responses did not provide sufficient content for analysis due to few nurses having made these decisions when interviewed.

Problems. Comparison of the number of problems listed among and between *input* documents and the POC indicates complete discordance. Input documents contained lists of problems with some overlapping and some unmatched problems. For example, the *intake* forms consistently contained more problems as compared to the *referral* documents for the same admission. Two intake forms contained problems not on the related referral documents. Intake forms tended to have fewer problems as compared to the related transition documents. Referral documents tended to have more problems as compared to the associated transition documents. The presence of lists of patient problems that lack agreement does not provide a clear picture to the nurse, as illustrated by the following exchange.

> Interviewer: *"After you read through that [referral, intake documents], did you have any thoughts that there was more or less on the list of problems than what was noted there?"*
> Nurse 3: *"Not until I really get there. I have to actually ask*

the person and assess."

In addition to mismatches among input documents, for each observation there was a mismatch between each *input* document and the POC. *Referral documents* consistently contained more *problems* as compared to the related POC. Three POCs contained one or more problems not included on the related referral document. A similar pattern was present when intake forms were compared to POC, with one exception: For only two admissions the problems on the intake form matched the problems on the POC.

Medication management. Input document and Phase 1 interview data (input) were present for 5 admissions. Data output, constructed from POC and Phase 3 interviews was present for 9 admissions. Of the 6 admissions for which both input and output medication management data were present, half had input that matched output.

Services. Information was present on all intake forms. Data output regarding services from documents was present for all admissions. Of the 12 admissions with both input and output data, 3 did not have input that matched output. One admission had an additional service on the output and 2 admissions had one more service on the input as compared to the POC.

Visit Pattern. Due to scarcity of *visit pattern* data among input documents, interview data were included as input data. Input document and interview Phase 1 (before home) data were present on 6 admissions. Output data were universally present. Of the 6 admissions included in the analysis, 2 did not have input that matched output: These admissions had fewer visits on the input document.

In summary, data quality, when comparing input and output documents, was weak for patient *problem* and *services* decisions. *Medication management* and *visit pattern* decisions data quality was very weak due to frequent absence of data.

Discussion

This is the first study of the availability, content, and quality of information that a HHC nurse has at patient admission. The three input documents (i.e., intake, referral, and transition) available to nurses as they made the 4 clinical decisions had the same information source and referring facility/physician, and were intended for different audiences: clinicians, intake nurse, and patient (respectively). The availability, content, and quality of the documents were variable. Nurses' identification of the transition document as the most valued and trusted source for medication information makes it the top priority when recommending improvements in data transfer. Missed medications, wrong doses, or wrong medications can lead to adverse events and unfortunately are too common during transitions in care.[9]

The *intake* document had the patient *problems* listed, and tended to be the sole and consistent data source for *services*. During member checking, intake nurses stated that they controlled the telephone conversation with the referring facility to make sure the needed information was elicited. *Referral documents* tended to have a list of *problems* and a *medication list*. Agency management informed us they had strongly encouraged local SNFs and hospitals to send referral documents with the information needed during the admission.

The mismatch of *problems* among all documents was unexpected. The POC contains far fewer problems as compared to input documents. This mismatch and decrease in the number of problems require further investigation regarding: (1) whether problems are missed; (2) whether and why nurses choose to address certain problems over others; or (3) whether national or agency policy restricts the types and number of problems addressed during an episode. Considering the poor quality of documents, it is unclear how the nurse decides which input problems to include or not include on the POC.

Medication management input and output information was infrequently available which was problematic in light of nurses reporting the need for medication management information during admission [10]. Input documents (*intake, referral and transition documents*) rarely had *medication management* information available and infrequently had *visit pattern* information. Nurses relied on obtaining this information during the in-home patient assessment. Electronic transfer of this information could increase efficiency and decrease time spent collecting it. It also could alert nurses to patients likely to have issues with medications, a risk factor for readmission [11]. This unavailability calls for standardized measurement of cognition, physical function, and self-care ability to assist the next level of care in understanding what challenges may exist. Unfortunately, the Impact Act, which calls for a uniform comprehensive assessment across all post-acute care settings, does not include acute care settings, the most common referral source [12].

Services input and output information was available for almost all admissions. Availability of services input information was due to the agency's universal elicitation and documentation on intake forms. Despite this effort, quality of services data was not high. Considering that the source of intake information was the referral facility, nurses in HHC may assess information differently than staff in the hospital [1].

Visit pattern had a paucity of input data and universal inclusion in the POC which indicates the importance of the patient assessment in obtaining information for the visit pattern decision. The low quality of visit pattern information is a hurdle for a HHC agency which strives to apply frontloading (provision of 60% of planned skilled nursing visits during the initial 2 weeks of the home health episode [2]) of skilled nursing visits for high risk patients to reduce 30-day hospital readmissions. The rationale is to enable nurses to identify and intervene on issues early in the episode before a readmission is necessary [13].

The low availability and quality of information needed for all 4 important clinical decisions indicate an information deficit during the transition of care to HHC. As a result, nurses may rely on the patient or caregiver during the patient assessment for the missing information. However, the patient may not always be the most reliable historian and clinical information maybe incorrect or misunderstood by the patient [14]. From a human information processing perspective, adequate and accurate information is the basis for making subsequent appropriate clinical decisions [15], and providing safe patient care [16]. Further, nurses cannot determine which patients to visit early and often until after their first visit which may not occur until two or more days after hospital discharge.

To address these information deficits we recommend improving interoperability capability and EHR design. Interoperability is supported with the international data standard, the Continuity of Care Document (CCD) [17] which summarizes and categorizes patient transition document information useful for transitions. The CCD is intended to be shared by SNFs, hospitals, and other health facilities as patients transition between settings. While the CCD is structured to contain problems and the medication list [5], it does not contain medication management, services, or visit pattern information. Our analysis indicates that nurses rely on patient assessment in the home to support medication self-management and visit pattern decisions. If this reliance is due to the nurse's need to elicit this information in person,, including this information in

the CCD may not be an effective intervention. However, if this information seeking pattern is because this information has historically been unavailable and if the pattern is amenable to change, future research should address whether nurses would rely on input information if it were available. If so, the information should be considered for inclusion in the CCD. At a minimum, the referring clinician's recommendation regarding the timing of the first visit could be of great value. Screening tools indicating higher risk patients may help.[18]

Regarding *services* data, communication of functional status or previous service use from the referral source would provide valuable information about the need for continued services. However, this information is not contained in the CCD.

Anticipating that interoperability will replace the use of paper input documents, we provide EHR recommendations. First, the EHR should be redesigned to capture CCD data (i.e., problems, services, functional level) and, after nurse review and authorization, the data could populate the POC, eliminating nurse transcription of input data and reliance on transition documents. Further research is needed to ascertain whether, if additional information was included in the CCD, nurses would use this information and rely less on gathering information with the patient assessment.

A second recommendation acknowledges the value of the intake document. The intake nurse should be able to record problems and services needed. Upon nurse authorization, the selected information input by the intake nurse could populate the POC.

Research design is a strength of this study. The field study was designed to collect qualitative and quantitative data, to support our mixed methods analysis. Limitations of the study include the sample size (six nurses and 12 patient admissions) and the setting elements (we examined one rural home health agency that used one EHR). To improve the generalizability of findings, future work is needed that increases: (1) sample size; (2) heterogeneity of nurse and patient populations studied; (3) number of different EHRs examined, and (4) number and type of referring sources.

Conclusions

Home health care nurses at a rural agency who admitted patients relied on three paper documents for information to make four important clinical decisions included in the plan of care. Universally we found a mismatch in content related to the four decisions among input documents, between each input document and the POC, and between the set of input documents and the POC. None of the documents nor the POC contained structured, actionable, electronic data. EHR design recommendations include data interoperability from referring facilities, information incorporated electronically instead of on paper, and structured and actionable input and POC data. These recommendations address information deficiencies for 2 of the 4 important clinical decisions which underscores the importance of the home visit for information elicitation.

Abstract

In home health care, the patient problem list is an important component of the admission and care planning processes and determines the subsequent care received. We examined the information received from the referring facilities and its relationship with the final patient problem list generated at home health care admission. Researchers observed 12 admissions and collected available documents related to the admission and care planning process. Problems identified in documents provided to admission nurses (input documents) and in documents subsequently created by those nurses (output documents) were coded to form a standardized set of problem terms across the documents. Documents available, distribution of problems within the documents, and concordance between input and output documents were assessed. A varying number of the 17 unique problems found across the documents were distributed by document type. Patients were referred to home health care with more clinical problems than were documented in the output documents.

Introduction

An accurate, complete, and current list of patient problems is valuable for concisely communicating a patient's clinical status among numerous and diverse clinicians and across care settings [1]. Annually, 12 million patients in the United States are referred from hospitals, skilled nursing facilities (SNF), and physician offices to home health care (HHC) [2]. HHC patients are typically older adults with multiple chronic conditions and have on average nine problems (health related needs that may benefit from clinical intervention) [3]. These problems are often associated with multiple chronic medical conditions that affect patient function, self-care management, and hospitalization risk. As some problems are chronic and stable, not every problem is addressed during a HHC episode.

During the HHC admission, a nurse makes critical care planning decisions including identifying the problems to be addressed in the plan of care (POC) (i.e., orders for ongoing assessment, patient and caregiver education, case management, and performing procedures and treatments). Too often the HHC nurse conducts the admission visit with fragmented, incomplete, or inaccurate knowledge of the patient's clinical condition [4],[5]. Inaccurate or incomplete problem lists could lead to inappropriate, missed, or delayed care [1]. In addition, 20% of HHC patients in the United States are readmitted to the hospital within 30 days of discharge [6]. An adequate transfer of information leading to accurate care planning may assist in providing higher quality care and preventing early readmission for a large and growing population of older adults [7],[8].

This paper presents findings from a field study examining the information received from the referring facility and its relationship to the final patient problem list generated at HHC admission. This examination is part of a larger mixed methods study characterizing HHC admission and care planning practices at the point of care. The overall goal is to develop recommendations to improve the HHC admission process and to identify opportunities for technology standards that support transitions in care to HHC via electronic health record (EHR) systems.

Methods

We conducted observations of the admission process and analyzed paper and electronic documents to examine the relationship between HHC admission documents and the problems in the problem list. The Drexel University Institutional Review Board approved this study.

Setting. The research setting was a small, rural Pennsylvania HHC agency serving a majority white population with low socioeconomic status. Agency nurses used a laptop-based commercial EHR system from Allegheny Software Publisher, designed for use at the point of care. Nurses also received and reviewed paper documents from the referral facilities and generated additional paper and electronic documents. Six nurses volunteered for the study and provided consent for participation. Patients observed in the home provided consent. To facilitate data collection, the agency scheduled the nurses to return to the agency after visiting each patient in the home. The agency was reimbursed for the nurses' time.

Data Collection. The six nurses were each observed admitting two patients each (12 admissions total). Figure 1 highlights the admission process information flow from the referring facility to the admitting nurse documentation of problems in the EHR. Phase 1 includes the intake process where initial documents are prepared for the admission nurse. Typically, via a telephone call, the intake nurse collects information from the referring facility. The referral facility also faxes referral information. If the intake nurse determines that the patient is to be admitted, he or she documents patient information, including medical diagnoses, on a standardized paper intake form. The intake form and referral documents are added to the paper patient chart and the admission nurses thereby have access to them.

Phase 2 of the admission process occurs in the patient's home. Armed with the paper chart, the admission nurse visits the patient. If not part of the faxed referral, the nurse may ask the patient or caregiver for the Discharge Summary (also sometimes

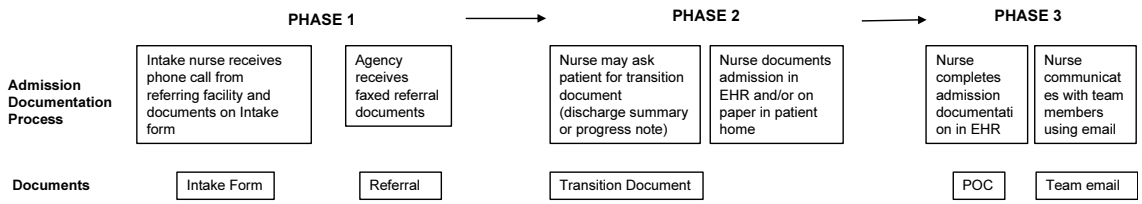

Figure 1. Phases of Home Care Admission Processes and Documents Created and/or Available.

referred to as discharge instructions) or Progress Note, called transition documents herein. With care instructions to reference, the documents are typically given to the patient at discharge from the referring facility.

In the home, the nurse documents in the EHR, on paper, or both [9]. Electronic documentation includes: (1) the patient's current health status recorded in the Centers for Medicare and Medicaid (CMS) mandated Outcome and Assessment Information Set (OASIS), [10] a standardized assessment instrument, and (2) a free text POC document with problems (nursing diagnoses) to resolve or support and related interventions, along with the patient's health goals.

Phase 3 is the completion of the admission and the creation of a team email. For this study and agency, this phase occurs at the agency and typically lasts approximately less than two hours. Not part of the EHR, the team email is a free text document summarizing the list of patient problems and the POC for the other nurses on the care team. Its purpose is to notify team members with timely, comprehensive information. This action avoids any delay in communication caused by inability to synchronize patient information on the laptop with the EHR database in a timely manner.

Research team members photocopied or photographed available documentation generated by the nurses including the POC, problem lists, and team emails.

The researchers, drawing on their HHC and nursing expertise, hypothesized that the intake document would paint the picture of the patient. They expected that additional problems would be added once the OASIS was completed. They also expected that the nurse would communicate all of the problems in the POC. The POC would then support problem prioritization.

Data Analysis. To standardize the vocabulary and reduce variability, the team used line by line coding to map each problem (medical and nursing) to terms in the Omaha System Problem Classification Scheme (Omaha System) [11]. This scheme is a standardized terminology often used in home and community-based settings. The scheme is recognized by the American Nurses Association as a recommended terminology. In 2007 it passed the Healthcare Information Technology Standards Panel (HITSP) Tier 2 selection criteria for Use Cases. It is integrated into the National Library of Medicine's Metathesaurus, Logical Observation Identifiers, Names, and Codes (LOINC®); and the Systematized Nomenclature of Medicine Clinical Terminology (SNOMED CT®) [12].

The Omaha System provides standardized signs, symptoms and problem labels for 42 problems organized in four domains (i.e., Environmental, Psychosocial, Physiological, Health Related Behaviors). Example problems include Cognition, Pain, Medication Regimen, Respiration, Circulation, Skin, Mental Health and Physical Function [13]. Omaha System expert, KB educated co-author NL about the Problem Classification Scheme definitions and problem signs and symptoms. Then the two co-authors conducted the coding together for two cases to establish coding rules. They then coded separately. To reach consensus they discussed terms on which they disagreed or were unclear. For example, the OASIS assessment "Able to bear weight and pivot during the transfer process, but unable to transfer independently" was coded in the Omaha System as the problem "Neuromusculoskeletal Function".

Each specific problem from each paper and electronic document was entered as a unique row into an Excel spreadsheet. Columns included one document per column, ordered by phases. Both nursing and medical problems were included in the analysis. Counts by document type for each problem were calculated and matches across the columns were identified.

Distribution of problems. After coding we identified the number of unique problems among the 12 admissions, regardless of which document contained the problem. We examined the overall distribution of problems among types of documents. We assessed which types of documents had more unique problems as compared to other documents. We calculated the median number of unique problems occurring on each type of document per admission.

We investigated the distribution of specific problems among the types of documents to discern patterns in appearance of problems in documents. We identified whether specific problems tended to occur more often in certain types of documents (e.g., pain appeared mostly on POCs). We also identified the set of problems that occurred most often in each type of document to see whether problems co-occurred among documents.

Concordance analysis. We assessed the concordance of problems documented (whether they matched across phases and documents) and discordance (whether they were missing from one or more phases or documents). We compared the content of the set of documents available to the nurse during the admission (input-referral, intake, transition document-discharge instruction/progress note) to the content of the electronic artifacts produced when documentation was completed (output-POC, team email). We determined whether either output document contained the complete set of problems that appeared across output documents. We conducted the same analysis for the three input documents. Then we compared the selected input document(s) and the selected output document(s) to determine concordance for problem sets between input and output. We identified problems that were matched between input and output documents.

For the quantitative analysis, we calculated the total number of problems for each observation and the median across all observations. We used the above comparison of input problems to output problems for each observation to calculate the number of problems that appeared in: (1) both input and output; (2) input and not output; and (3) output and not input. For these three categories, we then calculated the total number and median across all observations.

Case studies. We illustrate the analyses with two admission case studies. One case has all the documents. The second case lacked the transition document. We present the median number of unique problems on each document, the median number of problems on each dyad of input and output documents, and the total number of unique problems.

Results

The documents varied in content, length and detail. They contained a variety of problem terms to describe the patients' health needs.

Assessment of documents. Referrals, intake forms, POCs, and team emails were available for all observations. Seven transition documents (discharge instructions or progress note) were available before the visit (as part of the referral documents): Five of which were also available during the visit (requested in the home). The data on these documents were not standardized across referral sources; the information on a few documents was illegible or missing. Patient problems were found in all types of documents among the observations. However, two POCs contained no problems; instead they contained plans for assessment and health promotion interventions.

Identification of problems. Following standardization of problem terms to the Omaha System Problem Classification Scheme, we identified 17 unique problems across the documents and observations. Referral documents had the most problems per admission (median 7; 2-9) (Figure 2). Team emails had the next highest number of problems (4, 2-9). Intake and transition documents each had a median of 2 (ranges of 0-5 and 1-8 respectively). The POC had the least number of problems (1; 0-2). Overall, the median number of problems decreased from input to output.

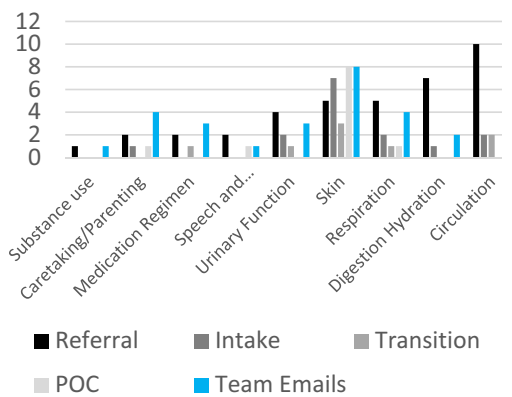

Figure 2. Occurrence of Actual Problems across Documents

Distribution of problems. Documents tended to differ as to which of the 17 problems occurred most often or at all (see Figure 2). Three problems occurred across all document types among the observations: "Skin" (occurred 28 times), "Respiration" (17 occurrences) and "Communicable/ infectious condition" (21 occurrences).

Concordance analysis. A complete set of problems was not found in any of the input or output documents. Accordingly, we used all available input documents, and both output documents in our concordance analysis of input documents as compared to output documents.

None of the 12 admissions had the same set of Omaha System problems on input documents as compared to output documents. All admissions had more problems on the input documents as compared to the output documents. For three admissions, the set of problems on the output documents was a subset of the problems on the input documents. The remaining nine admissions had one or more problems on the output documents that did not occur on the input documents, as well as having one or more problems missing on the output documents that were present on the input documents.

Although the set of problems did not exactly match between input and output documents, admissions did have individual problems that were matched between input and output documents. Here we report the medians (and ranges). In general, for each admission, a total of 8 (4-12) problems occurred on input and output documents. Among these problems, 3 (2-6) matched between input and output for each admission. Also, 3 (0-5) problems appeared on the input documents and not on the output documents. And, 1 (0-3) problem appeared on the output documents and not on the input documents.

Case studies. Analyses of two representative admissions are presented for further elucidation: an admission with all the documents, and an admission lacking the transition document. Admission 1 contained 8 problems on the referral, 4 problems on the intake form, 2 problems on the transition document, and 2 problems on the POC, and 9 problems on the team email. Among the input documents, 2 problems on the referral also occurred on the intake form and not on the transition document. Two other problems on the referral did not appear on the intake form but did appear on the transition document. The referral had 6 problems that did not appear on the intake form nor on the transition document. The intake form had 2 problems that occurred on neither the referral nor the transition document. Therefore, among the three input documents, 10 problems appeared. No single problem appeared on all three documents, and no single document contained all 10 problems. The 2 problems in the POC appeared in the team email. The 5 additional problems in the email did not appear in the POC. Of the 10 problems on the input documents, only 7 problems appeared in both the input and output documents. 3 problems appeared only in the input documents and not in the output documents. The dropped problems were Personal Care, Communicable/infectious condition, and Digestion-hydration.

A second example is admission 10 which lacked the transition document. This admission had 6 problems on the referral. Five of these problems also appeared in the intake form. No problems from the referral appeared on the POC; two problems did appear on the email. One problem on the referral did not appear on any other form. The POC problem, "Skin", did not occur on any other document. The team email had two problems, neither of which appeared on the POC. One of these problems, "Neuromusculoskeletal Function", did not appear on any other document. In summary, this admission had 8 problems; all but two of the problems appeared in the referral. Only 4 of the 8 problems on the input documents appeared on the output documents. The dropped problems were Urinary Function, Circulation, Nutrition, and Communicable/infectious condition.

Discussion

We investigated the content of problem data that the HHC nurse had at patient admission and the content of problem data that the nurse documented in the EHR and communicated outside of the EHR to the care team. This study focused on the source and congruence between documents available to the nurses when formulating the list of problems for the POC that they plan to address during the HHC episode. This study, in a rural home care agency, is the first of which we are aware, to examine this question. Findings are intended to inform point-of-care HHC EHR design, and to inform policy decisions related to interoperability along the transition in care from referral source to HHC.

Assessment of documents. The faxed referral documents contained the most problems compared to any other document.

The intake form, which was written by the home care agency nurse using information elicited from the referring facility, was universally available. The transition document was accessed in the patient home for less than half of the admissions. The team email, while universally present, was not part of the EHR. Instead, it was a communication work-around to address timeliness and information accessibility issues of the EHR. The POC, while universally present and part of the EHR, did not always contain problems and was in free text.

None of the documents were uniform or contained standardized information. Without standardization information can be lost or hard to find as our findings indicate.

Distribution of problems. The absence of any apparent pattern to the distribution of problems across documents provided no insight to nurse decision making. No document contained a complete set of patient problems. Thus, the initial referral document could not be relied on as the single source of problems. Others have reported that problem lists from hospitals and physician practices are likely to be inaccurate or out of date [1], [14], [15]. Further, these documents are often faxed from the referral source and contain multiple pages for a nurse to look through during the time constrained admission visit [16]. In addition, referral documents also contained both problems and interventions, especially for SNF patients, which puts further demands on the nurse's time to sort through dissimilar information. Similar to the other input documents in this study, referrals were not digitized or structured so as to be available for data management (e.g., copied to structured data fields for viewing or computing).

The intake form did not always contain the total set of problems appearing on the referral form. Intake forms matched the referrals in one admission and had fewer problems for the other admissions. The lack of completeness of the intake form and the occasional absence of the transition document suggest that neither could be relied on as a single source of patient problems.

Neither output document, team email nor POC, contained a complete record of patient problems. The team email, among all the documents, was second to the referral for the number of problems. The team email did not contain all problems documented in the POC. Nurses inconsistently documented some of the same problems in both email and POC. Redundant and conflicting documentation may require unnecessary expenditure of time and effort by the nurse, as well as introducing opportunity for transcription error and omission.

The POC, although part of the EHR, was not a complete source of problem information for the follow-up nurse. The POC unexpectedly contained fewer (or no) problems as compared to all other documents. Compared to team emails, the POC contained one quarter of the problems. For one quarter of the admissions, the set of problems on the POC did not match the set of problems on the team email. A potential reason for the mismatch may have been due to the fact that POCs tended to also contain interventions, evaluations, and health promotion activities, without a clear place designated where the nurse was required to document a finite problem list. Another potential cause for the mismatch is that the POC, being unstructured text, had problems which were not actionable: A nurse could not document against the problems when delivering care. As a consequence, the nurse was unable to determine if a patient problem was active or resolved. This data structure and flow do not support high quality patient care.

Our analysis of the distribution of problems among documents found that patients tended to have on average 8.5 problems at admission, which concurs with the finding of 9 problems in a prior study [3]. Findings also indicate that the problems skin, infection, and respiration are seen as important to communicate across all documents. This finding was clinically resonant with the nurse expert on the team (KB).

To the best of our knowledge, this is the first study to identify that patients are referred to HHC with more clinical problems (median 7) than are documented in the EHR plan of care (POC—median 1) or informally communicated to the team by email (median 4.5). None of these documents were in the EHR as structured data. This finding that patient referral documents contain more problems than are communicated to the care team indicates that admission nurses make decisions of which problems in the referral documents to include in the patient's care episode.

Concordance. The admitting nurse had access to the referral document, an intake form and infrequently, the patient's transition document. However, for no admission did the set of problems on the combination of these paper forms match the set of problems on the POC combined with the email.

Nurse decision-making related to inclusion and exclusion of problems between input documents and POC is unclear. We observed a decrease in number and mismatch of problems between input documents and output documents. The mismatch between input and output may be due in part to new information the nurse gathered during patient assessment in the patient home. Also, the EHR failed to provide structured language for describing patient problems and tracking their status over time.

EHR design recommendations. The decrease in number and mismatch of problems is an issue which could be addressed with EHR redesign and interoperability capability. Accordingly, we provide the following EHR design recommendations.

First, the EHR should capture and communicate problem data from the referral source. This recommendation relies on interoperability, the electronic movement of structured data among EHRs. The international data standard, the Continuity of Care Document (CCD), supports this capability [17]. The CCD is expected to be shared by health facilities as patients transition between settings. Relevant to this analysis, the CCD is structured to contain a list of patient problems [16]. Accordingly, we recommend that problems from the referral source be structured as per the CCD. Following communication of problems from the referral source to home care, the homecare EHR should map referral problems to a nursing problem terminology. Preferably the nursing terminology should be a standard terminology, such as the Omaha System [11]. The patient problem list should be viewable by the nurse. The problem should cascade through the EHR to the POC, avoiding nurse transcription of input problem data and the risk of losing information across documents.

Two recommendations are related to reducing redundant documentation. The software should enable the intake nurse to record problems viewable by the admitting nurse, and the problems should cascade through to the POC. In addition, the software should be designed to limit the number of times a problem is documented in the EHR, preferably to one. Our finding that the referral documents contained more problems as compared to the other documents, combined with our observation that referral documents tended to contain many pages [16] suggests the need to categorize referral problems to enable nurses to identify active problems. We suggest that problem modifiers such as resolved, actual, health promotion, or potential would be helpful to communicate the full array of patient issues [11]. Such descriptors would clarify the status of problems related to a hospitalization to retain the history of events and clarify which problems are resolved, are being actively worked on, or require preventive maintenance.

A fourth recommendation supports nurse workflow. The problems should be documented as structured data and be

actionable such that a nurse can document interventions and the status of the problem against the problems.

Two recommendations are related to eliminating the workaround of producing a team email to communicate the POC. We propose that the problem data should be readily viewable in a structured summary available to the care team, so as to eliminate the need to send the team email. Also, the EHR should be configured to support the timely update of patient information accessible by the care team.

A strength of this study is the research design. The field study was designed to collect and analyze quantitative data, to produce quantitative findings. Study limitations include a small sample size of six nurses and 12 patient admissions as well as the setting elements of one rural home health agency that used one EHR. Future work to further the generalizability of the findings would increase heterogeneity and sample size of nurse and patient populations studied, and the number of different EHR systems investigated.

The study was not designed to ask the nurse why selected problems were included in the POC and other problems were dropped. Future work to address this question would require near real time analysis of input and output documents and immediate review of this analysis with the nurse. In addition, future work could occur in acute care where a patient-centered assessment near discharge could identify patient problems from the patients' perspectives to share with the HHC admission team. Transmitting that list to HHC and studying the effect of having this information ahead of time are next steps.

Conclusion

This rural HHC agency relied on 3 paper input documents from the same referring source, each containing different sets of problems. The variation in problems may be due to the different intended audiences for the communication: clinicians at the referring facility, clinicians at the HHC agency, and patients. Input documents contained almost twice as many problems as compared to the output documents. However, no input document contained a complete list of problems. Following the home visit and patient assessment, new problems appeared in the output documents, and some problems on the input documents were omitted in the output documents without explanation or documentation of such. This observation underscores the importance of the home visit and further EHR functionality. Assessing the patient in the home often produced additional problems beyond those communicated from the referral source. The important output documents were the plan of care and a team email both of which were outside the EHR. This study illustrates serious issues related to EHR design and problem lists. The team email contained far more problems as compared to the plan of care. The usage of the team email highlights EHR design deficits related to the plan of care and team communication. A lack of timeliness of information; lack of structured, actionable data; and lack of interoperability provide opportunities to improve the design of this EHR.

Evaluating the Scope of Clinical Electronic Messaging to Coordinate Care in a Breast Cancer Cohort

Abstract

Care coordination has received attention as an opportunity to improve healthcare delivery. Current work to quantify provider coordination has primarily relied on identifying shared patients, but neglects to understand communication patterns. We applied social network analysis to electronic health record (EHR) secure messaging data to compare networks of providers who share patients and networks of providers who communicate about patients. We studied 2175 stage I – III breast cancer patients who received outpatient treatment from 1758 providers at a large academic medical center in the southeastern United States. Patients in our cohort were involved in 94324 appointments and were the subject of 307144 message threads. We found that 9.9% of provider-provider pairs that shared patients were mutually involved in electronic communication about their patients. EHR data sources can be used to evaluate provider communication across a clinical enterprise, which can help identify opportunities to improve collaboration and reduce provider burnout.

Keywords:
Transitional Care, Workflow, Communication

Introduction

Care coordination is a multidimensional concept involving care integration and information sharing across providers and settings. Care coordination has been recognized as an approach to deliver high-quality care [1]. Inadequate care coordination is common, often caused by lack of communication between care providers [2]. Without effective care coordination, patients often experience poorer outcomes and higher costs [3,4].

Improving care coordination has been recognized around the world as an opportunity to improve healthcare delivery [1]. The United States [1], Australia [5], and many countries across Europe [6,7], have all implemented programs to improve coordination between care providers. One approach in the United Kingdom, Coordinate my Care, was implemented by the National Health Service to improve information sharing for palliative care patients [7]. Similarly, the SIKS project in Denmark aimed to integrate chronic disease care and improve care coordination [8]. With the aging global population and onset of complex chronic diseases, care coordination has become increasingly important as patients are required to receive care from multiple specialists across geographically distributed locations.

Health information technology and clinical information systems are central to care coordination. Electronic health record (EHR) systems offer important collaborative functionalities such as clinical messaging and shared patient charts [9], which are used by individuals in various clinical roles to support the shared goal of providing optimal patient care [10]. Similarly, technologies such as patient portals and personal health records allow patients to collaborate virtually with their care team and coordinate care without a clinic visit [11]. Other technologies such as health information exchanges can allow providers from multiple institutions access to patient data at the point of care [12].

Studying care coordination and communication between individuals is a critical way to gain insights for process improvement and optimization. One approach to evaluate care coordination and communication is through analysis of the extensive clinical data stored in the EHR [13]. The secondary use of routinely collected data from clinical environments can offer valuable insights into the collaboration patterns and routines of clinical personnel.

While the importance of care coordination is recognized, few studies have been conducted to quantify the scope of care coordination. Understanding provider communication patterns is a key first step to quantify care coordination. In our prior work, we found that medical oncologists treating breast cancer patients are connected to an average of 737 providers by a shared patient, and have as many as 114 new relationships per year [14]. In this study, we seek to advance the understanding of provider coordination by evaluating the scope of electronic communication between providers treating breast cancer patients at a single institution.

Methods

This study was conducted at the Vanderbilt-Ingram Cancer Center at the Vanderbilt University Medical Center (VUMC). VUMC is a large academic tertiary care center, located in middle Tennessee, with a large referral population from the Southeastern United Sates. This study was approved by the Vanderbilt University Institutional Review Board.

Study Population

We extracted data from the Vanderbilt University Tumor Registry on patients with stage I, II, or III breast cancer, who were diagnosed between January 1, 2011 and November 2, 2016. The Vanderbilt University Tumor Registry collects diagnosis and treatment data on all cancer patients who were either diagnosed or received part of their first course of treatment at VUMC [15]. Data from the tumor registry included a unique patient identifier, date of diagnosis, and staging information. Similarly, for each respective patient, we extracted all outpatient appointment data corresponding to an appointment after cancer diagnosis. Appointment data included a unique patient identifier, a unique provider identifier, and an appointment date. Patients who had at least one outpatient

appointment in the six-months following their diagnosis were included in the study. We also extracted secure clinical messaging logs from the EHR to understand the scope of communication between providers after the patient's diagnosis between January 1, 2011 and November 1, 2017. Messaging data included a unique provider identifier, message thread identifier, message date, and message length. In both the appointment and messaging data, we mapped each provider identifier to their unique national provider identifier (NPI) to determine specialty.

Network Representation

To understand physician relationships associated with the treatment of a patient in our cohort, we modeled the data as a social network. A social network consists of *nodes*, or entities between which a relationship occurs, and *edges*, a connecting tie between two nodes representing the existence of a relationship. Both nodes and edges can assume properties such as size or color to represent network features. To understand and compare relationships between providers, we create one network to represent potential coordination via outpatient appointments with a shared patient from our cohort, and another network to represent secure communications between providers regarding a patient in our cohort. We filtered the messaging network such that only provider-provider pairs who were connected by a shared patient were included. To visualize the network, we assign node and edge colors by network inclusion.

We created the outpatient appointment network using a method of temporal edge creation [14]. Temporal edge creation represents relationships that are likely to occur by treating a patient during overlapping time periods. To create the network, we start by extracting a list of all providers involved in the outpatient care of a patient in our cohort as the list of nodes. To create edges, we first order the list of all appointments by patient and appointment date. We iterate through the appointment list by patient, recording the first and last interaction between a provider and patient. For each patient, we record the list of provider pairs involved in the care of a single patient during an overlapping time period as our set of edges. We aggregate provider-provider pairs across patients by taking the sum of patients for whom both providers are involved in care over the same time period.

Similarly, to create the clinical communications network, we begin by extracting the list of providers involved in a clinical communication thread about a patient in our cohort as the node list. We create edges by taking the pairwise combination of providers involved in a single communication thread about a patient. Provider-provider pairs are summarized by a count of unique message threads in which both providers were involved.

Data Analysis

To analyze relationships between providers, we created two types of networks: a network of all providers involved in the care of a patient in our cohort and a network of providers involved directly in breast cancer treatment and their immediate connections. We defined medical oncologists, radiation oncologists, surgical oncologists, and plastic surgeons as providers involved directly in breast cancer treatment due to the frequency with which they are involved in the first course of breast cancer patients' treatment. We conducted all analyses using the igraph [16] package within R 3.3.1 [17].

To compare messaging between providers and patients, we calculated descriptive statistics. We assessed provider-level statistics by secure messaging involvement. To understand similarity between messaging and appointment networks, we compare node and edge sizes and analyze edge overlap. In the appointment network, we define edge size as the number of unique shared patients between provider-provider pairs; the node size is the number of unique patients treated by a provider. In the messaging network, edge size is defined as the number of shared message threads involving a provider-provider pair. We similarly quantify connectivity across the entire network to calculate *network density*. Network density is interpreted as the percentage of possible edges that are present in the network. For each individual provider, we calculated *degree*, or the number of direct relationships to a node.

Results

During our study period, there were 2267 patients diagnosed with Stage I – III breast cancer. 92 patients did not have an outpatient appointment within the six months following diagnosis, leaving 2175 patients in our study cohort. Table 1 summarizes the messaging data. Patients in our cohort had 94324 appointments with 1758 unique providers. There were a total of 625137 messages in 307144 messaging threads sent about patients in our cohort with an average follow-up time per patient of 32.9 months from diagnosis. 222168 (72.3%) message threads involved at least two individuals and 14484 (4.7%) involved at least two billing providers who were involved in at least one appointment (appointment providers). 1093 (62.2%) billing providers were involved in messaging about a patient in our cohort.

Table 1 – Message Thread Statistics

	Message threads	**Mean threads per patient**	**Mean threads per appointment**
Total	307144	142.3	3.7
Involve:			
One individual	88266 (28.7%)	41.1	0.45
At least two individuals	222168 (72.3%)	102.8	1.13
At least one appointment provider	112460 (36.6%)	52.1	0.57
At least two appointment providers	14484 (4.7%)	7.5	0.07
At least one cancer appointment provider	62856 (20.5%)	30.8	0.32
At least two cancer appointment providers	7371 (2.4%)	4.6	0.04
Patient	47496 (15.5%)	38.9	0.24
Patient and an appointment provider	16341 (5.3%)	14.9	0.83
Patient and a cancer appointment provider	6748 (2.2%)	8	0.03

Table 2 presents statistics for the full network of providers. There were 2610 provider-provider pairs connected by a shared patient and message thread, which accounted for 9.9% of the

total edges in the graph. There were 2610 provider-provider pairs involving 761 distinct providers who directly exchanged secure messages. Providers who sent messages communicated with an average of 6.9 other providers. Each provider-provider pair involved in messaging communicated an average of 5.7 unique message threads. 34.6% of message threads were sent within one day before or one day after an appointment with the respective provider. In 9.4% of provider appointments, providers communicated through a message thread within one day before or after the appointment.

Table 2 – Provider Network Statistics by Messaging Use

	Appointment and View Messages	Entire Graph
Number of Nodes	761	1758
Number of Edges	2610	26233
Average Shared Appointments	6.8	2.0
Average Shared Message Threads	5.7	3.9
Network Density	0.90%	1.70%
Mean Degree	6.9	29.8

Across the entire network, 25 providers were related directly to routine breast cancer treatment. These 25 providers were involved in 50.9% of all messaging threads between two appointment providers about our patient cohort. We present the messaging statistics for cancer specialists in Table 3. Surgical oncologists were involved in 6314 unique message threads, more than any other specialty. Likewise, each surgical oncologist, on average, was involved in 1064.2 unique message threads with 69.3 collaborators. Each medical oncologist, on average, communicated with 134.3 specialists, more than any other specialty. Across all four specialties, radiation oncologists had the fewest number of messaging threads (537) and number of provider-provider edges (91). 31.9% of all edges and 76.1% of all weighted edges involving a radiation oncologist were with another cancer specialist. Medical oncologists had 13.2% of edges with another cancer specialist, the fewest of any of the specialties involved directly in breast cancer treatment. However, when accounting for the volume of communications, 64.6% of the total edge weights involved a medical oncologist and another cancer provider. This 389.4% increase from percent of edges to percent of weighted edges was the largest of any specialty. Surgical oncologists had the highest percentage of weighted edges with other cancer providers (83.2). Medical oncologists had the largest overlap between shared patients and shared message threads with another provider (18.5), followed by plastic surgery (11.5), surgical oncology (11.0), and radiation oncology (7.3).

Discussion

In this work we analyzed communication patterns between providers during their treatment of breast cancer patients. Using social network analysis and graph statistics, we were able to quantify collaboration between providers by comparing physician messaging connectivity to patient sharing through outpatient appointments. Other studies have applied quantitative methods to study provider connectivity, but these studies have commonly relied on appointment data or claims data, which do not necessarily indicate clinical coordination or collaboration. In our previous work, we conducted a social network analysis of data from the Vanderbilt University tumor registry to detect differences in breast cancer provider connectivity by patient stage [18]. Another study by Hussain and colleagues used SEER-Medicare data and found that increased patient sharing led to improved mortality in Stage III colon cancer patients [19]. Similarly, Landon and colleagues used Medicare claims data to identify networks of physicians who likely have close relationships [20,21].

To our knowledge, this is one of the first studies to quantify provider collaboration using secure communications deployed throughout a clinical institution. Our quantitative approach is supported by the use of EHR messaging data. The EHR messaging functionality offers a secure and HIPAA compliant way for care team members to communicate about a patient's care. EHR functions such as secure messaging have been identified as a means for care coordination in previous work [22]. For providers within the same EHR system, care coordination is enabled by this form of asynchronous communication. Our results demonstrate the substantial volume of clinical communications between providers treating breast cancer patients to coordinate care. This form of communication is not available to providers who do not share the same EHR and practice at the same institution, which likely limits their ability to sufficiently coordinate care. Our results highlight the baseline need to implement electronic tools to enable care coordination between providers, particularly as EHR messaging functions are not availabile to providers practicing at separate institutions.

In our network, the 2175 patients in our cohort were the subject of over 222168 message threads between at least two individuals. 14484 of these threads involved at least two appointment providers. We found that each patient, on average, was the subject of 142.3 message threads. This staggaring number of communications represents substantial work required of the care team that is outside of an appointment. Our results indicated that 9.9% of the total provider-provider pairs were involved in secure communication in addition to sharing patients. However, medical oncologists had a much higher overlap of 18.5% among all connections and 48.4% among other cancer providers. A 2016 study by Shanafelt and colleagues found that physicians who reported high amounts of EHR use such as secure messaging were at higher risk of professional burnout from the amount of time spent on clerical tasks [23]. From our oncology provider network, we found that medical oncologists are involved in nearly 960 message threads, with one provider involved in 1942 threads over our study period. In the early stage breast cancer treatment, such as the population that we studied, the medical oncologist is tasked to coordinate care between specialists. We hypothesize that providers involved in large amounts of messaging could suffer from collaborative overload, which limits performance and productivity [24].

Our approach to analyze provider communication is not without limitations. Our study compares two common clinical tasks supported by the EHR: patient appointments and provider messaging. We do not account for other forms of direct communication, such as tumor boards, in-person discussions, pages, phone calls, or email messages. However, at VUMC, EHR-based secure communications are the preferred method of provider-provider communication and are heavily utilized within our institution. Our method also does not account for methods of indirect communication between providers, such as viewing clinical documentation or sending encounter notes between providers. We could also analyze other EHR artifacts, such as the transaction logs of orders and clinical notes, to understand providers who are communicating passively.

Table 3 – Appointment and Messaging Network Statistics for Physicians Involved Directly in Breast Cancer Treatment.

	Medical Oncology	Surgical Oncology	Radiation Oncology	Plastic Surgery
Number of Providers	8	9	3	5
Appointment				
Number of Appointments	21597	12870	5451	9525
Number of Provider-Provider Edges	4263	3648	1047	1412
Mean Specialty Node Size (range)	444.5 (140, 957)	327.9 (47, 575)	274.25 (25, 904)	216.6 (76, 553)
Mean Edge Weight (range)	8.1 (1, 686)	7.6 (1, 447)	8.8 (1, 622)	7.7 (1, 409)
Mean Degree per Node (range)	480.5 (310, 731)	401.1 (120, 628)	229.8 (32, 636)	264.4 (143, 550)
Edges with Cancer Provider (%)	285 (6.7)	246 (6.7)	131 (12.5)	158 (11.2)
Edges with Non-Cancer Provider (%)	3978 (93.3)	3402 (93.3)	916 (87.5)	1254 (88.8)
Edge Weight with Cancer Provider (%)	15742 (45.4)	13396 (48.0)	4808 (52.0)	5774 (53.4)
Edge Weight with Non-Cancer Provider (%)	18944 (54.6)	14500 (52.0)	4433 (48.0)	5048 (46.6)
Provider-Provider Messaging				
Number of Messaging Threads	5818	6314	573	805
Number of Provider-Provider Edges	1047	594	91	184
Mean Specialty Node Size (range)	959.5 (468, 1942)	1064.2 (243, 2668)	205.3 (14, 584)	180.6 (35, 386)
Mean Edge Weight (range)	6.5 (1, 419)	12.4 (1, 1748)	7.5 (1, 80)	5.0 (1, 54)
Mean Degree per Node (range)	134.3 (82, 217)	69.3 (37, 105)	31 (6, 78)	38.4 (22, 55)
Edges with Cancer Provider (%)	138 (13.2)	144 (24.2)	29 (31.9)	78 (42.4)
Edges with Non-Cancer Provider (%)	909 (86.8)	450 (75.8)	62 (68.1)	106 (57.6)
Edge Weight with Cancer Provider (%)	4426 (64.6)	6146 (83.2)	516 (76.1)	658 (71.3)
Edge Weight with Non-Cancer Provider (%)	2430 (35.4)	1242 (16.8)	162 (23.9)	265 (28.7)
Percent overlap among all edges	18.5	11.0	7.3	11.5
Percent overlap among edges with another cancer provider	48.4	54.9	21.4	48.7
Percent overlap among edges with another non-cancer provider	15.8	9.5	4.5	5.5

Understanding communication patterns between providers affords the opportunity to identify clinicians who work together closely, such that we can begin to identify clinic models for long-term chronic disease treatment and follow-up. We found that provider-provider pairs who were involved in messaging shared more patients than provider pairs who were not involved in messaging. These results suggest that providers who share multiple patients work together more closely than providers who share fewer patients, as hypothesized in other studies [19]. We also found that nearly 35% of message threads were within one day of an appointment. Appointment providers were involved in secure messaging within one day before or after nearly 10% of appointments. Similarly, there were an average of 7.9 messages sent per appointment. Work from Reid and colleagues found that implementing a co-located medical home clinic model provided more time to coordinate care between specialists and reduced provider burnout [25]. We hypothesize that providers who communicate closely may benefit from a co-located medical home clinic model by supporting inter-personal communication between specialists who collaborate frequently.

Our results indicate that only 1.4% (25) of the providers in our network were cancer specialists, suggesting that patients receive care during their cancer treatments from a breadth of providers. Unsuprisingly for our patient population, 50.9% of the messages between appointment providers involved these cancer providers. Results from our oncology specialist messaging network indicate that medical oncologists and surgical oncologists had the largest degree, or number of provider collaborations, with 134.3 and 69.3 collaborations per provider, respectively. This finding reflects the importance of these two specialties in coordinating early-stage breast cancer care. Surgical oncologists had a greater percentage of edge weights with other cancer providers and the largest overlap among edges with other cancer providers, compared to the medical oncologist. The medical oncologists had a greater number of provider-provider communications with non-cancer providers than any other cancer-related specialty. Similarly, medical oncologists had a 18.5% overlap between communications and shared patients with other providers. These results suggest that the medical oncologist is highly important in coordinating care between specialists, while the surgical oncologist is integral in coordinating care between cancer providers during cancer treatments.

Conclusions

Cancer treatment is complex, requiring multiple modalities delivered by many care providers. Initiatives have been implemented to improve coordination between care providers, but there does not yet exist a quantitative approach with which to evaluate care coordination. Current studies to understand coordination between providers have utilized payor claims and appointment data to suggest potential collaboration by identifying shared patients between providers. We employed a social network analysis approach to compare provider-provider relationships through shared patients and provider-provider communication about shared patients. We found that approximately 10% of relationships through shared patient were also involved in secure messaging. We also found that medical oncologists had the largest overlap between networks across all specialties, suggesting that medical oncologists are key to coordinating care across all providers associated with a patient. Applying social network analysis to EHR secure messaging data allows us to identify highly collaborative provider-provider pairs that can be used to further evaluate care coordination and drive improvements to healthcare delivery.

Abstract

This article illustrates the maturation process of innovative technologies in the healthcare domain.

The role and the involvement of the stakeholders are explained, as well their interaction in the ecosystem. We focus on how the synergy between partners improves efficiency, boosts product development and accelerates market access.

The spiral of the innovation concept is introduced to illustrate the different stages ensuring the correct development of a medical technology. This iterative cycle drives the product maturation, according to medical needs and feedback, and ensures the correct implementation of the innovation in the clinical framework.

We finally illustrate how the innovation process is applied to successful drive the ongoing SERENE-IoT project: the spiral of innovation concept is specifically adapted to fit with the project requirements with the final ibjective to identify a panel of medico-economic indicators and to establish the medical service delivered and the opportunities in order to capture the full benefit of the proposed technology.

Keywords:
Delivery of Health Care, Medical Device

Introduction: The Innovation in Healthcare

The Clinical Investigation Center - Technological Innovation (CIC-IT) structures play a crucial and strategic role in the innovation process. The CIC-IT structures were established to accelerate the transfer of technological innovations in the healthcare domain to clinical practice: prognostic, diagnostic and therapeutic. One particular objective is to facilitate the translation from fundamental research to the industrial product [1]. To accomplish this mission, a CIC-IT must support the "Healthcare Innovation Technology" (HIT) as it matures [2, 3]. Thus, a CIC-IT will be able to support this innovation, either intermittently during one of the HIT maturation phases or in a more "exhaustive" way (i.e. accompanying the process of innovation maturation, from the genesis until the clinical evaluation).

A CIC-IT is able to participate in the evaluation of:

- The performance and safety of the proposed innovation,
- The balance between benefits and risks for the claimed added value,
- The usability prior to placing the HIT on the market,
- The expected medical service improvement.

However, in order to appreciate the potential contributions of a CIC-IT in the HIT maturation process, it is first necessary to describe this process and then identify the potential contributions of CIC-IT within it.

A HIT can be categorized in the following way according to [4]:

- "Breakthrough" innovation addresses a medical problem by "disrupting" the current state of the art, introducing ruptures in the area of usages and involving strong modifications regarding the indication or the use of a Medical Device (MD);
- "Integration" innovation integrates new technological/scientific concepts to upgrade a MD, in response to a clinical need;
- "Incremental" innovation is characterized by a significant improvement of a MD, without disrupting the conditions of use in the clinical practice.

It also happens that a technological innovation, which was not created specifically for a medical need, can be used in the medical environment and can have strong benefits in the area of the healthcare.

Regardless of the category, a schematic maturation process for innovation in healthcare technologies has to be clear in order to be helpful for its use in different contexts. The actors and the technical, scientific and medical aspects involved in this process, as well the regulatory, economical and industrial frames will be discussed in the next sections of this article.

Stakeholders in the Healthcare Ecosystem

Because the healthcare ecosystem has a particularly high number of stakeholders linked with complex interactions that vary depending on the countries, culture and local regulation, bringing innovation into this ecosystem is complex. Innovation in healthcare can impact all the stakeholders at various levels in the very complex ecosystem of health [5, 6]. Ideally all the stakeholders should take into account the many factors involved from the genesis phase and all along the maturation process [7]. We propose a generic view of the healthcare value chain (summarized in Table 1) distinguishing five key player roles.

The Patient

The patient (or user associations, or target population) is the first player concerned by innovation in healthcare. The innovation should bring a higher quality of health service and should improve the benefit/risk ratio of the diagnostic or therapeutic act involved. The patient is obviously central to the maturation process, both in the upstream phases of innovation

(identification of a specific need) and in the downstream phases (during clinical evaluations in order to evaluate the performance and the security of the MD and the delivered medical service). As an example, patient associations can contribute by identifying needs uncovered by routine practice, by providing expertise on the reality of needs and on the constraints of use.

The Healthcare Professional

Healthcare professionals are the professional stakeholders in primary contact with the patients. They are responsible for good patient care. All medical and paramedical specialties are concerned. All the actors in this category can contribute to the design and maturation of the innovation in their domain of competence, ideally from the earlier phases. Healthcare professionals are at the root of meeting medical needs: they provide the first answers to drive the future steps of maturation. The early involvement of medical experts along the medical maturation process will help to determine the relevance and the early adoption of the proposed innovation for its future implementation in the clinical framework.

Other Healthcare Actors

Other healthcare actors can be also identified:

- Public Health Authorities are responsible for the evaluation of the healthcare benefit, the definition of the policies for reimbursement of the acts, the definition of the management and cost coverage of health products;
- Other competent authorities are in charge of monitoring the safety of MD;
- The local authorities and the healthcare insurance organizations.

These stakeholder groups lead to the identification of priorities for the health of the population at the national level and can be involved in the regulations, laws and authorization for clinical investigations. In fact, the expertise of the High Authority of Health may lead to the reimbursement of the proposed innovation and then rapidly accelerate its deployment.

The Researcher (or Innovative Technology Provider)

The researcher, working in a public institution or in a private company, designs, develops, validates and implements the technological-scientific innovative solution. Ideally, this solution responds optimally to a previously identified medical need. In the case of pure technological-scientific "breakthroughs", the proposed innovative solution can give rise to "clustered" innovations, made from and inspired by the first idea.

The Industrial Manufacturer

At the end of the successful maturation process, the industrial manufacturers will intend to commercialize the product resulting from the innovation. More generally, this stakeholder group represents all the economic actors that will contribute to the relevance of the innovation in the market.

The industrial manufacturer is responsible for the quality of the innovation, from the prototype to the certified market product. This actor is the only one in charge to provide and distribute the MD in compliance with the quality assurance policy.

The success of these actors is the result of early, close and well-coordinated collaboration.

Table 1 – Stakeholder Analysis for Innovation in the Healthcare Ecosystem.

Stakeholder	Role	Benefits	Costs
Patient	Clinical need, Purchaser	Improvement of life quality	None
Healthcare professional	Clinical feedback, Purchaser	Improvement of practice	User learning
Researcher	Innovator	Intellectual property, dissemination	Development
Manufacturer	Product, Market access	Turnover	Regulatory, Quality

The Spiral of the Innovation

The cycle of innovation represents the stages of the development of an innovative MD and identifies the collaboration and interactions among the stakeholders [8]. Different actions have to be anticipated from the idea (whose intellectual and industrial property has to be protected) until it achieves market penetration (which has to be planned, ideally from the beginning) and beyond. These actions will accelerate the availability of innovation responding to the unmet clinical need and can be described as a "spiral of innovation" cycle, as summarized in Table 2 [9, 10, 11, 12].

Table 2 – Stages of the MD Innovation Cycle.

Stage	Key phases
Concept and Design	Medical challenge, Needs, Methodology, Benefits/Risks
Tests on pre-product	Users feedback, Usability, Maturation, Market study, Intellectual property analysis
Clinical prototype	Compatibility with clinical environment, Risk analysis
Product and Marketing	Clinical trials, European Conformity (CE) mark, Regulatory frame, Usability, Market access and product follow-up, Indicators

Rigorous methodologies, specific to clinical trials of this domain, will be used to obtain the objective evidence, adapted to the degree of maturation of the innovation.

Thus, the development of an innovative MD, compatible with first clinical uses, will enable the achievement of first evaluations in the current clinical practice. First evaluations may be undertaken within the legislative framework whatever the class of the MD, CE marked or not. This first biomedical research will determine the feasibility of the use of the innovative MD for the patients.

A real process of maturation of the innovation will follow thanks to the validation within specific biomedical research, in order to obtain the evidence of the maturation degree of the innovation. In the case of an unmarked CE product, this research may contribute to demonstrating a favorable risk/benefit ratio in view of the CE marking application. Specific biomedical research will provide additional evidence that will impact future clinical studies in order to demonstrate the benefit. The implementation of biomedical research at a larger scale will generate the objective evidence (or not) of the

benefit for a target population, from which the public health benefit of the innovation can be estimated.

SERENE-IoT (Secured & EneRgy EfficieNt healthcarE solutions using IoT technologies): A Successful Example of Innovation Process

Context of the project

Since the mid-2000s, connected devices have impressively increased their place in the market of Internet of Things (IoT) thanks to the widespread use of smartphones and numerous dedicated consumer applications. In particular, a new branch appeared in healthcare: the Internet of Medical Things (IoMT). Yole Development estimates that there are more than 45M IoMT devices today and that there will be more than 235M in the market in 2020 [13].

This digital revolution is rapidly changing healthcare systems towards a new concept focused on smart health. The convergence of healthcare and high-tech mass-market ecosystems is coming to a point where things and people are increasingly connected, as with the IoT, and where healthcare is partly divided between hospital, private structure and home. This opens the gates to new technological challenges in order to ensure solutions in the domains of energy efficiency, data collection/transmission/storage security, connectivity and architecture and device management and configuration. In particular, these solutions have to be applied facing new European regulations (2016/679 – 2017/745 – 2017/746) which drive the development of MD (software included) and data privacy.

The objective is to move from the existent smart watch model to a new smart health system. Benefits are multiple: the patient experience and follow-up are improved because of remote health personalized data monitoring that is able to detect abnormalities faster to alert healthcare professionals, device maintenance needs are optimized via remote configurations, healthcare professionals can remotely monitor patient health and treatment compliance and device performance far from their offices, patient families can help in the follow-up of patient wellness and healthcare systems reduce human errors and falsifications.

The long term goal is to provide a global Big Smart Data platform to aggregate and correlate large volumes of data from disparate MD with health outcomes to deliver advanced insight on disease prevention and prediction.

Objectives of the Project

SERENE-IoT will consider the beneficial impacts for the patient with an increased quality of life and for the health system with an expected cost saving, while also increasing access to care for the population. SERENE-IoT addresses the needs of patients remotely followed by professional caregivers by developing advanced smart e-health IoT devices and architecture in Europe.

Following the definition proposed in the Yole report [13], SERENE-IoT has the ambition to cover 4 market segments: implantable devices, self-monitored devices, professionally oriented devices and assistance devices for people lacking autonomy.

The core values of the project are:

- High quality of healthcare services;
- High level of trust (security, safety, privacy, robustness);
- Efficient execution of required operations and tasks;
- Interoperable and compatible information technology systems;
- Reduced costs compared to current traditional care.

In this context, SERENE-IoT focuses on 3 medical challenge domains:

- Domain 1: Remote Healthcare by moving care services from hospital to home;
- Domain 2: Early detection of Methicillin-Resistant bacteria;
- Domain 3: Fall Prevention.

In line with the medical innovation cycle until the step “Clinical Prototype”, the goal is to develop 3 clinical prototypes of new MD supporting security, safety and privacy and their complete validation inside a secured end-to-end IoT system platform. With this, the project will contribute to the standardization of a healthcare data structure to ensure MD and system interoperability.

Therefore, SERENE-IoT develops the following connected clinical prototypes (see Figure 1):

- A low-power medical IoT module validated with two MD (class IIx) providing homebased remote healthcare service;
- An early detection system (first low-power mobile detector) of Methicillin-Resistant Staphylococcus aureus bacteria;
- A fully wireless insole for fall detection and gait monitoring.

Figure 1 – Clinical Prototypes of the SERENE-IoT Project.

In the 3.5 year timeframe of the project, the goal is to clinically validate these devices (with mono and multicentric studies) in the operative environment under the coordination and supervision of the Grenoble-Alpes University Hospital (CHUGA) and through the expertise and the “Medical Innovation Cycle” concept developed by the CIC-IT of Grenoble.

The three demonstrators will be used to provide the necessary validation of advanced concepts needed by European industry for the development and manufacture of products and services in remote medical-care. Importantly, SERENE-IoT will contribute to the evaluation of a secure, end-to-end, IoT system platform in “real-life” scenarios (including the use of the proposed healthcare data structure), while demonstrating the resulting benefits. Certification and industrialization phases will follow the SERENE-IoT project.

Partnership (Consortium)

The SERENE-IoT consortium (over three countries: France, Germany, Spain) aims to provide a balanced and holistic view leveraging different types of partners (large firms, SMEs and academics) covering the overall Health Innovation Technology ecosystem (from IDM/OEM to end-user service provider).

Looking at Figure 2 below it is evident that none of the involved partners can cover the whole value chain and be successful on its own. Only a close collaboration of the different stakeholders will enable technological innovations, and then products, that support a real and qualified medical service validated by healthcare professionals to be achieved at the end. This is the key reason to assemble the SERENE-IoT partners in a single project sharing a common goal. SERENE-IoT should be considered as a business "seed" for the demonstrators, who will establish all the conditions to contin-ue later on though medical innovation up to the introduction of a product on the market in maximizing its chance of success.

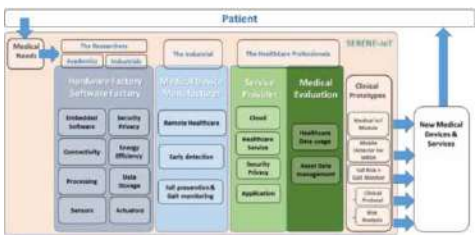

Figure 2 – Only a Close Collaboration Among the Various Stakeholders can Successfully Propose Technological Innovations.

Role of STMicroelectronics

STMicroelectronics is a global leader in semiconductors with the expertise and resources to propose disruptive microelectronics-based platform solutions to make a positive contribution to lives of people. As a large firm able to provide solutions to MD manufacturers, STMicroelectronics is in the strong position to assume the European coordination of SERENE-IoT across the healthcare value chain. From this vantage point, STMicroelectronics can push disruptive technologies across the value chain to consolidate learnings to the next evolution of its portfolio.

Project Flowchart and Short Description of the Tasks

Figure 3 below shows the different model steps, starting from a medical problem expressed by health experts (H), industry (I) or research (R) entities always around the patient (P) and resulting in real needs, through placing the "Product" on the market.

Based on our experience, the time scale for the complete cycle can be around 10 years while the time from the "medical problem + ideas" to "Clinical Prototype" is 3 to 4 years. Note that the blue/green area domain in Figure 3 includes the model steps ("Product concept", "Technical Prototype" and "Clinical Prototype") devoted to developing the technology needed to solve the identified medical problem. The remaining steps ("Pre-product" and "Product") are devoted to clinical intensive evaluation/test and maturation to bring "Clinical Prototype" to a real and certified product in accordance with the protocol defined, having its certification and having followed the required industrialization phases. These two last steps are the unique responsibility of the industrial manufacturers developing the product and, because of the difficulty of performing this in a collaborative way, is not part of the SERENE-IoT project.

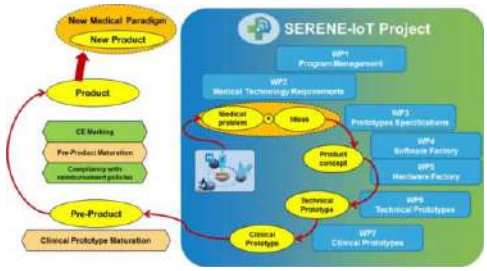

*Figure 3 – The **S**piral of **I**nnovation (resuming the main stages of innovation diffusion) **S**pecifically **A**dapted for the SERENE-IoT **P**roject.*

Role of CIC-IT Grenoble

The role of the CIC-IT Grenoble in SERENE-IoT is to support and drive the project within the innovation cycle, with the aim to clinically validate the proposed devices at the CHUGA.

The CIC-IT Grenoble has been involved in the early stages of the innovation cycle in order to share expertise in the clinical domain with the consortium, to accelerate the complete understanding of the medical need and to facilitate the definition of the functional and operational specifications of the proposed HIT via iterative feedbacks with the clinicians. This collaboration should contribute to shortening the HIT maturation process, from idea to demonstration of the benefit for the target population.

The missions of the CIC-IT Grenoble in the SERENE-IoT project are:

- To define user cases identifying the scenario for future implementation of the clinical prototypes in the hospital framework, in order to anticipate the possible drawbacks and to target the opportunities;
- To work on the usability of the clinical prototypes, either in support of the parallel technological developments (for example, to define the software / hardware specifications as requested by the clinician) and to collect information on the device usage for the further optimization based on user feedback (i.e. patients, clinicians, medical and technical services);
- To establish the clinical studies (i.e. writing of clinical protocols) to evaluate and validate the implementation of the clinical prototypes in a real environment.

The outline of these missions for the CIC-IT Grenoble will be:

- To demonstrate the feasibility of acquiring the relevant information through the IoMT devices developed in the SERENE-IoT project;
- To understand the possibilities for future standardization of the proposed end-to-end chain;
- To study the problem of deploying and integrating such architecture in a complex infrastructure;
- To ensure the safety and the integrity of the collection, transfer and access of the patient data along the IoMT end-to-end chain in compliance with the current regulations, in particular with the General Data Protection Regulation (GDPR);

- To estimate the medical service delivered with the objective to optimize the care of patients, the work of caregivers and to identify medico-economic indicators;
- To use the "big data" generated in the study in the development of diagnostic, prognostic and therapeutic predictive models.

Conclusions

In conclusion, innovation in the healthcare domain has an important multidimensional facet that involves the synergy of stakeholders at technical and scientific, juridical and regulatory, industrial and economic levels.

The innovation, from the idea to the final product, involves different phases that can be resumed schematically in an iterative process. This innovation cycle has multiple consequences in terms of relationships between the consortium partners. With respect to a dynamic and efficient behavior, a proficient work emerges that ensures a beneficial agreement that gives sufficient incentives to market actors in order to constantly improve products and services in the healthcare system.

In this paper, we demonstrated that the "the spiral of the innovation" concept can drive effectively a HIT. In particular, the maturation cycle of the SERENE-IoT project currently benefits from the contribution of the CIC-IT of Grenoble. First, the proposed MD will be developed faster than the current state-of-art: the objective is to finalize the first clinical validation for the proposed prototypes in 3.5 years, the time of the project, compared to the 8-10 years, as reported in other projects. Second, the active involvement of the CIC-IT (via its support concerning regulation knowledge, its contribution in terms of clinical use cases, needs and feedback and the work on usability) allows the partners to improve the technological developments. Finally, the clinical studies will evaluate and validate the implementation of the clinical prototypes in the clinical frameworks.

In the long run, this methodology will decrease the costs of innovation and increase the potential synergies of partners in healthcare domains. We consider that this represents a collective challenge and an opportunity that all players in healthcare must embrace in order to achieve a faster access to the latest innovative technologies providing a better and cost-effective benefit for the population.

Abstract

Recent advancements in mediated communication technologies enable unfettered communication between patients and their providers. We explore patients' utilization of different direct and mediated communication modalities in a Direct Primary Care (DPC) clinic and the patient characteristics that predict their communication behavior patterns. Based on this knowledge, we developed 2 patient personas that explicate the nuances of patients who tend to prefer visiting the clinic in person versus those who use mediated modalities more often. We hope this study may inform future work in understanding and supporting patient-provider communication in a new technical environment. The results suggest that patients and their health team alike may be incentivized to voluntarily adopt and utilize multi-modality communication in a DPC setting.

Keywords:

Patient-Specific Computational Modeling, Patient Engagement, Primary Health Care.

Introduction

Patients living with chronic conditions ideally are expected to take on more responsibilities of their own care due to the limited resources (e.g., physician time) in traditional clinical visits [1]. Evidence has shown, however, that the long-term and nuanced nature of chronic conditions makes it more effective for physicians to involve in patients' self-management actively [2; 3]. The direct primary care (DPC) model offers to address this conflict by allowing patients to have unfettered access, either in person or through mediated communication channels, to their physicians for everyday health decision-making tasks. It is hoped that the collaborative relationship between patients and their physicians facilitates the much-needed frequent shared decision-making and gives patients the tools and confidence to manage their health with the active support of their physicians.

The advancement in medicated communication technologies for health, such as mHealth and patient portals, enables patients' multimodality access to their physicians and medical records. Those technologies are especially relevant for patients with chronic conditions due to their need for long-term shared decision-making. A recent review investigated 47 tools for mediated communication between chronic patients and their health care team [4]. The authors noted great diversity in functionalities such as direct text-based communication between patients and care teams, the reporting of patient-generated data, and the delivery of behavior-related interventions [4]. Another recent study suggests that patient portal use is associated with improved glycemic control in patients with diabetes mellitus [5]. It is therefore important to explore factors associated with the usage of mediated patient-provider communication technologies and identify potential opportunities to promote engagement.

With unprecedented freedom of choice for patient-provider communication, we are able to observe patients' behavior patterns across multiple communication modalities and learn their preferences of different modality for various situations. The extraction of patient characteristics for communication patterns will further allow us to better reach different patient segments in health care settings, such as care management [6], public health [7], and community wellness [8]. For example, in the care management setting, understanding the behavioral characteristics of patients may help care managers evaluate intervention effectiveness [6]. The increased patient understanding will further enable targeted communication for coordination of care among and between patient and care team, which has been identified as one of the key success factors of care delivery models for high-need patients [7]. It is also expected to help design health communication campaigns for population health management. For example, the Center for Disease Control in the U.S. provides Health Communication Works toolkit [8], which leverages a previously developed risk communication model to identify patient persons and to offer an evidence-based approach to audience-centered messaging.

Prior studies examining patient factors associated with mediated communication technology adoption found that diabetes patients who use mediated communication channels tend to be younger, male, with higher morbidity, and use more medications [9]. There is a paucity of studies on patients' communication patterns beyond technology adoption and the usage of different functionalities, such as the number of messages in each conversation and how frequently they send compared to receive messages. Less is known about patient characteristics other than demographics as well as access to and acceptance of technologies, such as their health trajectory over time and medication types.

In this paper, we answer the key research question: *What are the patient personas for communication modalities use in a direct primary care setting?* Communication modalities examined in this paper include office visits, secure messaging, video chats, EHR portals, and phone calls. Patient personas are collections of patient characteristics that describe a typical patient and their communication modality use behaviors. A simple example is a patient who goes to the clinic in person once a year and talks to her doctor through secure messaging infrequently may be a relatively younger, healthy person who lives further away from the clinic. We develop such personas for the purpose of clarifying the starting point for technology, intervention, and policy design.

Methods

Research Site

The research site of this study is a R-Health clinic based in New Jersey. The R-Health Direct Primary Care (DPC) model is a value-based model of care focused on delivering personal, convenient, and effective primary care to its members for a regular monthly fee. Providers are free from the typical incentives of volume-based fee-for-service primary care, and thus able to engage patients across multiple communication modalities. Members can use secure messaging, video chats, electronic health record (EHR) portals, traditional phone calls and office visits to communicate with their health care team. Since they are not required to ensure that interactions happen under a billable event, providers are free to engage with the patients in a manner that is most effective. Therefore, patient-provider communication behaviors are mostly organically developed through long-term negotiation between patients and their healthcare team. By the end of October 2018, a total of 2427 patients have visited the R-Health clinic and 2487 patients have communicated with their health care team through at least one mediated communication modalities.

Data Set

The data analyzed in this study is a comprehensive data set across all communication modalities available at R-Health. For in-person visits, the data set includes information such as date and time of visit, reason for visit (e.g., new patient visit, follow-up visit, emergency visit), status of visit (i.e., canceled or not). For mediated communication, the data set specifies the communication medium, messages nested in conversations for text-based communication, and the type of conversation (e.g., support and standard). The data set also includes demographics, lab tests, vitals, medication forms and intake routes, medication intolerance statuses, medication fulfillment routes, allergy statuses, and Hierarchical Condition Categories (HCC) [10].

To assure meaningful data analysis, we processed the data set at the patient level by re-organizing multiple records per patient (e.g., records on mediated communication and vitals) into frequencies (for cases of categorical entries) or distribution (for cases of continuous entries). To avoid producing results due to recording inconsistency, we also constructed binary variables for those that reflect frequencies (e.g., whether they have allergies). All variables are then standardized to have a mean of 0 and a standard deviation (SD) of 2. This process improves the interpretability of results from clustering and regression by removing the effects of scales.

Missing data are handled in two different ways. For variables that describe behavior counts (e.g., total number of conversations a patient is involved in), where missing data represent no behavior, missing data are replaced with 0s. For variables that describe properties (e.g., age) and where 0s stand for a meaningful state (e.g., interquartile range (IQR), median absolute deviation (MAD)), missing data are replaced with the variable median. Missing data are handled after the standardization of the dataset to avoid influences on the standardization process.

The final dataset includes all 678 patients in the cohort and 224 variables, including 103 features (i.e., independent variables), and 121 responses (i.e., dependent variables). Due to the large numbers of features and responses analyzed in this paper, traditional statistical methods (e.g., multivariate linear regression) are not able to capture the full picture depicted by the rich data set, and we adopted more sophisticated machine learning methods in an attempt to paint a more complete picture.

Data Analysis

We conducted data analysis in three steps. First, we explored the variable space with cluster analysis by partitioning cases around medoids (PAM) [11]. PAM is a more robust version of the k-means approach because it "minimizes a sum of dissimilarities instead of a sum of squared Euclidian distances"[11]. Then, we excluded the variables that yield the same medoids, which are less differentiable of personas. Excluding those variables enables the building of more concise machine learning models and subsequently more distinct personas. After that, we conducted cluster analysis again and performed multi-task regression with clustered structure (MTR_CMTL) [12] on the remaining 75% training and 25% testing data. We also performed the same regression on meaningful patient segments to provide in-depth insights into the nuances of different patient groups.

Machine Learning Framework

The goal of this study is to extract patient personas associated with various communication behavioral patterns in terms of modalities (e.g., office visit, secure messaging) and behavioral outcomes (e.g., frequency, intensity). In addition, given a set of patient markers that include social determinants (e.g., distance to care), clinical characteristics (e.g., allergies, medication change) and health status based on vital signs (e.g., body mass index (BMI), blood pressure), the task of patient persona extraction is cast as classifying the communication behavioral patterns by simultaneously modeling all markers and their effects.

Since some of these communication patterns might share a similar structure of patient markers, we adopt a multi-task learning framework, in which a multitude of patient communication behavioral patterns are modeled together to improve the accuracy of the classification from modeling each of them alone. Our dataset contains patient markers associated with communication patterns. The change of markers over 6 and 12 months are coded as features to be incorporated into modeling. The classification of each communication pattern using all patient markers and marker changes is thus considered as a learning task.

The objective of the multi-task learning framework is thus to learn the shared structure among the multiple learning tasks while minimizing the classification errors of each learning task. The formulation in Equation (1) combines both the objective value of empirical risk $\ell(\mathrm{W})$ and $\Omega(\mathrm{W})$ from a convex form of k-means clustering, which places penalty to enforce a clustering of the weight vectors w_i's towards the mean of the cluster.

$$min_{\mathrm{W}\in\mathrm{R}^{\mathrm{d}\times\mathrm{m}}}\ \ell(\mathrm{W}) + \lambda\Omega(\mathrm{W}) \qquad (1)$$

This formulation enables us to balance the need for finding the shared structures among the multiple learning tasks and for identifying the regression models that fit to the data empirically. The set of m learning tasks learn linear regression models over $\mathrm{X} = \mathbb{R}^d$ from pairs of input features (i.e., patient makers) and each output variable (i.e., continuous response indicating the occurrences of communication pattern), $(x_i, y_i), \mathrm{i} = 1, \ldots, \mathrm{n}$, where $x_i \in \mathrm{X}$ and $y_i \in \mathrm{Y}$. X and Y are the sets of input features and continuous response output variables respectively, W is the set of weight vectors, and m is the number of tasks.

We then experiment with how modeling multiple communication patterns together could improve prediction accuracy. The models learned this way can be further evaluated

with the error measures, e.g., root mean squared error (RMSE), mean average percentage error (MAPE). We also qualitatively assess the weights over the multiple learning tasks to better understand the reasonableness, the simplicity, and the usefulness of the model.

Results

Cohort

The cohort involved in this study are patients between 19 and 65 years of age (mean = 49.1, SD = 10.6) and with diagnosed obesity, hypertension, or high cholesterol. The cohort includes 421 (62.1%) females and 257 (37.9%) males. The diagnoses are reflected in the ICD 10 codes available in the EHR, E66* (including .01, .09, .3, .8, .9), E78* (including .00, .01, .1, .2, .3, .5, .6, .9), R03, I10, I11.9, I12.9, I15.8, I15.9, I16.0. According to those criteria, 678 patients are included in this study.

Modeling

After the first round of cluster analysis with the PAM method, variables that produce the same medoids between groups are deleted. This process points to 63 (out of 131) variables for further analysis. Interestingly, the reasons for communication (e.g., follow-up visits), properties of treatments (e.g., the form of the medication), demographics (e.g., age, sex), and access to technologies (e.g., email, phone) are not among the variables that differentiate the groups. However, almost all variables that describe patient-provider communication patterns and patients' health status are preserved due to their ability to differentiate the groups.

We then performed cluster analysis on the remaining variables and two distinct clusters emerged, describing two groups of patients with vastly different communication behavior patterns. The first group relies heavily on mediated communication (i.e., the mediated group), such as secure messaging, video chats, and phone calls, and the second group tends to visit the clinic for face-to-face interactions more often (i.e., the direct group). Figure 1 shows a 2D visualization of the two groups. Multi-task learning models further identify factors associated with the two different behavior patterns and enable the development of patient personas. However, the multi-task learning models fitted for the data in this study have a high error, as indicated by the root mean squared error (RMSE = 0.5977) and mean absolute percentage error (MAPE = 1.8148), considering the standardized data set used for analysis has a standard deviation of 2. The rest of the results section describes results from the two types of models.

Patient-Provider Communication Behavior Patterns

Overall, patients in the mediated group made fewer appointments. When considering the possibility of recent enrollments, those patients also have fewer average appointments since their first visit to the clinic, whereas patients in the direct group make more appointments and have more average appointments per year.

Patients in the mediated group tend to receive more messages from the clinic compared to patients in the direct group and tend to send more messages than receiving them. When examining distinct conversations that are comprised of multiple messages, we found that patients in the mediated group tend to be involved in more conversations as well. The two groups do not differ in terms of the average number of messages in each conversation. Interestingly, the distribution of the messages, but not the conversations, differs between the two groups. Patients in the mediated group have a consistent number of messages in each conversation, marked by their low IQR and MAD values, while patients in the direct group tend to exhibit a larger variance in terms of the number of messages in each conversation.

When patients in the mediated group communicate with their providers, either in person or through mediated channels, those communication behaviors tend to occur after 9:00 am and their direct group counterparts tend to do so before 9:00 am, indicating a high likelihood of late night and early morning

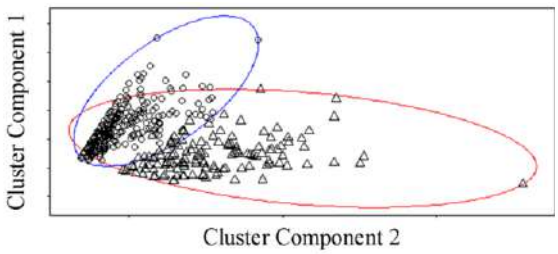

Figure 1 – A 2D visualization of 2 patient groups defined by multi-dimensional communication behavior patterns. The 2 components explain 70.28%[1] of the variation between the 2 groups.

emergencies. In addition, patients in the mediated group tend to be transferred to other clinicians in the clinic's network more often and those in the direct group tend to be referred out. The latter is common when the patients' health condition requires specialists, and they tend to stay with the DPC clinic for ongoing care.

Predictive Features of Communication Behavior Patterns

The multi-task learning framework (more specifically, MTR-CMTL) revealed that patients' health status and its change are the best at predicting patients' communication behavior patterns. Table 1 shows the top 7 features that contributed the most to each of the seven learning tasks of communication behavioral pattern classification.

Overall, patients whose home address is closer to the clinic tend to communicate with the clinic more often across all modalities. Patients with more lab test records, medication dose changes and refills tend to visit the clinic more frequently and communicate with their health care team more frequently through emails and phone calls, but less often through secure messaging.

However, this observation seems to be in contrast with those from the change in patient vitals. For example, patients whose weight, BMI, and body temperature increased over the last 6 months and 12 months tend to be in contact with the clinic less often, either in person or through mediated communication channels. This observation may be a result of noises added from combining the two patient groups. Considering this possibility, we segmented the data from the two groups and performed multi-task regression on each group separately. The distinctive predictors now clearly have different effects on the two groups.

Predictive Features of the Two Emerging Personas

In the rest of this section, we report the results from the cluster analysis, enhanced by the two sets of multi-task regression. Table 2 shows the summary statistics and top predictive features of the two groups (i.e., the mediated and the direct group).

According to the vitals taken at patients' latest visit to the clinic, patients in the mediated group tend to have lower average body

Table 1 – Top 7 features contributing the most to the 7 MTR-CMTL learning tasks, color-coded by the size and direction of coefficients. All the features are reported as after standardization. Med_dose_change: medication dosage change; n_tests: number of lab tests; med_refill: the count of the person having had medication refills done as shown in EHR; 6month_temp_change and 12month_temp_change: body temperature change in 6 months and in 12 months; home_clinic_dist: distance between the home zip code and the clinic; 12moth_hr_change: heart rate change in 12 months.

weight and higher blood oxygen percentage. However, a higher weight is associated with more direct and mediated communication. Patients in the mediated group are more likely to have reported an allergic reaction at least once and experienced more types of allergies compared to the direct group. Having reported an allergy at least once is associated with the increase in all communication behavioral patterns in the mediated group. Meanwhile, patients who have reported more different types of allergic conditions are more likely to use mediated communication channels less often. For the direct group, patients who have more allergic reaction reports are more likely to be associated with higher usage of all communication channels.

Compared to the latest vitals and reports of allergies, features that have better predictive powers for communication behavior patterns are health status 12 months before patients' latest clinical visit and their health status change over 12 months and 6 months. Patients in the mediated group tend to have lower body weight as well as higher diastolic and lower systolic blood pressure 6 and 12 months prior. Also, patients in the mediated group tend to experience decreased systolic and diastolic blood pressure and decreased heart rate over 6 and 12 months, while they are more likely to experience a slight elevation in body temperature during the same period.

The direct group, in comparison, tend to experience increased blood pressure, weight and BMI over 6 and 12 months. For the mediated group, the decreases in blood pressure, weight, and BMI over 6 months and 12 months respectively are associated with a higher number of clinical visits. While the improvement in health status over 6 months for patients in the mediated group is associated with lower usage of mediated communication channels, the improvement over 12 months is associated with higher usage of mediated communication channels. For the direct group, increased body weight and body temperature are associated with decreased in-person clinical visits.

Patients in the mediated group tend to change their medication less frequently but have more instances of refills, which can be achieved through mediated channels. Those in the direct group, on the other hand, tend to have more lab tests that have to be performed in person. Surprisingly, patients in the mediated group with home addresses further away from the clinic tend to contact the clinic less often both in-person and through mediated modalities. This observation is the same as the direct group.

Those observations seem to suggest that patients in the mediated group tend to have better general health status compared to those in the direct group, as suggested by the proxy outcome measures relevant to their health condition.

Discussion

Cluster analysis and multi-task regression revealed two distinct patient personas with nuances in terms of factors that predict communication modality usage. Figure 2 illustrates the two personas, highlighting their major behavioral differences and the variables that predict the major differences. The personas offer guidance on the modalities care teams may prioritize to reach out to patients with different characteristics in the DPC setting.

The results suggest that patients who frequently and more steadily use mediated communication modalities tend to be in better health and have improved health over time, *vice versa* for patients who more frequently visit the clinic in person. Due to the retrospective nature of the analysis, it is unclear whether more frequent mediated communication improved health or patients with better health have fewer needs for in-person clinical visits. Analysis over longer periods of time comparing patients' health upon transferal to 6 months and 12 months after

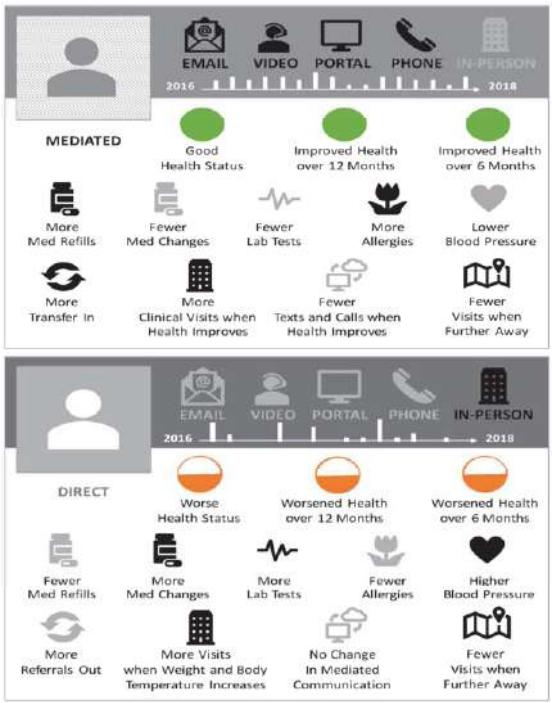

Figure 2 – Two personas for the mediated group and the direct group highlighting the differences in their choice of communication modalities and factors associated with those choices. (left) Mediated group; (right) Direct group.

transferal may produce a clearer picture with causal implications.

Mediated communication modalities are widely used among R-Health patients and have provided viable and valued alternatives to in-person visits, especially for patients who live further away from the clinic and need short and prompt consultations for emergencies and quick questions outside of normal business hours. This unfettered access to physicians tends to create a larger workload for the health care team in a traditional care delivery model [3], but in the flat-fee DPC care model physicians are incentivized to use whichever modality their patients prefer to assure frictionless interactions wherever and whenever necessary to deliver appropriate and effective primary care.

The freedom of choice between multiple communication modalities also enhances patient engagement and satisfaction. This is supported by the patient satisfaction survey at R-Health in August 2018, where many patients expressed their appreciation of multi-modality communication with their health care team in the form of free text comments: "I love the personal care and attention. I get texts etc. from dr. I love it.", "… the service is very convenient. I'm able to set appointments, see my test results, and consult with my doctor on my terms.", "Can consult with doctor over phone and over portal.". The personas, therefore, are a depiction of patients' free choices of communication modality as suited to their preferences and situations.

The personas emerged from the data used in this study do not completely agree with the literature. For example, prior studies found that diabetes patients who use mediated communication channels have worse health [9]. Another study on patients at a facility of Department of Veterans Affairs argued there is no significant association between health status and patient portal usage [14]. Our findings suggest that patients who prefer mediated communication tend to be in better health status. Also, we found that health status and health status change, more than the other factors examined in this study (e.g., demographics, reasons for visits), seem to have stronger associations with communication modality choice. These findings also add to the debate on other issues, such as whether demographics are associated with patients' choices of communication modality ([9] suggests a connection, [14] and our analysis did not identify such connection).

The results of this paper should be interpreted in the context of the reliability of the models we built. While the clustering model performs well at distinguishing between the two groups (i.e., explaining 70.28% of the variation of the data points in the two groups), the regression models are affected by high noise (i.e., RMSE = 0.5977). As a result, although the analysis points to two distinct groups of patients with different choices of communication modalities, confidence in the predictive features are low. Nevertheless, the results reported in this paper is one of the first on patient-provider communication modality choices and predictive features in the DPC setting to the best of the authors' knowledge. The research team is compiling a new and larger data set with more variables and cases in order to build more robust models and reduce noise ratio. More recent results based on the new data set will be presented at MEDINFO 2019.

Conclusions

Patients who are members at R-Health Clinic use multiple communication modalities to connect with their health care providers in the DPC model. Our analysis suggests that there are two distinct groups in modality choices, including a direct group and a mediated group. Multi-modality communication seems to thrive in the DPC model, and mediated communication is highly utilized by both patients and their health care team. The unfettered access to care is expected to foster better patient-provider relationship. The increased level of patient understanding would further lend support to many downstream applications such as designing targeted care management and communication strategies and personalized care plans, as suggested by the U.S. National Academy of Medicine report [7]. More research is needed to explore the characteristics of patients who prefer different modalities and use this knowledge to better engage patients in primary care settings.

SIGICAM: A New Software to Improve the Patient Care Supported by a Constraint-Based Model

Carla Taramasco[a], Rodrigo Olivares[a]

[a] *Universidad de Valparaíso, Valparaíso, Chile*

Abstract

Health facilities are care centers that receive patients with different requirements. The management of patients falls to the clinical staff trained for this activity. However, given the demands of the population, the task of managing beds is sometimes too complicated when carried out manually. In this work, we propose the design and implementation of a technological platform that provides an improved optimization approach. It manages the patient-bed allocation efficiently, by considering hospital resources given the number of units and patient diagnosis. This tool was deployed in hospitals of the Atacama regional health service in Chile, boosting the work of the clinical staff of the health facility.

Keywords:
Beds, Health Facilities, Health Resources

Introduction

Recently, health facilities are approaching digitalization as a process of improvement to boost their services. They highlight this approach as a critical factor for the management of health resources and an increase in the efficiency of the clinical services. Informatics services such as Electronic Medical Record [1], traceability in clinical documents [2], medical examinations [3], among others, have taken health to the next level in order to enhance the quality of patient care.

When we focus our efforts on improving patient care, we inevitably entrust ourselves with the task of offering the best available resource [4]. Here, we must define what tasks should performed by the clinical staff and also, we allocate resources to the patient. This decision is not trivial. For instance, what is the ideal bed for a patient? When answering this question, it is necessary to know patient requirements and both features and characteristics of available beds. For instance, patients may need complex clinical tests, specialized care, mandatory isolation, and more. Also, it is essential to be able to classify beds by aspects like age, gender, critical levels, and others.

In the current literature, the patient bed assignment problem has been studied as a particular case of the scheduling problem [5,6]. It corresponds to a typical and recurrent task in hospitals or medical centers. It consists of finding an assignment of available beds for patients with critical medical assistance [7]. Studies have resolved this problem by using a structured mathematical model [8, 9]. Other works have used an efficient approximate algorithm to solve a linear programming model that uses soft and hard constraints but does not include critical medical information [10].

In this work, we propose software supported by a new mathematical approach that improves the patient care process just in time when a bed is required. Our software works from emergency control to the hospitalization of the patient. In this process, the mathematical model uses features of patients for finding the best available beds. It generates a list of potenial beds, and the user decides which bed will be best for the patient.

The software has been deployed in the health services of the Atacama, a region of Chile. During its use, we have detected that the patient care process has improved due to users (nurses) having total visibility of available beds and the assignment process is more efficient.

The remainder of this paper is organized as follows, first we detail the problem statement. Second, we present the proposed software. Finally, the conclusions of this work are detailed.

Problem statement

People demand more and better services, this is a fact. In many situations, these demands trigger a collapse in public health services, especially in hospitals and medical centers [11]. People arrive at hospitals, those who require admission need to be assigned a bed, and at this moment, they become in patients of the health service. According to their needs, each patient presents variables such as age, risk, gender, if they require isolation (or not), among others [12]. Furthermore, beds are a scarce resource that should be optimized, but this is not always the case. In Chile, this process is directed by a national policy. Therefore, we must respect it. Ministry of Health defines the protocol for receiving patient requirements for bed availability. The detail of this protocol is shown in Figure 1.

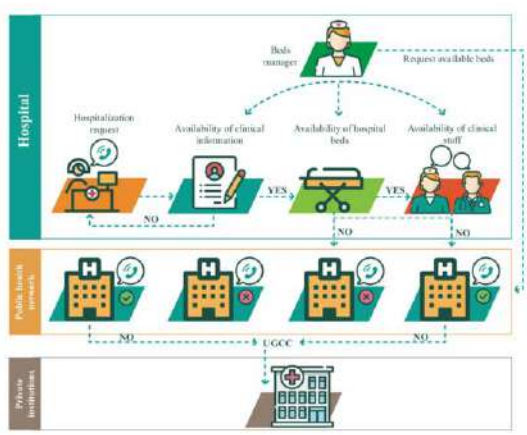

Figure 1– Request protocol for bed availability.

There beds are not always available, and those that are vacated must be treated correctly to satisfy the needs of patients. In

order to accomplish that, it is necessary to know the properties of each bed to ensure efficient assignment. The properties of beds are the type (basic, critical), classification (neonatal, pediatrics, adult, older people, etc.), gender, type of insulation, among others. All these properties must be considered when assigning a patient to the best available bed. However, what would happen if the only available bed is an adult type and a teen needs it? Current optimization models and mixed linear methods determine that it is not possible to assign it [13].

To address this problem, we developed new software, boosted by a new binary model bed assignment problem, that minimizes the inter-movement of patients, and also considers constraints. There is exsisting work that takes a similar approach [14].

Search process

When we designed the software, we defines a search process based on two-stages, as shown in Figure 2, and Figure 3.

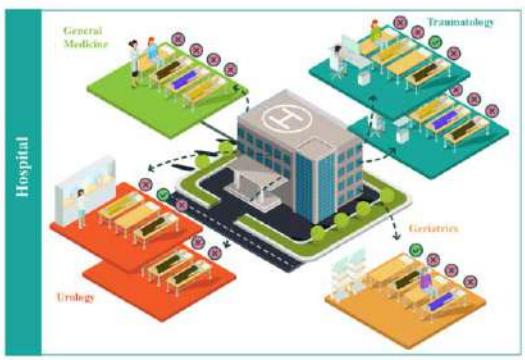

Figure 2– Internal Search Process (hospital).

Figure 3– External Search Process (public health network).

The first stage allows us to find the best bed into the hospital that belongs to the regional health service. If it is not possible to find this match, the next stage begins. We take the best available beds and we perform the assignment patient-bed searching in all public assistance network. We designed this process in order to initially reduce the search space, and to use potential solutions that exhibit good performance from the beginning.

For the software to work correctly, we need to control the following aspects:

- The configuration of hospitals and units (set of rooms) is known and this set does not change during the decision period.
- Needs of patients will not change during the decision period. For example, if a patient needs isolation, their critical level is maintained during the phase of bed search.
- Beds remain unavailable while in use by patients, until discharge.

Decision variables

To initiate the model, we describe the binary decision variables: bed (b). This variable is used to determinate if a bed is available or it is assigned to a patient: 1 if the bed b of a specific type and it belongs to a particular room is assigned to a patient, 0 otherwise. In our case, all beds belong to a specified room, and they are defined by a type.

Regional health service have several hospitals, and each hospital is characterized according to its complexity. If a hospital has intensive care units (ICU) or it has critical patient units (CPU), we can say that this hospital is defined as complex. Not every hospital is designated as complex because of limited resources/equipment. Complex hospitals and normal hospitals, both have basic beds available to assign. However, only complex hospitals have *critical* beds.

Additionally, we use $f_r = 1$ and $m_r = 1$ if at least one woman and one man, respectively, is in room r, 0 otherwise. This value is computed after to search for an availability bed. Finally, we define $y_{pl} = 1$ if patient p is consistent with age policy l, 0 otherwise.

Constraints

Next, we present the following constraints that we should cover but could be violated. It is important to mention that hospitals, units, and rooms, have non-variable capacity during the resolution process.

- c_1: **Assignment**. Each patient is assigned to only one bed, and only one bed is assigned to a patient.
- c_2: **Risk and dependence**. It indicates the severity of the patient and it is classified into 3 categories:
  - *Maximum risk* is assumed for the patient. A critical bed must be assigned to the patient. In case that there is not one available critical bed, a normal bed will be equipped as a critical bed.
  - *Medium risk* is assumed for the patient. A critical bed will be found but if there is not, a normal bed will be assigned.
  - *Minimum risk* is assumed for the patient. A normal bed will be assigned to the patient.

  This constraint is extremely relevant, however, due to the shortage of critical beds, there is a high possibility that even being a critical patient the assigned bed will not be the critical type. Therefore, this constraint can be violated. Complexity hospitals can transform a normal bed into a critical bed.
- c_3: **Isolation**. In the health systems, contagious diseases develop that in some cases can be more serious than the disease originated abroad. This constraint may not be satisfied because hospitals follow internal protocols to modify a room using

special equipment. This process allows the patient to be "isolated" in a room with other persons.

- c_4: **Unit policies**. Each hospital offers a set of units that it groups a set of rooms. A patient-derived to a unit should be assigned to one bed of a room of this unit. However, if it is not possible finding one bed in a specified room, by default, he/she will be assigned to one bed into a general room.
- c_5: **Gender policies**. If a patient declares belonging to the male gender or the female gender, the assigned bed must belong to a room with this characteristic. This constraint may not be satisfied because it is possible to modify a room as in the isolation restriction.
- c_6: **Age polities**. This constraint considers the choice of the hospitalization area. Since the beds are heterogeneous according to the age range, it is possible to determine 4 types: neonatology, pediatrics, adult, elderly. If there is no available beds with the desired age feature, an adult bed will be assigned to the patient. A preliminary study conducted to there are more adult beds than any other type. Therefore, we can conclude that this constraint may not be covered.
- c_7: **Distance**. If a patient requires one bed and no beds are available at the current hosptial, it is necessary to transfer the patient to the nearest hospital. Nevertheless, the nearest hospital may not be the best alternative according to patient requirements. In this case, it is necessary for finding the best bed in another hospital that may not be the closest. This case can be violated.

Resolution

To give an efficient response to the model, we perform this model by using an approximate algorithm. This technique is known as bat algorithm.

Bat algorithm was proposed Xin-She Xang [15, 16] and it is inspired by eco-localization behavior (biosonar) that belong microbats. Rules that led this algorithm are:

1. All bats use echolocation to perceive the distance they have to objects or obstacles. They can differentiate between food, prey, or obstacles in their way.
2. Bats randomly fly, with velocity v_i position x_i. When they are looking for a prey they adjust their frequency f_i by changing their wavelength and volume A_o. Bats can adjust their frequency and adjust the pulse emission radius$r \in [0,1]$.
3. The volume varies from a positive value A_0 to a minimum value A_{min}.

The bat algorithm proposes the change of position using three equations:

1. Calculate the frequency of the bat.

$$f_i = f_{min} + (f_{max} - f_{min})\beta \quad (1)$$

2. Calculate the speed of the bat considering the frequency as input data.

$$v_i^d(t+1) = v_i^d(t) + (x_i^d(t) - \hat{x}^d)f_i \quad (2)$$

3. Calculate the new position of the bat.

$$x_i^d(t+1) = x_i^d(t) + v_i^d(t+1) \quad (3)$$

Updating position can alter the binary domain of the problem. However, the algorithm proposes an adaptation to the domain by using the sigmoid function and a probabilistic selection. Algorithm 1 describes the procedure to find a solution.

Algorithm 1: Bat algorithm

Input: Parameters of the problem
Output: List of available bed.

for all bat x_i, $(\forall_i = \{1, \dots, n\})$ **do**
  for all dimension d, $(\forall_d = \{1, \dots, m\})$ **do**
    $x_i^d \leftarrow Random\{0,1\}$
  end for
  $A_i \leftarrow Random[0,1]$
  $r_i \leftarrow Random[0,1]$
  $fit_i \leftarrow cost\_function(x_i)$
end
$globalfit \leftarrow +\infty$
while $t < T$ **hacer**
  for all bat b_i, $(\forall_i = \{1, \dots, n\})$ **do**
    $rand \leftarrow Random[0,1]$
    if $rand < A_i$ **the**
      $A_i \leftarrow \alpha A_i$
      $r_i \leftarrow r_i^{t=0}(1 - e^{-\gamma t})$
    end
  end
  $\{minfit, minindex\} \leftarrow min(fit)$
  if $minfit < globalfit$ **then**
    $globalfit \leftarrow minfit$
    $\hat{x}^d \leftarrow x^d_{minindex}$
  end
  for all bat b_i, $(\forall_i = \{1, \dots, n\})$ **do**
    $\beta \leftarrow Random[0,1]$
    $rand \leftarrow Random[0,1]$
    if $rand < r_i$ **then**
      For all dimension d, $(\forall_d = \{1, \dots, m\})$ **do**
        $x_i^d \leftarrow \varepsilon \bar{A}$
        $rand \leftarrow Random[0,1]$
        if $rand < \frac{1}{1+e^{-x}}$ **then**
          $x_i^d \leftarrow 1$
        else
          $x_i^d \leftarrow 0$
        end
      end
    fin si
    $rand \leftarrow Random[0,1]$
    if $rand < A_i$ **y si** $fit_i < globfit$ **then**
      $f_i \leftarrow f_{min} + (f_{max} - f_{min})\,\beta$
      for all dimension d, $(\forall_d = \{1, \dots, m\})$ **do**
        $v_i^d \leftarrow v_i^d + (x_i^d - \hat{x}^d)f_i$
        $x_i^d \leftarrow x_i^d + v_i^d$
        $rand \leftarrow Random[0,1]$
        if $rand < \frac{1}{1+e^{-x}}$ **then**
          $x_i^d \leftarrow 1$
        else
          $x_i^d \leftarrow 0$
        end
      end
    end
  end
  $t \leftarrow t + 1$
end
retornar $\hat{x}$

To find an optimal solution, it is usually necessary to combine the exploitation and exploration processes. In this context, the

variability of the solutions is given by the adjustment of the volume A and the radius r, as shown in equations (4) and (5).

$$A_i\,(t+1) = \alpha A_i\,(t) \quad (4)$$

$$r_i\,(t+1) = r_i(t=0)[1-e^{-\gamma t}] \quad (5)$$

Software

Finally, the implemented software has successfully been deployed in Government Regional Health Services. The user can access in http://www.sigicam.cl. Primary functions are described as follows:

- Each user logins to the application by using a specific account. After login, the software alerts the user if patients have been waiting more 12 hours for an available bed. At this moment, the users can see a "waiting list" (highlighted in red).

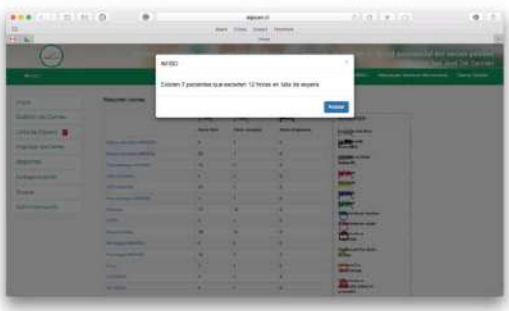

Figure 4– After login.

- From the "waiting list", the user can assign a specific bed using a list of beds deployed in the "floor map".

Figure 5– Assign manually a bed.

- When a patient is registered in the platform, the users can decide if it is the application itself who assign the best available bed or not. The system shows a list of best beds according to features or conditions of the patient. Here, the optimization model works to help users quickly find a bed. This list is rated.

The software provides additional functions, such as internal movements, external movements (government hospitals or private health facilities), daily monitoring and update of risk-dependence, statistical information, reports, among others.

Finally. we can say that our software supports the nurse's work, which in turn directly impacts the quality of patient care. Furthermore, the platform highlights bed occupation rates by the hospitals and shows how efficiently the beds are being used. This information includes the stay times of each patient and, above all, the waiting times that each patient suffers when there are no available beds.

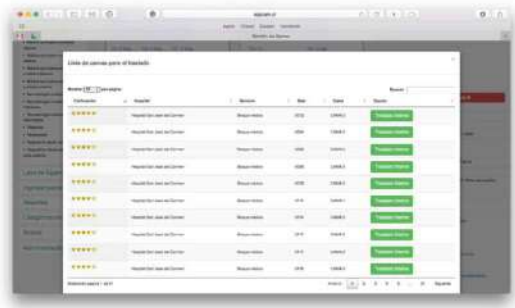

Figure 6–Semi-automatic assignment of beds.

Conclusion

In this work, we present new software to improve the patient care supported by a constraint-based model. The software can find the best available bed for patients and it alerts when one of them waits for more than 12 hours. For that, we design a constraint-based model using hard and soft constraints according to the needs of patients. Using those constraints, we implement the bat algorithm to optimize bed selection.

SIGICAM is a web-based implementation that coverages the resolution of the model on-demand for expert users. This software includes the comunication between the optimization approach and the functional features of the software.

As future work, we plan to develop a self-adaptive approach to the bat algorithm in order to improve the quality of the reached solutions. This self-adaptive approach will be based on the principle of the autonomous search, following the work conducted by Soto et. al. [17].

Abstract

This document describes the development of a Business Intelligence (BI) dashboard for tracking the drug-drug interaction (DDI) alerts implemented as Clinical Decision Support Systems (CDSS) in Electronic Health Records (EHR). CDSS are known for their potential to reduce medical error. The use of requirements in the development of BI dashboards is crucial to obtain successful software. In this work, the requirements were analysed using a score methodology, considering the relevance of the indicators and visualization methods. CDSS effectiveness and acceptance have been questioned, so it is fundamental to monitor their behaviour and performance. The dashboard was designed in order to satisfy the needed indicators. Using BI as a tool for monitoring the CDSS performance made it possible to operationalize the EHR content repository, maximizing the understanding in relation to the override and, by inference, to optimize the CDSS system by opening new lines of work.

Keywords:

Decision Support Systems, Clinical; Drug Interactions, Software

Introduction

Medical errors are a serious problem for the health system. The stages defined in the medication cycle are prescription, transcription, dispensation, administration, and monitoring. It is known that at least 50% of errors are generated during prescription. This can be due to lack of information about the medication used or the patient's background [1,2].

Clinical Decision Support Systems (CDSS) are recognized as a significant contribution to structured electronic prescription. They provide information about a specific need and responses that are similar to human reasoning. While there are no clear short-term benefits, previous work has shown that warning systems could reduce medical errors by 81% [3]. CDSS are able to identify up to 89% of medication-related errors and prevent 23% of them [4].

Despite providing warnings about potential harm and the initial promising outcomes, users often do not adhere to CDSS messages, overriding 49% to 96% of the time [5–7]. Reasons for nonaderance are diverse and reflect the complexities of clinical practice, where usually there is more than one correct decision when managing a specific case. Moreover, design and implementation could lead to ineffective alerts. Redundant alerts and those with lack of scientific evidence or usability are usually overridden and cause alert fatigue [8].

It is widely recognized that CDSS are based on rigorous scientific evidence, so that the advice they provide is equal or superior to the average in a health care system. However, contrary to other analytic decision software that is part of a medical device (for example, automatic infusion pumps), CDSS have no regulatory standards, and like any other software, they have flaws [9].

In this context, it is necessary to deploy a monitoring system during the implementation and ongoing use of CDSS. Not only would such monitoring allow design validation, detection usability problems, and inconsistencies in the knowledge base and rules, but it also grants a cycle of continuous improvement in order to optimize the tool.

In the last decade, there has been significant growth in the literature on the use of Business intelligence (BI) in the healthcare field. Electronic Health Records (EHR) contain massive clinical datasets. BI emerged as a technological tool with the potential to collect, manipulate, and analyse the dataset in the EHR repository in order to improve the evidence-based decisions and quality practices [10–12].

As was explained in our previously published report, CDSS of drug-drug interaction (DDI) alerts have been implemented in a Uruguayan healthcare network [13].

The purpose of this paper is to describe the development of a CDSS-DDI dashboard for a federated Health Information System (HIS) in Uruguay using Business Intelligence (BI) tools.

Methods

Definition of Key Progress Indicators

Previous to the availability of BI tools, CDSS alerts were manually monitored by the medical informatics staff. Manual monitoring was based on the team objectives, the literature and their knowledge of CDSS use. Different Key Progress Indicators (KPI) of that manual monitoring using Microsoft Excel where then the basis for the initial BI dashboard.

The objective of the KPI is to monitor the user's alert fatigue and alert adequacy, as well as design and usability aspects.

DDI alerts provided by the Buenos Aires Italian Hospital (HIBA) web service have been used in our system for more than two years and have allowed us to successfully collect valuable data. However, due to the amount of information generated, conventional tools are inefficient for data analysis and reporting.

In 2018 with already defined indicators, we incorporated a BI tool, Tableau, for the CDSS dashboard construction.

CDSS Dashboard Requirements

The CDSS dashboard requirements were established in agreement with the BI developer. The requirements were designed regarding priority levels from 0 (not a priority) to 5 (very high priority).

System Architecture

Our Healthcare Data Warehouse (DW) was built using Pentaho Data Integration (PDI) to extract the relevant data from the EHR and Enterprise Resource Planning (ERP). Both use DB2 as a transactional database. For the DW a combination of Postgres and MySQL was used.

The DataMart for CDSS alerts is a subset of this Data Warehouse. Each service, databases or Extract-Transform-Load (ETL) tools, runs as a Docker Container in a cluster. This allows optimizing resource allocation during the ETL process. For the consumption of this DataMart, Tableau was chosen, which is based on VizSQL, a proprietary language that integrates SQL data consumption with graphical visualization grammar. This allows postponing the actual specification of the final use of a specific element. The advantages of Tableau Hyper were used in the memory data engine to speed up analytical query processing. A Drug ID could be used as a dimension or measure filter (distinct count) by the end user in a very intuitive way. No SQL, no MDX, no extra burden and no need to wait for a new logical cube modification.

The validation of the cube and its data were carried out in iterative cycles with the medical informatics team and the BI developer, based on the comparison of previous results with some of the basic KPI obtained by queries and processed in Microsoft Excel.

As an initial stage, it was defined that the dashboard should not be integrated with the Electronic Medical Record (EMR) application or in other medical management tools but that it would be accessed from Tableau by the medical informatics team.

Results

Definition of Indicators

Some Key Progress Indicators (KPI) were previously defined and manually measured twice a year to monitor the clinician's behaviour and CDSS performance. The established KPI were:

- Number of CDSS-DDI alerts per 1000 prescriptions
- Number of CDSS-DDI per 1000 patients
- Number of CDSS-DDI per 1000 medical consults
- % of overridden CDSS-DDI alerts

Definition of Requirements

Considering the KPI and other possible data to be retrieved such as medical specialities, alert incidence per DDI pair and override justifications, a list of requirements for the BI dashboard was developed. The requirements with priority level over 3 where covered in the dashboard. Table 1 shows a description of the requirements with their priority assessment.

Table 1– BI dashboard requirements

Priority (0 – 5)	Requirement	Description
5	EHR as a source of information	Exporting data from EHR of three healthcare centres in Uruguay.
4	Automatic update	Real-time update.
5	Remote access	Provide access to specified dashboards.
4	Ad-Hoc Calculations	Related to the predefined indicators and metric.
5	Information retrieval	Data reporting based on dates.
4	KPI visualization	Real-time display of KPI evolution.
4	Advanced Chart Types	Ad-Hoc report with the selection of multiple dimensions and metrics: number of alerts, override justifications, DDI pairs, override, medical specialities.
5	Dataset exploration	Explore one CDSS case to audit the EMR.
5	Data security	Sensitive patient data should remain confidential.

Data Validation

Data architecture issues such as semantics, integrity, and security were analysed. A semantic standard was established to define, for example, what was understood by "Consult," what type of health professionals could be responsible for the consult, if it included a prescription or not, and if there was an alert or not. Regarding data integrity, all the components were evaluated, leading to the detection of some initially incomplete logs. For example, when the clinician decided to override the alert, the active drug information was not recorded in the data warehouse. For data security, data items that should be visible or editable according to the user´s profile and license duration were assessed.

Design and Development of the Dashboard

The requirements were embedded in the software as three modules:

1. KPI
2. Overall CDSS performance
3. Detailed CDSS performance

Module 1 was deployed as line charts. Module 2 (Figure 1) was developed in order to monitor the rate of prescriptions with DDI alerts, the rate of overridden or accepted alerts and the quantity and type of justifications for the override. Module 3 (Figure 2) was designed as an advanced chart to combine and visualize multiple dimensions and their relation (quantity of alerts, override percentage, medical specialities and DDI pairs involved).

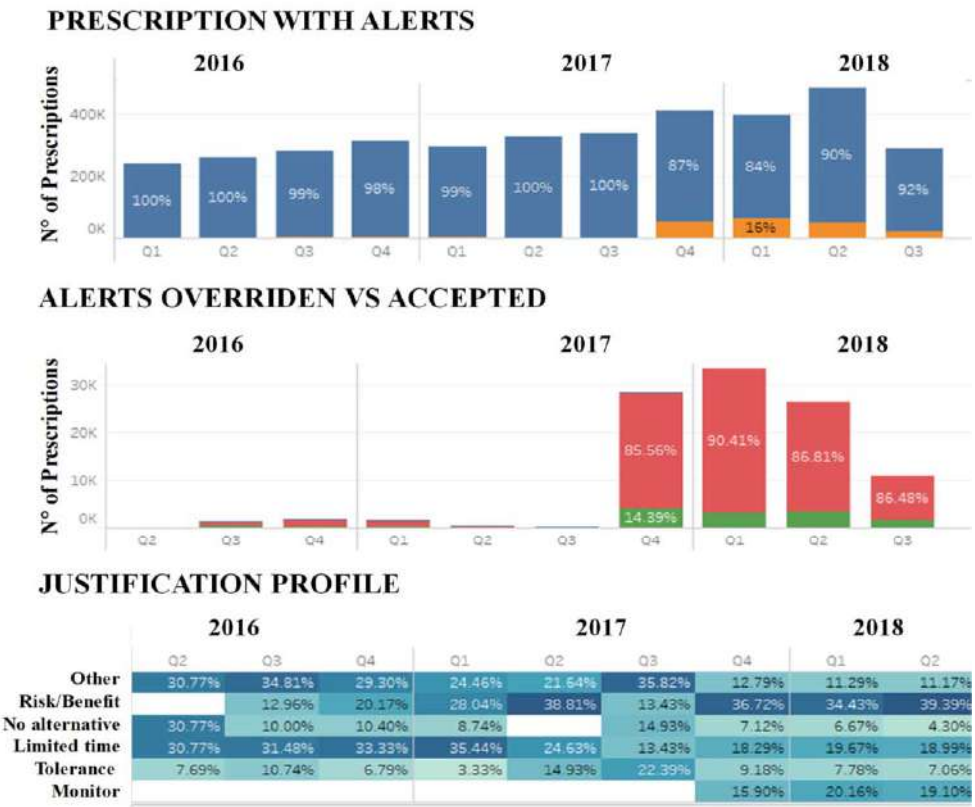

Figure 1- Module 2: The figure shows prescriptions with (orange) and without (blue) CDSS alerts, overridden (in red) vs accepted (in green) alerts and the justification profile for clinician alert override (higher percentages in darker tones).

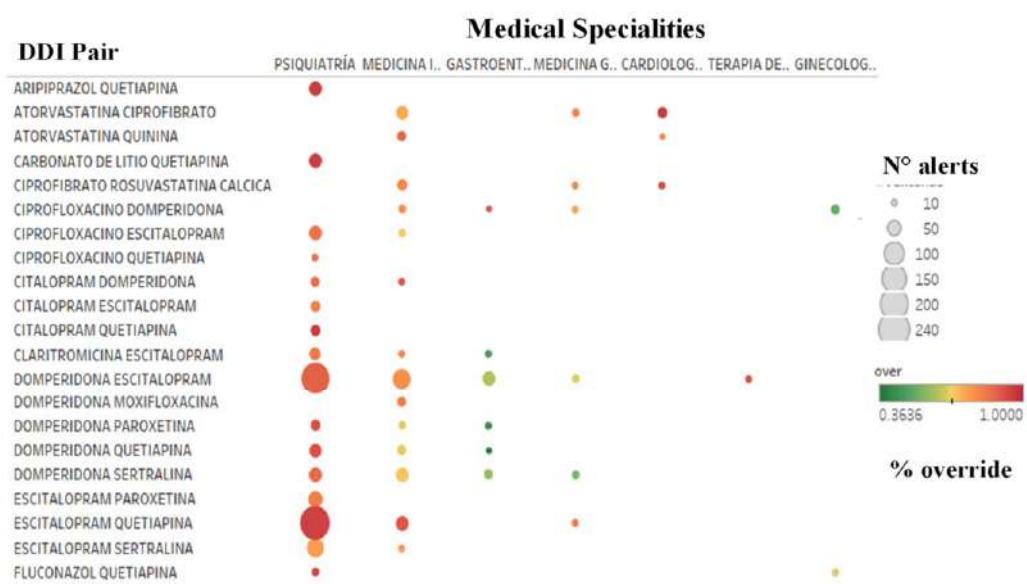

Figure 2- Module 3: medical specialities are in the x-axis and DDI pairs in the y-axis.The quantity of alerts is represented in the size of the spheres. The override percentage is represented in a colour range from green (lower override %) to red (higher override %

Discussion

CDSS can reduce errors and prevent the harm caused by them by alerting the clinicians. However, their effectiveness and acceptance have been questioned. The recommendation to improve these issues respecting the five rights is: "CDSS should be designed to provide the right information to the right person in the right format through the right channel at the right time" [14,15]. In order to achieve the five rights, it is fundamental to monitor CDSS behaviour and performance.

The EHR is a repository where the clinical data is stored, some structured and others unstructured. Data mining technologies are necessary to extract quality data and inference rules from the information stored in order to provide CDSS real-time monitoring. The benefit in employing BI is that it works with unstructured data while other tool doe not [16].

According to the literature, the use of BI technology with EHR allowed operationalizing the data warehouse of the EHR to improve the quality and safety delivered by the healthcare system [11,12,17,18]. This improvement is due to the potential of BI to support evidence-based practice and decision-making process [12].

To the best of our knowledge, there is no study regarding the use of BI for tracking CDSS. However, BI seems like a valid alternative to efficiently and effectively monitor CDSS. To test the integration of these technologies on a first pilot scale, a BI dashboard was developed for the previously implemented DDI alert system [13].

The BI dashboard for CDSS-assisted DDI alerts was developed as customized software. It was designed in order to satisfy the needed KPI. Before the dashboard, KPI were measured once or twice a month through a manual process that included Microsoft Excel spreadsheet calculations dependent on data requests to the engineer. The KPI were defined to track the prevalence of CDSS alerts and overrides. In order to have the number of alerts independent of the number of prescriptions, persons, and consults, CDSS prevalence was settled in relation to these attributes. The acceptance of the CDSS alerts was determined by the override percentage.

The use of requirements in the developing of BI dashboards has been reported as a crucial issue to obtain successful software [19,20]. In this work, requirements were analysed using a score methodology [20], considering the relevance of the indicators and visualization methods. The requirement analysis was outlined with a mixed approach that considered the goal of the tool, the characteristics of the user, and the nature of the information. The chart types were selected to visualize several variables in the same chart in order to obtain a process behaviour overview. At the same time, it enables the evaluation of data below or above the specified threshold.

BI is only useful if the information provided is built on quality-assured data. Otherwise, logic and inference rules can be flawed [12,21]. Hence, data validation is a critical issue even though it is not always considered by software developers. During data validation for this project, incomplete logs in the data warehouse were detected, caused by the lack of knowledge of their relevance by the EHR developers. Semantics and security were also reviewed. When CDSS-DDI are implemented in multiple healthcare centres, it important to recognize that one data field can have several meanings, especially if the EHR has several types of users. Unless the data field has the same meaning, it is impossible to integrate or communicate efficiently across the organization(s). Regarding data security, it is relevant to consider that the information managed is related to the patients and, in this way, it is sensitive information. Previous reports have described techniques to adopt secure barriers for EHR [22]. For this dashboard, we adopted techniques such as access control and data encryption.

In the current work, a modular approach was used to develop the DDI dashboard. Since it was important to have rapid visualization of the system behaviour, three modules were designed. The modules varried based on their level of specificity: the first is aimed for large-scale CDSS monitoring with KPI, the second provides in-depth analysis, and the last module mixes several variables in one chart to simultaneously convey large-scale and granular information. The indicators previously tracked manually, new indicators, and measurements that were previously unable to be processed manually were included in the development of the dashboard.

The increased autonomy and flexibility of users to get information and the efficiency and quality of the reports are only some of the benefits of using the developed dashboard. For example, the dashboard enables detection of trends in alerts overridden by the clinicians so the usefulness of these alerts can be analysed.

On the other hand, several challenges have been described in the literature for the appropriate integration of BI with the EHR. These were mainly non-technical factors such as organizational issues and lack of governance [23,24]. In this work, the most noticeable challenges were those related to data architecture.

Limitations

The current work has faced limitations related to data architecture. As mentioned above, initially, some crucial information for the dashboard was incomplete in the data warehouse. A second issue was to join data that, historically, were in separate data silos.

Future Lines

Considering the benefits obtained with this initial dashboard, the scope will be extended to other CDSS alerts and implemented in the EHR. Furthermore, based on the findings of this work, the data integrity of the EHR repository is being thoroughly reviewed. Based on last year's monitoring, a work line was initiated to optimize some drug pair rules in order to reduce the rate of overrides. Finally, the application of BI to other issues related to healthcare decision-making processes has been triggered.

Conclusion

The development of a BI dashboard for tracking CDSS-assisted DDI alerts in an EHR was described throughout this document. Alongside the definition of indicators and requirements, data architecture was crucial, the latter being the most challenging issue during development.

Using BI as a tool for CDSS performance monitoring made it possible to operationalize the EHR content repository, to maximize understanding of overrides, and to optimize the CDSS.

Abstract

Early recognition of skin cancer is vital to enhance patient outcomes. Teledermoscopy (TDsc), a telemedicine service, supports general practitioners (GPs) in gaining fast access to dermatologists' feedback to detect skin cancer. This study aimed to assess if GPs gain expertise in diagnosing skin disorders after continued use of TDsc, based on diagnosis classification by the International Statistical Classification of Diseases and Related Health Problems (ICD-10). A retrospective study was conducted on TDsc consultations sent by GPs to teledermatologists in the Netherlands (July 2015 - June 2018). GP sensitivity and confirmed cases in diagnosing skin disorders slightly increased over time. However, the total positive predictive value showed a decrease. In three years, 43 melanomas were diagnosed by the TD for which the GP did not provide a (correct) pre-diagnose. Though GPs appear to improve their expertise in skin disorder detection after continued TDsc use, TDsc remains imperative to early melanoma detection.

Keywords:
Skin cancer, telemedicine, ICD-10

Introduction

Melanoma, a malignant tumor of the skin, evolves fast and is currently recognized as the deadliest type of skin cancer [1,2]. Early recognition and treatment is essential in improving these patient outcomes. When diagnosed in the early phase, melanoma is almost always curable. General Practitioners (GPs) have a vital role in detecting and diagnosing melanoma early, as often the first care contact patients visit. However, literature shows that GPs expertise in detecting melanoma is insufficient [3-5]. Previous studies showed low agreement between GPs and dermatologists in diagnosing suspicious skin lesions [4,5]. In addition to the inadequacy in melanoma detection, long waiting times before consultation of a dermatologist also limits early melanoma detection. A telehealth service that supports GPs in diagnosing melanoma could be a solution to optimize early detection and access to specialist skin care services.

Teledermoscopy consultation (TDsc) is a growing online service for melanoma detection. In TDsc, dermoscopic images (10-30x magnification) are sent via a secured internet connection to a (tele)dermatologist, who examines these suspicious skin lesions online. The (tele)dermatologist then provides a patient's caregiver with an accurate diagnosis and advice on the need for referral based on the assessment of the dermoscopic images [6]. This service would thus provide the GP with direct feedback on the correctness of their pre-diagnosis of a patient's skin disorder. Research has shown that GPs expertise in melanoma detection increases after training [3] and that fewer melanomas were missed by experienced and trained consultants [6]. It therefore remains a question, whether a telehealth service will also enhance GP expertise in melanoma detection after continual system use.

Ksyos is a healthcare organisation in the Netherlands which provides TDsc consultation between the GP and teledermatologist [7]. While performing TDsc the GP takes an overview, detailed and dermoscopic picture of the suspicious lesion and sends it together with some patient characteristics and a pre-diagnosis in the Ksyos digital health record system to a teledermatologist (TD). The TD assesses the consultation and provides a diagnosis. Recording this diagnosis is mandatory for the TD but optional for the GP. Figure 1 gives an overview of this TDsc consultation process. Data from the Ksyos digital health record system shows that GPs indicate that they learned from the TDsc consultations and the total number of teleconsultations per GP is indeed decreasing over time. However, the question is if frequently diagnosing TDsc consultations and exposure to this service increases the expertise of GPs in diagnosing skin lesions after continual use.

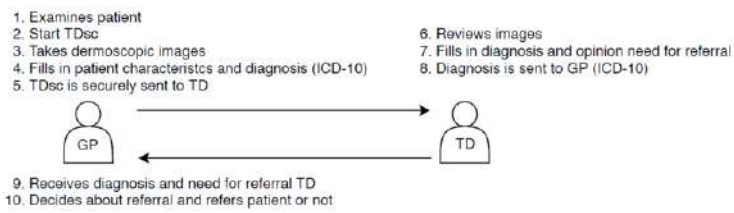

Figure 1 – Overview of the teledermoscopy consultation process between general practitioner (GP) and teledermatologist (TD)

Table 1 – 2x2 table to calculate sensitivity and positive predictive value

		Diagnosis TD (golden standard)	
		Diagnosis **confirmed** with ICD-10 code of TD	Diagnosis **not confirmed** with ICD-10 code of TD
Diagnosis GP	Diagnosis **present** according to ICD-10 pre-diagnosis of GP	**a**	**b**
	Diagnosis **absent** according to ICD-10 pre-diagnosis of GP	**c**	**d**

a = True positives, Diagnosis present according to ICD-10 pre-diagnosis of GP and confirmed by TD
b = False positives, Diagnosis present according to ICD-10 pre-diagnosis of GP and **not confirmed** by TD
c = False negatives, Diagnosis absent according to ICD-10 pre-diagnosis of GP and confirmed by TD
d = True negatives, Diagnosis absent according to ICD-10 pre-diagnosis of GP and **not confirmed** by TD

Positive predictive value (PPV) of GP = a / (a+b)
Sensitivity of GP = a / (a+c)

In the Netherlands, diagnoses given by the GP and TD within a TDsc consultation are classified to the corresponding ICD-10 code. The International Statistical Classification of Diseases and Related Health Problems (ICD) is an international diagnostic classification standard for reporting health conditions and diseases released by the World Health Organization [8]. This ICD-10 code can be used to analyse, compare and monitor diagnoses worldwide. Since July 2015, classifying diagnoses in compliance to this ICD-10 code has been mandatory in specialized care for reimbursement according to the Dutch Healthcare Authority (Dutch: Nederlandse Zorgautoriteit, NZa). And since this date, the 10th revision of this standard (ICD-10) has also been used in the Ksyos digital health record system. However, the effect of TDsc on GPs expertise in diagnosing skin disorders, based on the ICD-10 codes in the Netherlands has not been systematically investigated.

The aim of this paper is therefore to assess if, since the introduction of the ICD-10 codes in July 2015, GPs are gaining expertise in diagnosing (specific) skin problems conform ICD-10 after one, two and three years of TDsc use. In our analysis we specifically focused on the development in the number, ICD-10 type and correctness of GPs in pre-diagnosing skin disorders compared to the TD diagnoses. In doing so, we aimed to address the added value of continued use of TDsc for GP melanoma detection.

Methods

Setting and study population

We conducted a retrospective study in the Netherlands on the value of TDsc to GPs expertise in diagnosing skin disorders in three years' time. All TDsc consultations sent by affiliated GPs to TD between July 2015 and June 2018 and completed before the 18th of October 2018 were extracted from the Ksyos digital health record system.

A cohort of *experienced* GPs was selected for inclusion in the data analysis. GPs were classified as *experienced* if they performed at least five TDsc consultations for each of the included years, respectively (July 2015 - June 2016, July 2016 - June 2017, July 2017 - June 2018), and did not perform any consultation before January 2015. Unexperienced GPs were excluded in this study. The pre-diagnosis of the GP was compared with the diagnosis of the TD on the group level of the ICD-10 codes. Examples of group levels included are among others: C43-C44 *Melanoma and other malignant neoplasms of skin*, D00-D09 In situ neoplasms, D10-D36 *Benign neoplasms*, L20-L30 *Dermatitis and eczema*. The ICD-10 diagnosis of the TD was considered as the golden standard for the diagnosis confirmation.

Statistical analyses

The total percentage of cases a GP correctly diagnosed is calculated as the number of confirmed diagnosed GP cases by TD divided by the number of obtained TDsc cases minus the number of patients for which the TD did not provide a diagnose.

To assess the surplus value of continuing use of teledermoscopy the GP sensitivity and GP positive predictive value (PPV) in diagnosing skin disorders were calculated overall (total) and on the ICD-10 diagnosis group level for three subsequent years. The 95% confidence intervals (CI) of the PPV was calculated according to the Wilson score interval method without a correction for continuity [9].

The 2x2 table in table 1 shows the formulas used to calculate the PPV for each diagnosis category separately. The PPV was calculated as the proportion of consultations where the ICD-10 code was present according to the pre-diagnosis of the GP and confirmed by the TD divided by the total number of diagnosis scored within this group ICD-10 code by the GP. The sensitivity was calculated as the number of cases where the ICD-10 pre-diagnosis of the GP was confirmed by the TD divided by the total number of diagnosis scored within this group based on the ICD-10 codes of the TD.

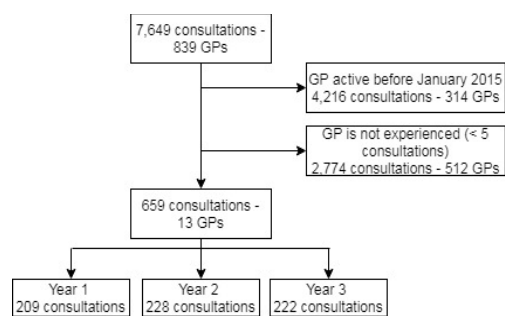

Figure 2 – Number of consultations

Results

In total 7,649 completed TDsc consultation requests by 839 GPs were extracted from the Ksyos digital health record system (figure 2). Overall, 314 GPs were active before January 2015 and for this reason the corresponding 4,216 consultations in the study period were excluded. In addition, 512 GPs did not perform five or more consultations for each study year respectively and were excluded. After exclusion, thirteen experienced GPs and 659 consultations were analysed (minimum of 20, maximum of 157 consultations per GP). The total number of consultations performed by the included GPs for each year were 209, 228, 222 respectively and were assessed among 32 TDs.

Table 2 – Number of (in)correct diagnosed GP cases and positive predictive value over three years' time

	Obtained TDsc cases	Not diagnosed by TD (%)	Not diagnosed by GP* (%)	Diagnosed by GP* (%)	Confirmed diagnosed GP cases by TD (%)	PPV [95% CI]	Incorrect pre-diagnosed by GP (%)
Year 1 July 2015- June 2016	209	26 (12.4)	170 (92.9)	13 (7.1)	11 (6.0)	0.85 [0.58-0.96]	2 (15.4)
Year 2 July 2016- June 2017	228	21 (9.2)	180 (87.0)	27 (13.0)	19 (9.2)	0.70 [0.52-0.84]	8 (29.6)
Year 3 July 2017- June 2018	222	33 (14.9)	155 (82.0)	34 (18.0)	25 (13.2)	0.74 [0.57-0.85]	9 (26.5)

Notes: PPV is calculated as the number of confirmed diagnosed GP cases by TD divided by the number of total obtained TDsc cases minus number not diagnosed by TD and GP.

* Total number = obtained TDsc cases minus the cases not diagnosed by TD

CI= confidence interval; **PPV**= positive predictive value

Sensitivity and PPV of GP in TDsc

No diagnosis was provided by the TD in 26 (12.4%), 21 (9.2%) and 33 (14.9%) of the cases. These cases were excluded from the statistical analyses. As shown in table 2, the percentage of confirmed GP diagnosed cases is increasing over years from 6.0 percent in year 1 to 13.2 percent in year 3. However, the GP's PPV is slightly decreasing over time from 0.85 [95% CI 0.58-0.96] to 0.74 [95% CI 0.57-0.85]. As presented in figure 3 the GP PPV though is increasing over time for diagnosis category L20-L30 *Dermatitis and eczema*. The number of incorrect pre-diagnosed cases by the GP is marginally increasing from 15.4 percent in the first year to 26.5 percent in the third year.

The sensitivity for all the diagnoses categories together increased from 0.07 in year 1 to 0.10 in year 2 and 0.14 in year 3. The sensitivity for the diagnosis categories C43-C44 *Melanoma and other malignant neoplasms of skin*, D10-D36 *Benign neoplasms*, L20-L30 *Dermatitis and eczema* (figure 4) also increased. The sensitivity for *melanoma* (C43-C44) improved from 0 out of 12 cases confirmed (0.0%) in year 1, 3 out of 22 cases (13.6%) in year 2, and 4 out of 16 cases confirmed (25.0%) in year 3 (total 7 out of 50 cases diagnosed as melanoma). The sensitivity for *Benign neoplasms* (D10-D36) improved from 5 out of 65 cases confirmed (7.7%) in the first year to 13 out of 79 cases in the third year (16.5%).

Added value of the teledermoscopy

Thirty-four diagnoses were scored by the TD to fourteen ICD-10 categories not chosen by the GPs (table 3). In these cases the GP did not fill in a diagnosis. Five consultations were scored by the TD as *no assessment possible* and for these cases no diagnosis was filled in by the GP as well.

The number of diagnoses inserted by the GP increased over time from 13 (7.1%) to 27 (13.0%) and 34 (18.0%) in year 1, 2 and 3 respectively. Conversely, this indicates to the added value of TDsc, which therefore starts out as relatively high as 92.9 percent of diagnoses are provided by the TD and were not filled in by GPs starting with TDsc. This number then slightly decreases after GP's continuing use of TDsc to 82.0 percent of the patients diagnosed by TD in year 3.

In three years' time, TDs diagnosed the majority of the patients as benign neoplasm (year 1 35.5%, year 2 43.0%, year 3 41.8%) or other disorders of the skin and subcutaneous tissue (year 1 37.7%, year 2 23.2%, year 3 33.3%).

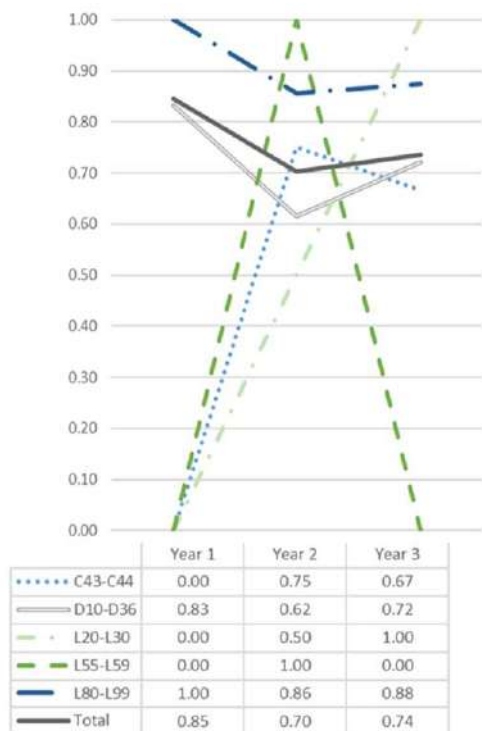

Figure 3 – PPV per diagnose category

In the first year, patients in TDsc were not diagnosed by the GP with the ICD-10 code *Melanoma and other malignant neoplasms of skin* (C43-C44). In the second year GPs diagnosed two consultations as benign neoplasms, while the TD diagnosed these patient cases as *melanoma or other malignant neoplasms of the skin* (C43-C44). In the third year one consultation was diagnosed as *radiation-related disorder* (L55-L59) by the GP, that was diagnosed as melanoma by the TD.

Overall, 12 (6.6%), 19 (9.2%) and 12 melanoma cases (6.3%) were diagnosed by the TD in three years' time respectively and not or not correctly pre-diagnosed by the GP. This suggests that in 7.4 percent of the total TDsc consultations performed in three years' time melanoma was detected, which were not and/or not-correctly pre-diagnosed by the GP. Also, 1 out of 3 (35.8%) of TDsc consultations were diagnosed as benign by the TD and not and/or not-correctly pre-diagnosed as such by the GP.

	Year 1	Year 2	Year 3
C43-C44	0.00	0.14	0.25
D10-D36	0.08	0.09	0.16
L20-L30	0.00	0.25	0.33
L55-L59	0.00	0.06	0.00
L80-L99	0.09	0.13	0.11
Total	0.07	0.10	0.14

Figure 4 – Sensitivity per diagnose category

Discussion

We conducted a retrospective study in the Netherlands to assess the potential value of TDsc to GPs expertise in diagnosing skin disorders over three years' time. Overall, of the total number of cases included in the study, the GPs provided more pre-diagnoses for each subsequent year from 7 percent in year 1 to 18 percent in year 3. Our study shows that the total percentage of correct pre-diagnosed cases of GPs is low, but during continual use of TDsc it slightly increased over time from 6 percent to 13 percent.

However, the number of incorrect pre-diagnosed cases also increased over time from 15.4 to 26.5 percent. This corresponds to a decrease in the overall PPV for all diagnosis categories. A possible explanation might be that after continual TDsc use, GPs might select the more difficult cases for TDsc and handle the less complex cases themselves. GP PPV specifically increased over time for diagnosis category L20-L30 *Dermatitis and eczema*. This may indicate that GPs become more attune to correctly diagnosing patients with dermatitis and eczema over time.

In general, GP sensitivity over all diagnosis categories showed a slight increase from 0.07 in year 1 to 0.14 in year 3. More importantly, GPs appear to become more sensitive in accurately pre-diagnosing skin disorders in the categories: C43-C44 *Melanoma and other malignant neoplasms of skin* and D10-D36 *Benign neoplasms*. As TDsc is especially important in early diagnosis of melanoma, these results are promising. When GP clinical expertise in recognizing melanoma improves, the sensitivity in melanoma detection increases. This finding is supported by a Cochrane review on accuracy of dermoscopy that shows that this sensitivity increases with more clinical expertise [6].

What we know from a previous study is that 95.1% of the GPs learned from the TDsc [10]. TDsc provides the GPs with direct feedback on the correctness of their pre-diagnosis by the confirmation of the TD. However, the system does not provide any active feedback on the GP performance. Literature on audit and feedback mechanisms shows that feedback leads to minor improvements in professional practice, but the effect is influenced by the way which the feedback is delivered [11]. New studies on analysing and advancing the effect of the feedback mechanism incorporated in TDsc consultations might lead to a higher GP learning curve.

Due to the rising number of correct pre-diagnosis of GPs, the percentage of TDsc in which the TD provides the GP with ICD-10 diagnoses decreases over time from 93 percent in the first year to 82 percent in the third year. This decrease might imply advancement in GP skin disorder diagnosing expertise. However, of the total TDsc consultations included in this study, in the subsequent three years 6.6%, 9.2% and 6.3% were diagnosed as melanoma by the TD for which the GP did not provide a (correct) pre-diagnose. In addition, two consultations which were pre-diagnosed by the GP as a benign neoplasm and a radiation-related disorder, were classified by the TD as *melanoma or other malignant neoplasm of the skin* (C43-C44). The high number of incorrectly diagnosed cases by GPs, indicates that the added value of TDsc after three years is still very high. However, these cases were not histopathological proven. Also, fourteen ICD-10 diagnosis categories were given by the TD which were not pre-diagnosed by GPs at all. This could indicate that GPs are unfamiliar with these diagnoses.

The results of this study reveal a potential learning effect of TDsc on GP skin disorder diagnose expertise. An increase in the number of pre-diagnosed consultations by the GP, an increase in diagnosis sensitivity and a modest increase in positive predictive value after three years for specific diagnose categories of TDsc usage were seen. However, overall, GPs pre-diagnose expertise of skin disorders appeared low in this study. Especially *Benign neoplasms* (D10-D36) and *other disorders of the skin and subcutaneous tissue* (L80-L99) appear difficult to diagnose by the GPs since a pre-diagnosis for these disorders was often lacking.

In this study GP were not obliged to fill in a pre-diagnosis, but the number of provided pre-diagnoses appears comparable to normal practice. In the study of Rijsingen et al. they assessed the quality of referral letters of GPs to the dermatologist of patients with skin tumours [4]. Their study showed that GPs do not always provide a diagnosis for suspicious lesions in referral letters to the dermatologist. A diagnosis was missing in 18.3% of the cases. In addition, only two out of eight melanoma were correctly pre-diagnosed in the GP referral letters. In our study, GPs detected 14 percent of all melanoma diagnosed by TDsc. The positive predictive value of GPs in melanoma detection for both studies was equal, 0.67.

Table 3 – Diagnosis categories chosen by Teledermatologist (TD) and not by General Practitioner (GP)

Category	Description
B00-B09	Viral infections characterized by skin and mucous membrane lesions
B35-B49	Mycoses
C81-C96	Malignant neoplasms, stated or presumed to be primary, of lymphoid, haematopoietic and related tissue
D65-D69	Coagulation defects, purpura and other haemorrhagic conditions
D70-D77	Other diseases of blood and blood-forming organs
H60-H62	Diseases of external ear
I80-I89	Diseases of veins, lymphatic vessels and lymph nodes, not elsewhere classified
L00-L08	Infections of the skin and subcutaneous tissue
L40-L45	Papulosquamous disorders
L60-L75	Disorders of skin appendages
M30-M36	Systemic connective tissue disorders
O94-O99	Other obstetric conditions, not elsewhere classified
Q80-Q89	Other congenital malformations
T08-T14	Injuries to unspecified part of trunk, limb or body region
	No abnormalities

One of the limitations of this study is that in Dutch GP practice diagnoses are registered according to the International Classification of Primary Care (ICPC) and recorded according to SOAP notes (Subjective, Objective, Assessment, Plan). The ICD-10 classification of diseases was thus a new classification method where GPs were unfamiliar with, when it was implemented in 2015. GPs becoming more familiar with ICD-10 coding might therefore have contributed to the increase in the number of (correct) ICD-10 pre-diagnoses registered by the GPs in our study. Hence, in this study we only included GPs who started with TDsc after the ICD-10 was implemented in the Ksyos system, to research how their pre-diagnosing patterns changed according to the ICD-10 coding in three years' time. Also, GPs might use TDsc in general practice to fasten the face-to-face consultation with the patient and not solely for support in diagnosing. If a GP correctly pre-diagnosed the patient, but did not fill-in this diagnosis in the system, this would affect the GP PPV in diagnosing skin disorders. During the time of our study it was not mandatory for the GP to fill in the ICD-10 code in the system and this would thus not be seen in our data. Though this study has several limitations, the strength of the study is that we had a large database available of TDsc users and were able to include only GPs who started with TDsc when the ICD-10 coding system was first implemented in the Ksyos system and had continued and frequent use of the system in the past three years. We could therefore accurately address their progress in expertise in pre-diagnosing skin disorders based on ICD-10 coding.

Conclusions

TDsc supports GPs in assessing suspicious lesions of patients and their need for referral to a dermatologist. Continual use of TDsc over the years appears to slightly enhance GP sensitivity in diagnosing skin disorders based on ICD-10 coding. However, GPs PPV for the main ICD-10 codes showed a decrease over the years. Though GPs become more perceptive in recognizing benign neoplasms (D10-D36) and melanoma (C43-C44), TDsc detected a high number of melanoma not correctly pre-diagnosed or otherwise not detected by GPs in this cohort. Hence, TDsc has the potential to enhance GP expertise in skin disorder diagnosing, but remains essential in early melanoma detection even after GP continued and frequent TDsc use.

Decentralized Privacy-Preserving Platform for Clinical Data Sharing and Analysis

Sui Jun Tong[a], Yong Yang[a], Wen Sun[a], Eryu Xia[a], Shao Chun Li[a]

[a] *IBM Research - China, Beijing, China*

Abstract

Collection and management of clinical data for administration and analysis is a time-consuming and complex task, especially when multiple data providers been involved. Even if people are willing to take on the burden for it, there is still no mature solution to protect data privacy for distributed data providers. Distributed ledger is an emerging technology that supports decentralized data sharing and management. Based on this, we present a platform which enables distributed and truthful data collection and serves privacy-preserving needs in clinical data management. Our system, built on Hyperledger Fabric, used smart contract to execute data aggregation and provide basic analysis methods. The system used ledger and world status to record data access history and other metadata. This decentralized platform enables data providers to proactively share and protect their data, Thus can simplify clinical data collection procedure and promote efficient collaboration between providers.

Keywords:

Data Sharing, Clinical Data Analysis, Decentralized Data Management

Introduction

Data analysis of electronic medical records has shown its great power in risk prediction, new treatment or cure detecting, and precision medicine [1]. To validate results and reduce bias, collecting data from multiple sources is a desired approach in such clinical research. However, since medical data are mostly isolated and stored with different healthcare providers, data collection and sharing for analysis is usually a time-consuming and complex task.

Even if people are willing to take on the burden for such tasks, traditional centralized data collection still has some weaknesses. First, data leaks may occur during the data sharing and consumption process; technically, data providers have no idea on who accessed the data. Second, the data authenticity and quality cannot be guaranteed. It is difficult to detect in a timely manner if the dataset has been modified or faked. Finally, the centralized approach sometimes prevents data providers from a fair collaboration, and the contributions of different providers are not traceable. Hence, a more transparent and trustful way for clinical data collection, sharing, processing, and analysis is highly desirable.

The emerging distributed ledger technology may offer a solution for the above issues. Derived from Bitcoin [2], distributed ledger technology, such as blockchain, is now widespread in both financial and non-financial areas. Popular blockchain frameworks, like Hyperledger Fabric [3,4] and Ethereum [5,6], allow people to build customized blockchain networks with self-defined smart contracts. The possibility of using blockchain for healthcare data management has recently gained more attention in both industry and academia [8, 9, 10, 11]. However, how to leverage blockchain to build a decentralized, privacy-preserving platform for clinical data sharing and analysis still remains to be explored.

In our work, we present a prototype platform which enables distributed and truthful data collection and serves privacy-preserving needs in clinical data management. We build our platform based on Hyperledger Fabric [4], which allows data providers to join the network by loading their data to a local peer. To guarantee data security and privacy, source data will not be exposed to a public network. Data consumers can only use the predefined smart contract to get access to the data, and all the data transmissions in our system will be encrypted. The ledger stores the metadata, access APIs, and access control policy of all datasets. All data access will be recorded to the ledger, which can be easily traced and verified. In addition, since the contributions of the distributed datasets can be defined and calculated, reward mechanisms can also be devised to encourage data providers to collaborate with each other. The decentralized nature of the proposed platform makes it easy to be deployed and scaled up in practice.

Methods

Compared to other medical data management systems [1,7,8], the proposed platform provides a secure, trustful, and convenient way for clinical data sharing and analysis. The framework of the proposed platform can be found in *Figure 1*.

As shown in Figure 1, the distributed data are integrated into the proposed platform in the data storage layer. The data providers, such as hospitals, keep their data on local databases and provide secure connections for local peers. The database servers are not part of the blockchain network, and thus cannot be accessed by other peers from other origins.

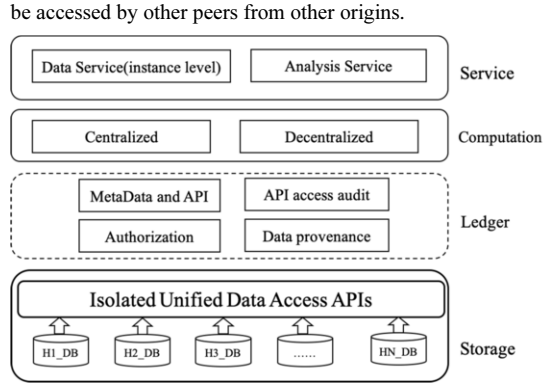

Figure 1– Framework of clinical data sharing platform

Data stored in the local databases will follow a common schema, so we can use unified data access APIs to query the data. Data providers are free to join or leave the network, and their data can no longer be accessed after they leave the platform.

The ledger layer can be generally regarded as the permissioned blockchain services, which is the main component of our platform. In our platform, ledger services are customized for different purposes. First, we use the ledger to store the metadata and APIs. After loading their dataset to the local databases, data providers need to invoke a transaction to record the metadata to the ledger, which contain the data schema and basic information of the loaded data. Each kind of data schema is associated with a list of APIs, which are predefined and announced with the data schema. Metadata and APIs are represented as the World States in our HyperLedger Fabric [3,4] implementation, and stored in CouchDB [4]. The ledger also record the authorization policy for the dataset. Access control can be managed by channel, by organization, or even by a certain peer. When a user invokes a query in our platform, the smart contract will verify the authorization of the user from the ledger. When transactions are successfully executed, the transaction information, such as transaction invoker, accessed datasets, and results will be recorded to the ledger, which can be used for auditing and contribution calculations. Thanks to the irreversibility and undeniability of blockchain, all the data recorded in the ledger are trustful. The final results can also be associated with a list of ledger transactions, which can be easily used to verify the data provenance and the analysis process.

Based on the distributed ledger layer, we offer two kinds of computing engines by different smart contracts. The centralized computing engine requires the driver to send sub-queries to different data provider peers, aggregate the query results, and return final results to the requester. It is similar to the MapReduce [12] computing framework. The decentralized computing engine is used to manage data providers' own information, executes typical blockchain transactions happened inside the local peer, and directly records the results to the distributed ledger.

We also provide two kinds of data services targeted to two types of demands. Instance level data services support ad hoc queries over row-level data records, and can be dispatched and executed in a local dataset. The analysis services contain fine-grained statistical APIs and predefined modeling pipelines which are more complicated and may involve multiple datasets. With the common data schema, a list of APIs, for both instance level data services and analysis services, are published to all the providers. The data provider does not have to accept all the APIs; they can choose the APIs that they would like to support during the dataset register, and disable some APIs if they have any concerns.

Results

Our prototype is easily implemented and receptive to adaptations and extensions in practice. Here we demonstrated an implementation on HyperLedger Fabric, upon which we simulated a research pipeline using a real-world dataset.

Implementation

The key components of our implementation include a permissioned blockchain network and functional smart contracts. First, we built a Fabric network to grant all the healthcare stakeholders the ability to join the platform. Then we write Chaincode as Smart Contracts to manage the data access APIs and providing data services on our demands.

Network Setup

Generally speaking, a clinical data collection and sharing platform has three kinds of stakeholders:

- **Data provider.** This can be a hospital or other healthcare providers who has the medical records and is willing to share the data with authorized users for research purposes. The data provider stores the source data and takes the responsibility for the data privacy and security.
- **Data consumer.** This can be a researcher who needs real-world clinical records for research, such as an insurance company or a pharmaceutical company for a business need, or a healthcare administrator for public health surveillance. A hospital can also be a data consumer. A data consumer uses the data and needs to pay for data services.
- **Miner.** This is a trustful third party who does not keep any data and only provides computing services, A miner can be a cloud service provider or other powerful server nodes.

Accordingly, our blockchain network consists of three kinds of nodes:

1. Data peer nodes, which store ledger data and maintain a connection to their local databases;
2. Miner nodes, which store ledger data, have the access to query or write the ledger data, but cannot access the source data; and
3. Client nodes, which provide data services, receive data query requests, and invoke transactions with miner nodes.

Each node has a unique identity, which cannot be faked by others. For security purposes, a network can have many channels, and each channel can share the same ledger. It is possible to isolate data access records by ledger. To build a Fabric network, we need to first generate the channel configuration, then create encryption materials and certification for the origin of each peer.

Smart Contracts

Smart contracts are the business logic of a blockchain network. In our platform, metadata and the access APIs are regarded as the data provider's assets. Smart contracts need to specify the data schema design, define what kind of assets the data provider should providing, and release a list of associated APIs. A smart contract also contains a detailed scoring or charge mechanism. As mentioned above, there are many different kinds of smart contracts serving different functions (also known as chaincode in Hyperledger Fabric framework):

- **Data chaincode.** This is installed and run on the data provider peer and has direct access to the source data. Each data provider installs their unique data chaincode, which holds the connection for its local dataset.
- **Service chaincode.** This is installed and run on the miner peer and acts as the central service. It receives queries from clients, sends transaction proposals to data chaincode, aggregates data, and returns final results to the client. Service chaincode uses a "chaincode invoke chaincode" way to execute a client's query and only return final results to the requester. Intermediate data will not be shown to the client side. Many miners could be equipped with the same chaincode.
- **Miner.** This is installed and run on every peer. It controls the dataset register and manages assets and

access records for audit purposes. The whole channel using the same management chaincode.

Transaction Flow

At the beginning, each data provider should load its datasets to the platform. Before registration, all the data providers should reach an agreement on the data schema, which can be defined based on standard practices or by some authoritative organizations. The common data schema would then be released to the platform.

Figure 2 shows a typical dataset registration transaction flow, which includes the following steps:

1. Data schema holder (could be any user) connects to network through Client/SDK.
2. Client/SDK proposes a request to management chaincode to create new schema.
3. Management chaincode creates a new table and updates it to the ledger.
4. Data provider formats their local datasets accordingly upon notification of the schema.
5. Data provider proposes a transaction request through Client/SDK to register an new dataset.
6. Data chaincode creates connection for local databases and updates metadata of the local datasets to the ledger.

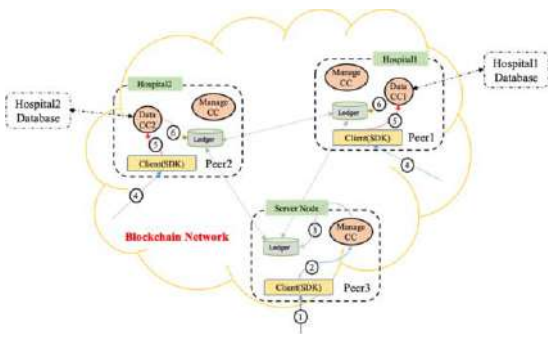

Figure 2– Transaction flow of dataset register

After loading the dataset, some predefined query can be executed on our platform. A common query workflow is shown as in *Figure 3*, which includes the following steps:

1. Data requester connects to network through Client SDK.
2. Client SDK proposes a request to service chaincode.
3. Service chaincode obtains all the available data chaincodes and proposes child query transaction to them.
4. Data chaincode answers the transaction proposal and returns query results to the service chaincode.
5. Service chaincode aggregates all the intermediate data, and returns final results to the requester.

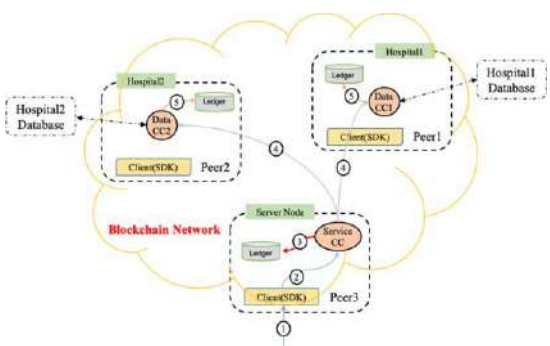

Figure 3– Transaction flow of query

Simulation

To demonstrate the use of our prototype, we simulate a use case using a real dataset. The medical record data was independently collected from three hospitals (below referred to as data centers) and organized based on the same data schema.

In this scenario, we create a channel with four organizations, include three data provider organizations and a data service organization. Each data provider has one peer node in the network. When the data provider detects a new data schema in the ledger, it first loads its own data to the local database (relation database such as MySql), and then registers the dataset with a secure connection to that database server via its peer. This peer will run a data chaincode after dataset registration, which is used to interact with the local database. Besides, we have another peer that provides data query and analysis services. That peer installs a server chaincode to call data chaincode and aggregates the results.

Table 1– Execution time for sample queries

Query	Parameter	Result	Avg. Execution Time (s)
getSum	Null	26974	3
count	mace=1	955	3
getRowdata	age<60	{rowdata}	12
getAvg	Age	67.3	3
getColumn	mace	{column data}	10
getLrModel	x_xolumns, y_xolumns	{model weight}	300
evaluate	model	auc:0.862	5

Table 1 shows the execution time for some sample queries. Here three kind of basic queries as well as LR model training and evaluation is used for testing. *GetSum* is use to compute the sum of all the dataset. *Count* is used to count the total records that satisfy the given constraint. *GetRowdata* is used to query instance level data and returns all the row data that satisfy the given constraint. *GetAvg* returns the mean value of a given column. *GetLrModel* performs the training process of a logistic regression model on the given columns. *Evaluate* applies a given model on the whole dataset, and returns the AUC score as the model evaluation result.

As we can see from the table, basic statistical queries could be performed with relatively low latency. But the performance was worse when the data processing logic became more complicated, such as complex instance level data services or modelling tasks. Considering the source data are scattered in multiple distributed data sources, a couple of minutes for a model training task should still be acceptable for typical use cases.

Conclusions

In our work, we present a prototype platform which enables distributed and truthful data collection and serves privacy-preserving needs in clinical data management. Through this, a researcher can easily collect the data they want, and the data provider will get fair payment and also keep their source data safe. Once we have enough datasets and performed further research on the platform, we can also use our platform as an audit system for clinical research reports.

Abstract

The number of patients with multimorbidity has been steadily increasing in the modern aging societies. The European C3-Cloud project provides a multidisciplinary and patient-centered "Collaborative Care and Cure-system" for the management of elderly with multimorbidity, enabling continuous coordination of care activities between multidisciplinary care teams (MDTs), patients and informal caregivers (ICG). In this study various components of the infrastructure were tested to fulfill the functional requirements and the entire system was subjected to an early application testing involving different groups of end-users. MDTs from participating European regions were involved in requirement elicitation and test formulation, resulting in 57 questions, distributed via an internet platform to 48 test participants (22 MDTs, 26 patients) from three pilot sites. The results indicate a high level of satisfaction with all components. Early testing also provided feedback for technical improvement of the entire system, and the paper points out useful evaluation methods.

Keywords:

Multimorbidity; Evaluation Studies; User-computer Interface.

Introduction

The World Health Organization estimates that 63% of all annual deaths (~36 million people) is attributable to non-communicable, chronic diseases [1] and the number of people with multiple comorbidities has increased considerably for some years, mainly due to the ageing of the population [2]. Elderly patients with multimorbidity (i.e., having at least two chronic diseases) [3] are at higher risk of safety incidents [2]. These could include incidents such as delayed diagnosis, no recommended treatment, drug side effects, drug interactions, over/under dosage of drugs, complications, infections, etc [2,4]. Increased risks in patient safety, in this context, may be explained by many reasons. Firstly, patients with multimorbidity are often polymedicated, with a potential decrease in treatment adherence and a possible increase of drug side effects. Secondly, patients may receive contradictory advice or treatments, due to the application of different guidelines that are designed to manage only single disease pathways. Thirdly, patients with multimorbidity are often cared for by several health and social care (HSC) professionals, who are not always coordinating and communicating throughout the patients' journey. For example, there is often a lack of communication between general practitioners (GPs) and secondary care specialist centres. Finally, these patients are often more vulnerable than others, due to their multiple diseases and their advanced age, which makes the care process even more complex.

C3-Cloud[1] is a European Commission supported Horizon 2020 research and innovation project, which aims at improving the provision of integrated care to patients with multimorbidity via enhanced ICT solutions. The research aims at resolving guidelines' conflicts (by reconciliation of varying recommendations from individual disease guidelines), supporting clinical decision making through clinical decision support services, and facilitating communication among multidisciplinary care team (MDT) members through an interoperable platform, which integrates patients' health records from existing Electronic Health Record (EHR) systems [5]. The project mainly focuses on elderly patients (65+) with diabetes, heart failure, renal failure and depression in different comorbidity combinations. Three European pilot sites are involved in the study: Osakidetza (Basque Country, Spain), RJH (Region Jämtland Härjedalen, Sweden) and SWFT (South Warwickshire NHS Foundation Trust, UK).

The C3-Cloud system consists of a variety of components:

- Coordinated Care and Cure Delivery Platform (C3DP),
- Patient Empowerment Platform (PEP),
- Clinical Decision Support Modules (CDSM),

[1] http://C3-Cloud.eu, Federated Collaborative Care Cure Cloud architecture for the needs of multi-morbidity and managing poly-pharmacy.

- Interoperability Middleware, which includes modules of technical and semantic interoperability, as well as privacy and security.

All these components constitute the solution that will be used for the technological trial of the C3-Cloud application. Following a user-centered development (UCD) approach [6], the solution has to be evaluated iteratively during its life cycle; during development and implementation with a restricted number of participants, during deployment with a larger number of users as well as during the routine phase for prospective cost-benefit analyses and real impacts.

The objective of this study is three-fold: the report of the user-centered functionality testing, the conclusions to further improve the C3-Cloud system and, for the community, to present useful methods among the UCD evaluation methods often used in health informatics.

Methods

This evaluation consisted of a number of questionnaires to collect user feedback regarding system functionality. The questionnaires were created based on a Delphi approach [7]. In the context of the project, a total of 51 pilot application requirements (PARs) and 72 use cases were defined covering the scope of all high level C3-Cloud components to depict expected functionality. Three different types of users interact with the system: multidisciplinary team members (MDTs) also known as health and social care professionals; patients; and informal care givers (ICGs), and are accordingly studied. This is in line with previous informatics research, e.g. OLD@HOME[8–10] and more recent research regarding patient access to health information [11–13]

This qualitative inductive study directly separated the demands or requirements with the use cases needed. For example, "as a patient, I need to access drug interaction information" is a PAR for the pilot sites and "Enabling patients to access self-management material" is a use case of the PEP component. A full list of user scenario descriptions and PARs is presented in deliverable D8.1 [14].

Evaluation Procedure

Following the Delphi approach [7], the evaluation framework was developed:

Brainstorming: Formulation and Evaluation of an Initial List of Relevant Questions

Based on an analysis of 51 PARs and 72 use cases, the first step was to formulate a list of questions, starting by a simple mapping (1 PAR to 1 use case) to identify possible links between the PARs. Secondly, the questions were grouped by profiles identified during the PARs' analysis process, in order to define one questionnaire per user profile. The workflow was based on a C3-Cloud key scenario linked to a use case and defined by application testing criteria.

Refining and Prioritization: Internal Review Based on a Cognitive Walkthrough by Experts

The initial questions were reviewed by the three pilot sites as well as by the technical partners of the C3-Cloud project. The results of the cognitive walkthrough [11] by five IT and clinical reviewers, allowed us to validate, modify, delete or add questions based on the updated PAR list and covered system functionality. Based on the review from the aforementioned experts, although addressing different professionals and individuals, the questionnaires could be appropriated to, two user profiles: 1) MDTs and 2) Patients & ICGs, as grouped respondents of the questions.

Think Aloud

During the test sessions, the think aloud method [11] was encouraged and the pilot site managers, who moderated the sessions, noted all comments of the participants. Feedback from the different pilot sites could be complementary. If feedback was raised more than once, it was reported only once. Examples, issued from the feedback, and how they were handled by technical partners to improve the C3-Cloud components, are reported in the Result section.

Evaluation Set-Up

We implemented an online application that allowed participants to answer questionnaires. The application site is available at https://c3cloud.irsan.eu. In the questionnaire, participants responded with [Yes], [No] and [NA] (for functionality, which was Not Available). When the response was [No], both MDTs and Patients/ICGs had the opportunity to specify and explain the problem faced by writing free text comments.

Participants

Overall, 26 elderly patients (> 65 years) and 22 MDTs from the three pilot sites: Osakidetza, RJH, and SWFT; participated in the testing. At the time of testing, only an English-language demonstrator and materials were available, and local sites considered this when recruiting test participants.

Test Sessions

The participants received login credentials for the online demonstrators of the C3DP (for MDTs) and the PEP (for Patients/ICGs) as well as training materials including a walkthrough that guided them through certain activities on the demonstrators. For the Osakidetza and RJH pilot sites, a language facilitator moderated each session, and was available for translation of the material and any other question raised by the participants. Think aloud notes taken during the test sessions generated a summary report.

Results

Overall 57 questions were formulated; 33 for MDTs and 24 for Patients & ICGs. Below, detailed results of the application testing for MDTs and Patients/ICGs, respectively, are reported, as well as examples of the questions in the questionnaires.

Evaluation by MDTs

Questions were categorized by the following main topics: Care Plan; Decision Support Module; Patient Data; Communication; and Notifications. The MDT responses [Yes], [No] or [NA] are reported, in percentages, in Table 1.

Table 1– Summary of MDTs average response rates to C3-Cloud application testing

MDTs' Response rates			
C3DP Categories	[Yes]	[No]	[NA]
Care plan	94 %	4%	2%
Decision Support Module	72%	0%	28%
Patient Data	75%	6%	19%
Communication	79%	3%	18%
Notification	89%	5%	6%

Questions related to Care Plan received the highest amount of [Yes] responses, 94%. The following questions received positive responses by all (N=22) participants:

- *"Are you able to create a new specialized care plan for the patient?"*
- *"Are you able to define new or update the planned intervention?"*
- *"Are you able to define new or update self-care activities (like exercise recommendations)?"*

The question "Are you able to update an existing care plan?" scored: [Yes] 82%, [No] 9% and [NA] 9%. The [No] responses were complemented with MDT comments, revealing that some update functionalities were missing. For example:

- *"I can update some elements of the plan as goals and activities and training material, but I cannot update the health conditions of the patient."*

From the free text feedback, further details about "health conditions," in a new care plan creation, were considered, together with improvement proposals from MDTs and responses from the technical partners. For example:

- MDT proposal: *"When creating a new care plan 'Addressed Conditions' may need rephrasing. It is also unclear how it is decided what conditions the list here suggests. The list can be very long if many conditions apply or are possible."*
- Technical partner improvement feedback: *"Addressed conditions will be removed, the SNOMED-CT codes of the 4 main diseases will be added."* Regarding the Decision Support Module, an average of 72% of the participants provided [Yes] answers to questions such as:
- "Does the Clinical Decision Support Module give you advice about treatment options such as i) new safety, treatment or lifestyle? ii) starting/stopping of medication, based on the most recent context of the patient including changes in recent remote monitoring results?"

There were zero [No] answers and [NA] responses were rated at 28% on average, meaning that all accessible functionalities were approved by the participants.

For Patient Data, average responses were [Yes] 75%, [No] 6% and 19% for [NA]. There were highly rated [Yes] responses >90% for questions such as:

- "Are you able to access patient data after the Care Plan Manager approved your membership to the Multidisciplinary Care Team?"
- "Are you able to review the patient's Health Records?"

A lower percentage of [Yes] responses were received, for example, regarding questions like:

- "Are you able to access the readings, that have been uploaded by patients manually or via remote monitoring systems such as wireless medical sensor devices?" with [Yes] 55% respective [NA] 36%.
- "Are you able to follow-up patients' activities, such as complications, side effects via questionnaires?" 68% responded [Yes] and 18% [No] which were completed with MDT comments like "Not recorded" and "Did not find them..."
- "Are you able to access information completed by the patient such as files uploaded via the PEP?" 64% responded [Yes] and 32% responded [NA].

Communication questions were related to message exchange between the MDT members or invitations to another specialist to join the care team. On average, 79% responded [Yes], 3% [No] and 18% responded [NA]. Questions regarded, e.g.:

- "Messaging - Are you able to send messages to other members of the MDT via asynchronous messaging?"
- "Invitation - Are you able to invite another specialist to join the patient's Care Team?"

Finally, responses related to **Notification** functionalities received an average of 89% [Yes], with questions such as

- "Are you able to notify the existence of the updated care plan to Care Team Members and to the patient?"
- All participants (100%) answered positively on
- "Can you see the upcoming activities in your calendar and in the Activities section of your dashboard?"

Evaluation by Patients and ICGs

For the Patient Empowerment Platform (PEP), Patient and ICG responses were categorized in the following main topics: Care Plan; Patient Empowerment; Patient Data; Notifications and Communication. The responses [Yes], [No] or [NA] are reported, in percentages, in Table 2.

Table 2 – Summary of Patients & ICGs average response rates to C3-Cloud application testing

Patients and ICGs Response rates			
PEP Categories	[Yes]	[No]	[NA]
Care plan	87%	4%	10%
Patient Empowerment	68%	8%	24%
Patient Data	48%	4%	48%
Communication and Notification	32%	5%	63%

Questions related to the Care Plan received average responses of 87% [Yes], 4% [No] and 10% [NA]. Examples of questions:

- "As a Patient or Informal Care Giver, are you able to access the care plan?" 96% of participants responded positively, and 4% responded [NA]
- "Do you receive enough advice and support about how to follow the care plan?"

[No] responses were provided, with comments such as:

- Not clear how to work through the system.
- Not obvious what needs to be done, when and how. Some guidance notes would be helpful.
- More time is needed.
- Needs to be more simple with clear single click pathways trough each of the components for the patient. A lot of the technical material in each patient activity is not needed by the patient and therefore confusing.

Patient Empowerment average responses were 68% of [Yes], 8% of [No] and 24% of [NA]. Example of questions:

- "Do you think that the information given could help you to improve your health and wellbeing?"
- 85% responded [Yes], 15% responded [NA].
- "Are you able to learn about treatment options through the PEP?" 61% [Yes], 8% [No], 31 %[NA].

- "Are you able to learn about drug benefits through the PEP?" 58% [Yes], 11% [No], 31 %[NA].
- [No] responses were completed, with patients' comments as: - *Not recorded, - Depends on which materials are presented, - I have not stopped/answered.*

Patient Data gathered average response rates of 48% for [Yes], 4% for [No] and 48% responded [NA]. Some examples

- "Are you able to access the readings uploaded to the system from remote monitoring systems (e.g., wireless medical sensor devices) from the PEP?"
- 42% responded [Yes], 8% responded [No], 42% lacked the functionality with [NA] responses.
- "Are you able to upload documents, such as a picture, to your PEP?" 54% responded [Yes] and 46% [NA].
- [No] responses were completed, with patients' comments such as: *"Not available", "I have not tried it*".

Communication and Notification average responses were 32% [Yes], 5% [No] and 63% [NA]. Example of questions:

- "Messaging - Are you able to contact MDT members via messaging from the C3-Cloud Platform?" 58% [Yes], 0% [No], 42% [NA]
- "Video calls - Are you able to join a video conferencing session with MDT members?" 8% [Yes], 92% [NA]
- "Notifications - Are you able to schedule an appointment with your Primary Care Provider?" 16% [Yes], 15% "No and 69% [NA]

Proposed Actions Based on the Evaluation

Based on the technical partners' feedback regarding the overall responses from participants, below is a summary of issues to be handled to improve the first version of the C3-Cloud system. These issues are currently being followed up in the project in relevant work tasks.

- Bugs – errors related to the expected functionality should be fixed.
- Training needs to be improved – related to the uncertainty of users regarding the functionality of the system, next steps, scope.
- Local configuration – local customizations need to be implemented during deployment.
- Evaluation questionnaires – More time to complete the tests and a way to report issues repeatedly..
- Language – issues related to native language usage on the platform, both for local configuration and content.
- Feature improvement – issues related to aspects such as unclear labels, layout, etc. Some comments for features could be out of scope but noted for future recommendations.
  - Incomplete/unclear specification – insufficient information to implement the improvement, for example: Care plan content, and concept issues – specific issues relating to care plan clarifications are required.
  - New feature – a new feature requested.
  - Visual guideline – information missing regarding visual guidelines or available accessibility settings.
  - Test data unrealistic – value ranges incorrect: can be improved with realistic test samples as provided by pilot sites.
  - Scope clarification – the scope of the project needs to be clarified [to whom?/technicians/developers/?] in order to implement improvements.

Discussion

Our findings indicate that with the help of a user-centered design methodology [6] it was possible to define the functional ICT requirements for the C3-Cloud project and further refine them through an early application testing by end-users. A combination of different techniques that complement one another should preferably be used as their collective application will be more powerful than applied in isolation [11]. Therefore we used different evaluation methods.

The first approach used, inspired by the Delphi method, permitted "to obtain the most reliable opinion consensus from the group of experts by subjecting them to a series of questionnaires in-depth and interspersed with controlled opinion feedback"[7] . The development of the questionnaires for application testing was therefore preceeded by and based upon the creation of pilot application requirements which were matched with the use case scenarios, and later reviewed by both IT and clinical experts. However, we are aware that a second review round by the experts may have improved the formulation of the questions.

During the test sessions, we observed some limitations regarding the contextual coupling and synchrony between the test enviroments that were based on PARs and case scenarios and the perceived relevance of some items of the questionnaires. This was highlighted by some of the responses from the participants such as: "not finding the option"; "not knowing"; "not been informed about it"; "not clear how to work through the system"; "not obvious what needs to be done"; "more time needed". Although we encouraged the think aloud method during the application testing, in some cases feedback was too vague to be interpreted. For example, such feedback included statements such as "Depends on which materials are presented" and "I have not stopped/answered". In such cases, participants need to be more specific about the problem they face, and the observers need to make sure they fully understand what the user means at that specific moment.

The analysis of feedback also highligted that it would have been advantageous to apply a shorther questionnaire that addressed some site-specific smaller discrepancies of the C3-Cloud platform and the language-related barriers. Most notably, the prerequisite of a good command of English caused both limitations regarding the recruitment of participants and an accurate understanding of nuances in the non-English speaking countries. Additionally, some participants felt that the questionnaire was not sufficiently detailed to allow them to express all their concerns with the C3-Cloud platform. Specifically, some suggested that it would have been more efficient to answer questions directly in the evaluation walkthrough document, which in turn would have enhanced their understanding of the entire test module in advance. Further, two participants did not feel that they wanted to use the patient empowerment platform in its current format at all.

Notably, as the majority of the participants were elderly, early testing in the development is crucial, as one could expect that such users would experience difficulties with the comprehension and adaptation of the novel C3-Cloud platform, but it could be hard to know in advance where in the system the unintended effects arise. This finding is in line with current research on evaluation methods in health IT, used for early detection an addressing of the unintended consequences of IT usage [12]. However, the overall response of the participants was that the system has great potential to simplify and enhance their engagement in and understanding of the care process. This was reflected by the high overall rate of positive [Yes] responses.

This study also demonstrated that with a multi-faceted user-centered design methodology it was possible to perform an early evaluation of a complex ICT infrastructure, involving different groups of end-users from three different pilot sites (in Spain, Sweden, and the United Kingdom), which in turn further consolidated the European-wide collaboration within the C3-Cloud project. This constructive evaluation was performed at an early stage of the development to achieve a fast improvement of the C3-cloud system. The results summarized in the section "Proposed Actions Based on the Evaluation" were communicated as user feedback to the techical partners, who have reconfigured and updated the C3-Cloud components accordingly. Incorporating the end-user's requests for change and modification has been completed before the pilot application deployment. The C3-Cloud platform, which has been developed by the results of this evaluation, will be subjected to further and more rigorous testing based on real life experience, with actual MDT members and patients/ICGs in the three pilot sites during the planned pilot study starting in April 2019.

Conclusions

This study demonstrates how an integrated application can be tested against the requirements, as elicited through an extensive European collaboration, to improve care for the elderly with multiple diseases. Mainly, application testing was performed without any adverse incident. The online platform worked well throughout the application testing sessions. The aim of this evaluation was not only to appraise the system's functionality, but also to investigate how to improve the C3-Cloud application and its implementation further. The results obtained reflect insights from MDTs, patients and informal care givers for both user-facing components: C3DP and PEP. Overall, this application testing is an early evaluation exercise in order to adapt the system, where needed, and to get the first users' feedback for further development. Integrating the questions into the evaluation walkthrough document, so that participants can answer the questions as they are testing the relevant sections, would make it simpler for the participants.

Abstract

Interest in sleep has been growing in the last decades, considering its benefits for well-being, but also to diagnose sleep troubles. The gold standard to monitor sleep consists of recording the course of many physiological parameters during a whole night. The human interpretation of resulting curves is time consuming. We propose an automatic knowledge-based decision system to support sleep staging. This system handles temporal data, such as events, to combine and aggregate atomic data, so as to obtain high-abstraction-levels contextual decisions. The proposed system relies on a semantic reprentation of observations, and on contextual knowledge base obtained by formalizing clinical practice guidelines. Evaluated on a dataset composed of 131 full night polysomnographies, results are encouraging, but point out that further knowledge need to be integrated.

Keywords:

Sleep Stages, Expert Systems, Semantics

Introduction

In the last decades, sleep has been considered more and more seriously either for wellness reasons, or for diagnosing sleep troubles. Its impact on quality of life and on health is henceforth well known. To diagnose a sleep trouble, the gold standard sleep exam is the polysomnography, which consists in recording, during sleep, the course of a set of physiological signals and then observe the brain activity, recorded by electroencephalography (EEG), the eye movements, recorded using electrooculography (EOG), and the muscle tone recorded using electromyography (EMG).

Sleep staging is a fundamental preliminary step to the diagnosis of sleep troubles. During this task, a sleep expert visually browses the polysomnographic curves in 30-second epochs, to assign one of the five sleep stages defined, since 2007, by the American Academy of Sleep Medicine in their international guidelines [1]. A sleep stage is assigned by considering different criteria observed on EEG, EOG, and EMG curves, and by considering the dynamics of sleep. Guidelines for visual scoring of sleep staging define, firstly, for each sleep stage, a set of criteria that need to be met for a sleep stage to start to be scored ("transition rules"). Secondly, another set of criteria is defined for a sleep stage to continue to be scored ("continuity rules"). Five sleep stages are defined: W (Wakefulness), N1 (Non-REM 1), N2 (Non-REM 2), N3 (Non-REM3) and R (REM). N1 and N2 correspond to light sleep; N3 corresponds to deep sleep; REM stands for Rapid Eye Movements. Even if software dedicated to sleep scoring include automatic scoring functionalities, they are not used in routine practice, since sleep physicians are not satisfied by their results [2].

Common approaches found in litterature for automatic sleep stages are based on machine learning techniques. Features, extracted from the acquired signals, are used to feed a classifier, that will be able, after a learning step, to make a decision on new samples. Many of these approaches use a single channel – generally a single EEG channel – to make the decision. Using an open dataset, they might not be compliant with the current guidelines, but with older ones, defined by Retschaffen & Kales in 1968 [3]. Machine learning approaches mainly ignore the domain of knowledge; moreover, sleep dynamics are unsufficiently integrated into the decision, since epochs are considered independantly from each other (through the segmentation of the analysis and decision).

Alternatively, semantic approaches are seen as satisfactory solutions to have a formal description of knowledge on a domain without ambiguity. Based on a formal modelisation of concepts and relationships of the field, they allow reasoning. This formalization results in semantic networks, conceptual graphs or, more often, in ontologies. They might be seen as a description of a state of the universe at one time, focusing on one interest domain, listing concepts and specifying relationships between them. However, the dynamic aspects that make the universe change from one state to another remain an issue to be modelised. From one time to another time, the world changes; thus concepts and relationships between them change also. The description of the universe at one time is different to the description of the universe at another time.

Expert systems are decision support systems composed of an observations base and a knowledge base. The observations base contains facts and events observed in the current state of the universe. Knowledge base contains inference rules allowing the system to make sense or assemble existing observations and facts and generate new events or new facts that will then be added to the observations base. Expert systems are knowledge-based systems and can be designed without any data. In the medical field, we benefit from existing knowledge that needs to be formalized into compliant inference rules.

In this paper, we present a dynamic expert system, using a formal representation of obervations using conceptual graphs and formalizing rules governing sleep-stages transitions and sleep events occurrences. The next section will focus on methods. Then, results will be presented and be followed by a discussion. Finally, we will give our conclusions in the last section.

Methods

An expert system with four modules

Our expert system is composed of four different modules: (1) the *events vector*, a time vector containing all events observed during sleep; (2) the *sleep stages vector*, a time vector containig all sleep stages assigned to each epoch during sleep; (3) the *events fusion knowledge base*, a knowledge base containing fusion strategies to fuse events (4) *five contextual sleep stage assignment knowledge bases*, five knowledge bases containing inference rules to apply in five different sleep contexts.

All these modules can be considered as an expert system. The observation base is composed of the *events vector* and *sleep stages vector*, composed each of facts of, respectively, low and high abstraction level. The knowledge base is composed of the *events fusion knowledge base*, and of the *five contextual sleep stages assignment knowledge bases*.

Events vector

All events observed during sleep are gathered in a time vector, where each event is identified by an identifier and a label. The vector captures the semantic type of each event, given by the identifier, but also its start and end. If necessary, other useful information can be added to the event; for instance, the lowest value of the saturation can be specified and attached to a desaturation. Each event is then formalized as a conceptual graph, giving its label, its start, its end and all other information that might be useful for the final decision.

Each event is represented by a conceptual graph. Conceptual graphs are a formalism that was introduced by John F. Sowa in 1984 [4]. Semantic concepts are linked by labelled relationships. Fusion algorithms have been defined to combine several conceptual graphs that share concepts.

For example, Figure 1 shows an event vector with all events occurring during the epoch. Representations of event 1 and event 2 are given on Figure 2.

Figure 1 – Events vector

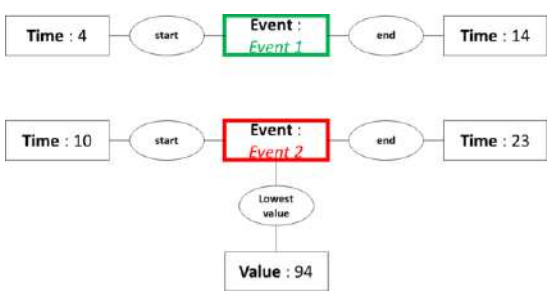

Figure 2- Conceptual graphs of Event 1 and Event 2

Sleep Stages vector

All sleep stages assigned by the expert system are stored in a sleep stages vector. Sleep stages are considered as high-abstraction-level information, obtained by combining and fusionning atomic information observed on other channels. This vector is initialized by specifying that, just before the start of the exam, i.e. the last epoch before the start of the exam, the patient was awake. Thus, we initialize the sleep stages vector with the W sleep stage assigned to the last epoch preceding the start of the exam.

An example sleep stages vector is given in Figure 3. Each cell represents a 30-s epoch. The vector starts with seven epochs of N2, followed by 15 epochs of N3, followed by eight epochs of R, followed by 2 epochs of W and ends with 2 epochs of N1.

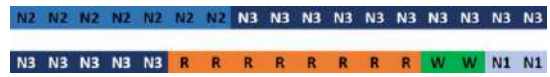

Figure 3 – Sleep stages vector

Events fusion knowledge base

Considered separately, events observed on each acquired channel may not be sufficient to asisgn a sleep stage. However, they may be different observations of the same physiological event. To be combined, it is hence necessary to fuse conceptual graphs to get a new conceptual graph representing a higher-abstraction-level event. Initially, they are separated; it is necessary to formalize the causal relationships that link them. Abstraction rules, combining all linked events to generate the physiological fact, can be applied to add the physiological fact to the observation base (the events vector).

Each rule of the events fusion knowledge base is formalized as a conceptual graphs fusion strategy. Fusion strategies follow the principles of the maximal join operator. Criteria required to fuse two conceptual graphs are defined. The resulting conceptual graph is entirely defined, on the basis of the concepts – and their values – of the fused conceptual graphs.

Figure 4 illustrates an example of fusion rules using conceptual graphs. Event 1 and event 2 are fused into Event 12, starting at starting date of Event 1, and ending at ending date of Event 2. Criteria to fuse these two events could be defined on start dates, end dates, or on the lowest value of event 2.

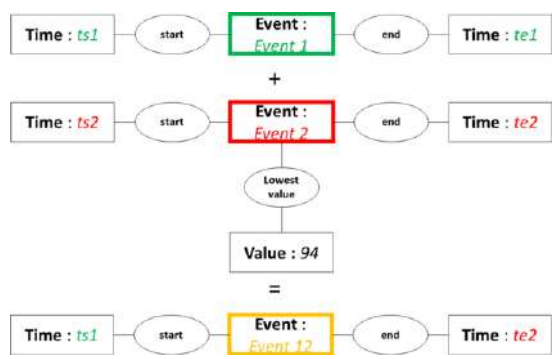

Figure 4 – Example of events fusion

Five contextual sleep-stage assignment knowledge bases

Depending on the current sleep stage in the previous epoch beeing considered as a sleep context, rules to assign a sleep stage to the current epoch are different, when applying the guidelines of the AASM. As a consequence, five different knowledge bases were defined, each containing the rules to apply in a given sleep stage. Depending on the current stage, each knowledge base contains rules to start a new sleep stage and rules to apply to continue scoring the current sleep stage. For each knowledge base, sleep stages are ordered. The inference step evaluates whether rules of a given sleep stage are met or not, testing all sleep stages successfully until one given sleep stage can be assigned. Ordering sleep stages allows to formalize priority rules, defined in the guidelines.

Rules to assign a sleep stage are based on binary criteria. Each criterion is met whether a high-abstraction-level event is met, or not.

Figure 5 illustrates an example of the five contextual knowledge bases. Depending on the sleep stage assigned to the previous epoch, a knowledge base is selected. Then, criteria are evaluated until one is met. It allows to assign a sleep stage to the current epoch.

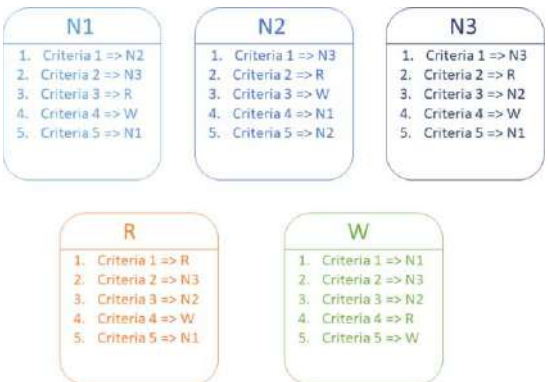

Figure 5 – Contextual Decision knowledge bases

Decision algorithm

Previously of the decision process, it is required that following steps have been done : (1) split the recording into 30-second epochs, (2) extration and recognition of low-abstraction-level atomic events, (3) representation of all extracted events by conceptual graphs, consistantly to a defined terminology.

Figures 6 shows a flowchart of decision process. It is composed of four steps.

1 - Move to the next epoch

A decision is made for each epoch of the recording, starting from the first to the last, moving from one epoch forward at each step, once a decision has been made and a sleep stage has been assigned to the epoch. At each step of the decision process, a "reading head" is moving to the next epoch.

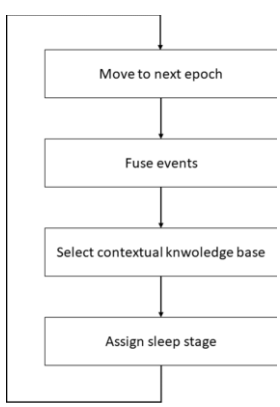

Figure 6– Flowchart of decision process

2 – Fuse events

We assume that events extracted previously to the decision process are low-abstraction-level events. To be able to make a decision, we need high-abstraction-level events. These events are obtained by events fusion using fusion strategies [5,6]. Fusion strategies used to fuse events are defined and formalized into the *events fusion knowledge* base. Representing events by conceptual graphs allows to fuse delayed events observed in different channels, which is necessary in physiological processes. Using events fusion, it is possible to abstract events from a given abstraction level to a higher abstraction level; it is also possible to integrate literal data to get a semantic event; it is finally possible to aggregate, or combine, events. This step is based on an expert system.

3 – Select contextual knowledge base

Depending on the sleep stage assigned to the previous epoch, we know the sleep context of the subject at the start of the current epoch. Regarding this context, the right knowledge base can be chosen, in order to select the right rules to apply to make the decision and assign the sleep stage.

4 – Assign a sleep stage

Having identified which knowledge base to use, and regarding events of the low- and high- abstraction levels oberved and inferred on the events vector, the system is able to assign a sleep stage to the current epoch. To achieve this task, ordered criteria are evaluated. Each criterion is defined as a logical combination of high-abstraction-level events observed. Rules are evaluated following a predefined order until a criterion is met. This allows to assign a sleep stage. Criteria are ordered according to priority rules.

Example

According to the guidelines, the N2 sleep stage should be assigned to an epoch, if a K-Complex, not associated to an arousal, is the first half of the current epoch.

Firstly, K-complexes and arousals need to be scored (manually or automatically). Then, K-complexes and arousals are fused, to classify K-Complexes into 2 categories: K-complexes associated to an arousal, and K-Complexes not associated to an arousal. In the next step, given an epoch, the right time period is observed to check whether a "K-complex non associated to an arrousal" was observed. For those epochs where this criterion is met, the N2 sleep stage is assigned. Otherwise, the criteria of other sleep stages are tested.

Results

Description of the dataset

The dataset used for evaluating our method was already used in [7]; Gathering 131 full night polysomnographies, it is composed of 148,407 epochs (1,237 hours). The first subset is composed of 101 polysomnographic recordings of patients suspected of suffering from Sleep Apnea Syndrome; the second subset is composed of polysomnographic recordings of ten control subjects having spent three consecutive nights at the hospital. Polysomnographic recordings were performed in the sleep pathologies unit of La Pitié-Salpêtriére Hospital (AP-HP, Paris, France) using the Grael HD- PSG TM device which is produced by Compumedics Limited® from Australia. All recordings have been fully scored by a sleep expert in accordance with AASM guidelines [1] using Profusion Sleep TM Software from Compumedics®. All 131 recordings were visually scored by two experienced sleep experts, in accordance with the clinical practice guidelines defined by the AASM, without using the automatic pre-analysis functionality. This scoring is used as gold-standard for our work.

Each recording is composed of more than 30 channels for the full-night polysomnography. In this study, we only need some

channels to be compliant with the clinical practice guidelines defined by the AASM: the EEG, the EOG and the submental EMG. Six EEG channels were recorded, following the international 10–20 system with a sampling rate of 256Hz: O1, C3, C4, Fp1, A1, A2. 2 EOG were recorded with a sampling rate of 256Hz: Left EOG and Right EOG; One channel of the submental EMG was recorded with a sampling rate of 256Hz. As recommended in the clinical practice guidelines defined by the AASM, EEG and EOG channels were filtered using a 0.3–35 Hz bandpass filter; EMG submental channel was filtered using a 10–100 Hz bandpass filter.

This study was approved by The Committee for the Protection of Human Research Participants, Paris VI (Comité de Protection des Personnes Ile-de-France VI, Paris, France).

Control subjects were received by a physician to be informed in detail about the purpose and the procedure of the research study. Informed consent was provided and signed by all subjects. A sleep physician performed a physical examination and a questionnaire to validate that they had no suspicion of a sleep disorder.

All subjects signed an informed consent form. All individuals included in our database followed instructions to refrain from alcohol and caffeine ingestion and to avoid engaging in prolonged and/or strenuous exercise before sleeping. All polysomnographies were recorded in a quiet, darkened room.

Measures

To evaluate the performance of our automatic sleep slating tool, we used different measures.

Agreement rate is a measure used to assess the results of the automatic analysis globall, i.e. including all sleep stages. It is defined as the ratio of epochs scored with the same sleep stage by the expert and the automatic analysis for each recording.

$$agreement\ rate = \frac{Nb\ epochs\ with\ same\ sleep\ stage}{Total\ number\ of\ epochs}$$

Because sleep stages have an unbalanced number of epochs, Cohen's kappa was also used. This measure takes into account that some epochs are scored identically by the automatic analysis and by the expert by chance

$$\kappa = \frac{p_0 - p_e}{1 - p_e}$$

Where p_0 is the relative observed agreement among raters (identical to agreement rate); and p_e is the hypothetical probability of chance agreement.

Other measures are defined to assess results obtained for each sleep stage. These measures are defined for binary classifications. All of them are defined considering the following confusion matrix

Table 1 – Confusion Matrix

		Automatic analysis	
		C	Not C
Expert analysis	C	TP	FN
	Not C	FP	TN

TP refers to True Positive elements. Both expert and automatic analysis have classified these events in the class of interest C.

TN refers to True Negative elements. Both expert and automatic analysis classified these events as not belonging to the class of interest C.

FP refers to False Positive elements. Classified as belonging to the class of interest C by the automatic analysis, they were classified as not belonging by the expert.

FN refers to False Negative elements. These events were classified as not belonging to the class of interest by the automatic analysis, whereas they were classified as belonging by experts.

Recall and precision are widely used in the field of machine learning. Recall is the ratio of elements belonging to the class of interest, that were correctly identified by the automatic analysis. Precision is the ratio of elements belonging effectively to the class of interest among all elements that were considered as belonging to the class of interest by the automatic analysis. Recall and precision are defined by following formulas:

$$\begin{cases} recall = \dfrac{TP}{TP + FN} \\ precision = \dfrac{TP}{TP + FP} \end{cases}$$

Sensitivity and specificity are used in the medical field to evaluate a diagnosis test. Sensitivity allows to know the performance of the test to identify sick individuals (=positive elements). It is equal to the predefined recall. Specificity allows to know the performance of the test to identify healthy individuals (=negative elements). Sensitivity and specificity are defined by following formulas:

$$\begin{cases} sensitivity = \dfrac{TP}{TP + FN} \\ specificy = \dfrac{TN}{TN + FP} \end{cases}$$

To balance recall and precision, the F Mesure was proposed, defined by the following formula:

$$F\ Mesure = 2 \times \frac{recall \times precision}{recall + precision}$$

To give more weight to recall than to precision, the F2-Measure was proposed as an extension of the F-Measure, with the following formula:

$$F_2 - Measure = \frac{(2^2 + 1) \times recall \times precision}{2^2 \times precision + recall}$$

Results

On the dataset of 101 polysomnographic recordings of patients suspected to suffer from sleep apnea syndrome, the obtained average agreement rate was 51.5; the average kappa was 0.36. All measures for all sleep stages are detailed in Table 2. Considering the control subjects, we obtained an average agreement rate of 56.55 and an average κ of 0.43 (see Table 3).

Table 2 – Measures obtained on Sleep Apnea Syndrome patients dataset

Measure	W	N1	N2	N3	R	MVT
Recall / Sensitivity	54.3	30.3	58.6	44.4	54.4	0.0
Precision	75.3	21.1	54.0	51.6	53.4	0.0
Specificity	92.64	86.26	73.86	91.4	91.6	99.5
F Measure	58.8	22.3	53.4	42.9	50.3	0.0
F2 Measure	54.5	25.3	55.8	42.5	51.6	0.0

Table 3 – Measures obtained on control subjects dataset

Measure	W	N1	N2	N3	R	MVT
Recall / Sensitivity	54.9	32.7	63.2	54.4	61.8	0.0
Precision	72.8	24.1	59.9	50.4	69.5	0.0
Specificity	92.7	86.4	74.9	86.1	91.6	96.7
F Measure	60.4	25.1	60.5	49.0	63.7	0
F2 Measure	56.6	28.1	61.9	51.4	62.2	0

As we can see, there are some differences between results obtained on the patients dataset and on the subjects dataset. This can be explained by the quality of the signals to process. Because of sleep troubles, signals from patients are very noisy, which make signal processing methods less efficient. Moreover, sleep troubles generated a highly disturbed sleep with many transitions; and as discussed by Thomas Penzel [8], transitions between sleep stages present the biggest source of differences between human sleep scorers.

Discussion

Our results may appear to be less performant than other results published in recent literature. All these works are mainly based on machine learning algorithms, and ignore, during the evaluation step, the intra- and inter-raters concordance. It was assessed by Danker-Hopfe et al. in 2009 [9]. Inter-raters rates are given by sleep stage in Table 4.

Table 4 – Inter-rater agreement rate (kappa)

W	R	N1	N2	z	N3
0.8608	0.9054	0.4608	0.7188		0.7285

As we see, most of results given in recent published works claim to have a higher concordance that what another human sleep expert would obtain. It means that their results are obtained by overfitting, which is not suitable.

On the contrary, our approach follows rules of practice guidelines. Our results show that these rules still need to be improved and expanded. Knowledge base might be enriched with transitions rules or experience knowledge.

The performance of identifying atomic events remains also to be evaluated.

Weaknesses of our approach include a relaince on the need to formalizing a complete knowledge base of rules to be applied to score sleep stages; medical knowledge is often incomplete, and knowledge acquired from experience is hard to formalize.

Strengths of this approach include its robustness, its flexibility, and its upgradeability. Its ability to use easy time-based rules helps contextualize decisions. Semantic reasonning is fully understandable and customizable by experts. Furthermore, in absence of formalized knowledge it can be hybridized with machine learning approaches.

Conclusion

In this paper, we present an approach representing information by semantic concepts. Temporal aspects are taken into account by reasonning on a dedicated framework, inspired by the Turing machine. Sleep stages are assigned by using different expert systems, one for each sleep context considered.

Abstract

Patient weights can be entered incorrectly into electronic health record (EHR) systems. These weight errors can cause significant patient harm especially in pediatrics where weight-based dosing is pervasively used. Determining weight errors through manual chart reviews is impractical in busy clinics, and current EHR alerts are rudimentary. To address these issues, we seek to develop an advanced algorithm to detect weight errors using supervised machine learning techniques. The critical first step is to collect labelled weight errors for algorithm training. In this paper, we designed and preliminarily evaluated a visual annotation tool using Agile software development to achieve the goal of supporting the rapid collection of expert-annotated weight errors. The design was based on the fact that weight errors are infrequent and medical experts can easily spot potential errors. The results show positive user feedback and prepared us for the formal user-centered evaluation as the next step.

Electronic Health Records, Data Curation, Patient Safety

Introduction

A child's weight is a vital parameter in pediatrics, with its importance ranging from general development to precise medication dosing. The latter is particularly important since many drug doses are weight-based. According to previous studies, about 20% of pediatric medication errors resulted from "improper dose/quantity," which is a much higher rate than that in the adult setting [1,2]. Consequently, weight errors can lead to under- or over-dosing and further cause patient harm [3]. Pediatric weights are recorded incorrectly in various ways: typing errors, conversion errors (e.g. scale in pounds, system in kg), and weight estimations instead of actual measurements. Capturing weight errors with high sensitivity and specificity, however, can be very difficult. Manual chart reviews are often required and they are time-consuming and impractical to comply with in busy clinical routines. Moreover, capturing weight errors is especially difficult in neonates and growing children in which age and gender only provide a rough estimate of the expected weight range. A myriad of medical conditions, both acute and chronic, can also drastically change weight patterns. Given that it is in these more complex cases that drugs are often prescribed, detecting incorrect weights and administering proper weight-based dosing are critical.

There has been previous research in developing informatics solutions to detect weight errors. One approach is based on z-scores, a score that indicates how many standard deviations an element is from the mean. Error detection methods using this approach are often rule-based and tend to use empirical cut-offs to determine weight errors based on age and gender. One well-known example is the program provided by the Centers for Disease Control and Prevention (CDC) of the United States [4]. These rule-based systems are efficient and good at capturing outliers, but often have low performance in subtler and/or more complex charts.

Our literature review shows a lack of automated algorithms to detect weight errors with high performance – both retrospectively and in real time. The closest we can find is the method developed by Dymont *et al*., which is based on exponentially weighted moving averages of standard deviations with rule-based decision [5]. This method was developed for the purpose of cleaning research data and identifying implausible values in growth data. While this method took personal weight history into account and can be optimized in individual datasets, it was not derived from training on all weight patterns in a dataset and therefore may fail to detect weight errors in more complicated patterns. Another limitation of this method is that it requires data after the point of interest to perform analysis (*i.e*., in a retrospective manner) and may not be very useful in real-time detection of weight errors as a clinical decision support tool.

To address this gap, we aim to develop an advanced algorithm with supervised machine learning techniques to detect pediatric weight errors, which can retrospectively detect weight errors and be deployed as a real-time clinical decision support tool. To achieve this goal, a critical first step is to collect a large body of expert-annotated weight errors. However, there are three challenges in collecting such an annotated dataset: 1) the low prevalence of weight errors (less than 5%) [6], 2) the tremendous amount of time required to manually review patient charts to identify true errors [7,8], and 3) various weight patterns with limited information. To overcome these challenges, we developed a web-based annotation tool utilizing visual analytics principles and human-computer interaction techniques to efficiently and effectively annotate pediatric weight charts. With this tool, weight data are converted into a set of growth charts and presented in an interactive user interface to support rapid collection of expert annotations. In this paper, we report the design and preliminary evaluation of the visual annotation tool.

Methods

Clinical Setting and Weight Data

The raw weight data were collected from the electronic health record (EHR) system of the Cincinnati Children's Hospital Medical Center (CCHMC) between January 2010 and June 2018. CCHMC is an urban, quaternary children's health system

in Cincinnati, Ohio in the United Sates with more than 600 inpatient beds and over 33,000 admissions as well as 1.2 million patient encounters annually. Each weight record consisted of an identifier, gender, and weight value (in kg) plus timestamp of each measurement. The patient identifiers were anonymized, and the timestamps were converted into the age in days when the weight was taken (with decimals to incorporate time of day). The data was stored in a file-based (SQLite) database to support downstream data manipulation and analysis. The weight data were summarized statistically to understand the distribution of key characteristics, including age, gender, and weight variability.

Pediatric Growth Chart

The display of weight data in our visual annotation tool was informed by the clinical growth charts developed by the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) in the United States [4]. This visualization of child's weights has been routinely used in practice both in paper-based charting and EHRs. The growth charts come with age-matched percentiles based on the distribution of the general population. In our design, the percentiles were adjusted based on gender and age groups. Specifically, each patient has two sub-charts: one from birth to age two (0 - 24 months) and the other from age two to eighteen. The reason of this split was due to practical considerations where following up on patient weights in the infant period (0 – 24m) often has much higher variability. Plotting weight points in the infant period with other points in childhood on the same growth chart would be impractical and may introduce challenges in our annotation tasks. Figure 1 shows an example of a growth chart for boys between 2 and 20 years old as reproduced from the CDC paper [1].

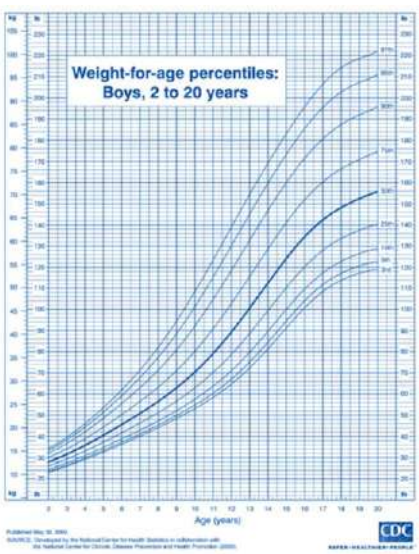

Figure 1 – CDC Growth Chart Example [4]

System Design and Evaluation

Our visual annotation tool was developed following the principles of the Manifesto for Agile Software Development [9]. The development focused on end users (medical experts) and their interactions with the software. The research team provided a working prototype over time to collect user feedback and respond to the changes. Specifically, the visual annotation tool was designed and evaluated in three phases: 1) Design of core functionality and user interface, 2) Iterative refinement through group discussion, 3) Experimental workflow and pilot testing. The detail of each phase is described in the following sections.

Phase 1 - Design of Core Functionality and User Interface

In the first phase, a focused group of clinical informaticians (PVC, SAS, and DTW) worked closely together to brainstorm the core functionality and user interface of the visual annotation tool., This group searched the literature and reviewed known data visualizations to inform the design of the tool with the goal of supporting effective and efficient collection of expert-annotated weight errors. In this phase, only the facial validity of the tool was evaluated. That is, the system was presented to and reviewed by the three group members to check if it had the potential to achieve the design goal.

Phase 2 – Iterative Refinement through Group Discussion

In the second phase, the visual annotation tool was refined in an iterative process by a larger group called "decision support analytics workgroup" (DSAW) at CCHMC. This group of clinical informaticians and medical experts met weekly to collaborate on projects and regularly discussed the weight error detection project and reviewed our visual annotation tool. The iterative refinement through group discussion lasted for several weeks, and an informal usability testing was conducted at the end of this phase when the visual annotation tool was functional enough. In this information usability testing, user feedback was collected and categorized, and the changes were made to generate the first stable version of the tool.

Phase 3 – Experimental Workflow and Pilot Testing

With the stable version of the tool, the research team developed a protocol to conduct a formal user study to examine the relationship between different combinations of tool settings and the efficiency and effectiveness of annotations on the weight data. The visual annotation tool was enhanced in two ways to support this user-centered evaluation and data analysis. First, it was able to record every click made by the user and produce usage logs. Second, it had an administration interface to manage users, assign datasets, and control tool settings.

To prepare for our formal user study, the protocol for the experiment was tested to refine the workflow. A small group of medical experts and clinical informaticians was recruited. Each participant spent an hour with the research team. In each session, a short introduction of the weight error detection project was given, followed by a brief tutorial to the visual annotation tool. Then, the participants were assigned two datasets, each containing 225 patient charts. The patient charts were randomly selected from the weight data (the charts with 4+ data points) and verified by the research team. After finishing the annotation tasks, the participants were asked to provide feedback on the interface design and workflow through a structured survey with open-ended questions. Specifically, the usability of the tool was measured by the Systems Usability Scale (SUS), a 10-question survey with a modified Likert scale from one to five with five being the highest [10]. After filling out the SUS survey, a short, structured interview was conducted to collect detailed feedback that was not captured by the SUS.

In terms of data analysis, the composite SUS scores were calculated based on the guideline, which range from 0 to 100. A system with a SUS composite score of 68 or above is considered as having "above average" usability. In addition, the time of task completion was calculated based on the usage logs. This experiment protocol was reviewed and approved by the University of Cincinnati Institutional Reviewed Board (#2017-2075).

Software Implementation

The application was developed using Shiny in R-studio. Shiny is a framework that supports the quick development of interactive web applications straight from R. This deployment has benefits in easy access with no extra client software installation. While Shiny has several benefits and can save much programming time, it has limitations like any other framework and libraries. Some inline JavaScript and jQuery were added to provide additional, optimized user experience. The visual annotation tool was hosted on an internal Shiny server behind the firewall and could only be accessed through a web browser by users at the University of Cincinnati (UC) and CCHMC in order to protect the weight data with the highest standard.

All chart annotations and usage logs were stored in a separate SQLite database. This allowed the original weight data to be left untouched and only a minimal data to be stored. The annotated patient charts and the process of annotation can be recreated by combining the data from both sources. As mentioned in Phase 3, an administrative interface was created as a separate Shiny application to support the workflow. The design and functionality of this administrative interface are out of the scope of the present paper.

Results

Weight Data

Table 1 shows the descriptive statistics of the weight data. Over 600,000 patient and their weight data points were extracted from CCHMC's EHR system. Maximum number of weights per patient and weight value taken were 2312 times and 632.2 kilogram, respectively. 47% of the patient (N=283,971) had at least four weight points, accounting for 88.6% of the individual weights (N=4,193,008). Random charts selected out of this subset were used to explore the graphical representation of the weight data and support the tool evaluation.

Table 1 – Statistical Summary of Weight Data

Characteristics		All Patients	Patients with 4+ data points
Number of Records		4,733,317	4,193,008
Number of Patients		604,147	283,971
Number of Females		291777	136404
Num. of Weights per Patient	Min	1	4
	Median	3	8
	Average	7.8	14.8
	Max	2312	2312
Weight Value (kg)	Min	0.0	0.0
	Median	23.2	23
	Average	33.1	32.9
	Max	632.2	632.2

Phase 1 - Design of Core Functionality and User Interface

Three core functions of the visual annotation tools are described in the following sections, including 1) individual patient chart display and annotation, 2) multiple charts in a grid, and 3) annotation flow.

Individual Patient Chart Display and Annotation

The display of individual patient charts was designed based on the CDC examples. Weight data were converted into growth charts with the *x*-axis being the age in days and the *y*-axis being the weight values. Digital display of weight charts had several benefits compared with their paper-based counterparts. First, the display was designed to automatically crop the *x*-axis to reflect the proper age range of the weights recorded. Second, the population percentiles were automatically adjusted based on age and gender. Next, the display always kept the upper (97th) and lower (3rd) percentiles in a chart, allowing the trend of the weights being interpreted correctly so that changes in weights would not be over- or under-estimated. Finally, users can zoom in a certain area of a chart and zoom out if needed. Figure 2 shows 4 patient charts with likely complex underlying pathology resulting in atypical weight patterns.

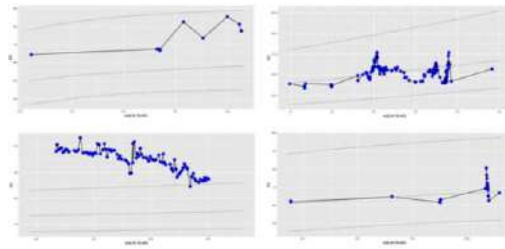

Figure 2 – Patient Charts with Complex Weight Patterns

Another core functionality of the tool was to label incorrect weight points (a.k.a. annotation), which was implemented using color coding. Users can click each weight point to indicate its error type. All the weight points were colored in blue by default. The first and the second click of a point turned the color into red and orange, respectively, and a third click brought it back to blue. The color indicated different error type: Blue:) a point is not an error (default setting), Red) a point is definitely an error with high clinical importance and likely causes patient harm (e.g. medication errors), and Yellow) a point may be an error with medium or low clinical importance. This color coding allowed users to focus on potential weight errors and quickly annotate patient charts.

In the cases where the weights in a patient chart were too confusing or too complicated to annotate, two additional checkboxes were provided to indicate such issues for the research team's information.

Multiple Charts in a Grid

Annotating individual patient charts one-by-one can be very time-consuming. As such, the idea of displaying multiple charts at once in a grid was introduced. Due to the fact that the majority of patient charts did not contain a weight error, it is expected that human eyes can scan through the charts very quickly and identify weight errors based on the trend. That is, patient charts containing errors or with complex weight trends would stand out visually and then could be viewed and annotated in the individual chart display. The grid size was designed to be adjustable (i.e. 3x3 or 5x5) through the administration interface. An example of the grid display is presented in Figure 3.

Annotation Flow

The individual patient charts can be annotated in two ways. One way was to annotate a chart immediately after clicking it in the grid. The other was to first go through the whole dataset in the grid views and select all charts of interest, and then annotate the selected charts one-by-one as a second step. The former is called "one-step annotation" (1SA), which was implemented by creating a pop-up of the individual patient chart when it is clicked in the grid (as shown in Figure 3). The latter is called "annotation" (2SA), where clicking a chart in the grid would only highlight it without a pop-up. After browsing thought all grids (whole dataset), the selected charts were displayed one-by-one as individual patient charts for annotation.

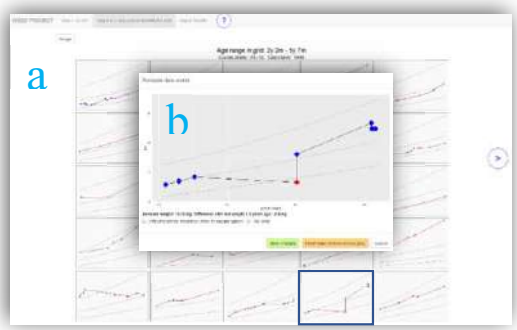

Figure 3 – Overview of the Main User Interface in One-step Annotation: a) Multiple Charts in Grid (5x5) and b) Individual Patient Chart Display as a Popup after User Selection.

Phase 2 – Iterative Refinement through Group Discussion

After the core functionality and user interface of the tool were created, the visual annotation tool was reviewed and iteratively refined in the DSAW meetings for several weeks. This phase was ended by the informal user testing with eight DSAW members. The user feedback was summarized in Table 2 in four categories. The overall feedback was positive, especially on the intuitiveness and the grid display of the charts, which confirmed our design to support rapid annotation. Improvements were made in annotation, interpretability, navigation, and system performance to produce the first stable version of the visual annotation tool.

Table 2 – User Feedback from Informal Testing in Phase 2

Category	Description	Action taken
Annotation	Points sometimes difficult to select	Radius for selection increased
	No easy way to reset annotation in a graph	Create a "remove all annotation" option
Interpret-ability	Get more detail about certain points	Hovering will display a point's weight and the time and weight difference with the previous one
Navigation	Instructions very limited	Tutorial mode and help button implemented
	Button to go to next page not intuitive	Button redesigned
System Performance	Large grids update very slowly	Mark chart instead of updating whole grid
	When new grid is loading, it seems that the app is frozen	Loading message now displayed
	Errors for accessing the app	With help of IT access now easier over network

Phase 3 – Experiment Workflow and Pilot Testing

In the pilot testing, five participants (two medical experts and three clinical informaticians) were recruited. Following the experiment protocol, each of them was assigned two datasets (225 charts per set) and provide feedback after completing the tasks. The average time to complete the first and the second dataset was 8.15 min (standard deviation, or SD: 2.8) and 6.3 min (SD: 2.1), respectively. There was a 2-minute decrease in completing the second dataset, which was due to the learning curve as reported by the participants, although the change was not statistically significant (p=0.097). The average SUS score was 78.5 (SD: 10.6), which confirmed the system to have above average usability. Additional feedback through the structured interview was positive, especially on the ease of use with intuitive user interface and fast learning curve. The workflow was confirmed to be reasonable and required no changes.

Discussion

In this paper, we reported the design and pilot evaluation of a web-based visual annotation tool to support the rapid annotation of weight errors. The tool was easy to use and has configurable settings (grid size and annotation flow), allowing users to optimize their annotation based on personal preferences. The intuitive design originated from the traditional growth charts and utilized a set of visual analytics techniques, providing expert users with a familiar yet enhanced chart review experience to identify pediatric weight errors.

At the time of completion of the current study, Conlen *et al*. published a paper at the Special Interest Group on Computer-Human Interaction in the Association for Computing Machinery (ACM CHI conference) about design principles for visual analytics in operations contexts [11]. This paper lists seven design principles that support and justify many of our design ideas of the visual annotation tool as discussed below. Principle 1 and 2 state that data must come with context and relationships between points must be shown. In our design, the adoption of digital growth charts with population percentiles provided a familiar experience for the annotators to interpret weights based on all other weight points in a chart (the context). Moreover, additional time and weight change information to the previous point can be viewed by hovering above a point of interest (the relationships). The context and relationships provided in our visual annotation tool were sufficient enough for experts to annotate weight errors in nearly all cases with high confidence, requiring no additional EHR data for interpretation, which may be hard to get and can slow down the annotation process. Principle 3 states that users should be able to travel through the data along the most important decisional dimension. In our design, the most important decisional dimension is the weight trend as a function of age in days and weight values. Given that abnormal weight patterns are rare but easily screened by medical experts, the individual patient charts were organized in grids so that users can easily page through the dataset to check the weight trends. Moreover, our design of displaying multiple instances at the same time in a resolution that preserves the overall pattern greatly increased the annotation speed, which is directly linked to Principle 7, where data should be shown at the resolution for the task at hand. In this two-level design (grid view versus individual charts), users can first identify suspicious patient charts and then annotate individual weight points as two distinct tasks. Principle 4 recommends that the user interface be flexible and able to adapt to the user's input. In our design, the grid size and annotation flow (1SA or 2SA) can be configured based on user preferences using the administration interface. Principle 5 indicates the need to surface issues early, which was done in our development process through the Agile Manifesto. Principle 6 requires that no data are removed, even if they are not used. By separating our input database (weight data) from the annotation database, it is ensured that only relevant input data was retrieved and never got overwritten or changed.

In addition to our effective design, the pilot testing confirmed the smoothness of our workflow and prepared us for the formal user-centered evaluation. In the pilot testing, participants were able to annotate 225 charts in less than 9 minutes. As reported by the participants, learning curve was quick since the participants were able to spend less time (2 minutes less) annotating the same amount of records. Extrapolating the results, 1500 charts may be annotated in 60 minutes, which indicates the achievement of our design goal to support rapid collection of expert-annotated weight errors.

One limitation in the pilot evaluation is the inability to validate the accuracy of annotation given that there was no "gold standard" (or ground truth) of weight errors. However, the gold standard may not be required in this case since we are focusing on the clinical importance of the errors, that is, whether abnormal weights can cause patient harm and subsequently require clinician's attention in busy clinical routines. We believe a reference standard generated by medical experts is sufficient for the development of an advanced algorithm to detect weight errors. Another limitation is the lack of formal user testing with a larger sample size. We have planned the next phase of the evaluation where 40 medical professionals will be recruited to further validate the visual annotation tool. Since our pilot testing has confirmed the smoothness of the experimental workflow, we are ready to move on to this next phase.

Once the tool is formally evaluated, we will use it to collect at least 15,000 patient charts as the reference standard, upon which machine learning algorithms will be trained to detect weight errors. The large amount of annotated patient charts enables the discovery of interesting and hidden patterns from the data using machine learning techniques, rather than predefined rules or thresholds. Our future work also involves developing a visual annotation tool as a generalized self-service tool for annotating time-series data since the concepts and process in the current scenario can be applicable to the datasets that are imbalanced (very few positives) and have temporality as a key dimension.

Conclusions

In this paper, we presented our design and pilot evaluation of a visual annotation tool to rapidly collect expert-annotated weight errors for the training of machine learning algorithms. The design and evaluation were rolled out in three phases, namely, Design of core functionality and user interface, Iterative refinement through group discussion, and Experimental workflow and pilot testing. The results showed positive user feedback and confirmed the achievement of our design goal to support effectiveness and efficient expert annotation. The pilot experiment prepared us for the formal user-centered evaluation in a lab setting as the next step. We will continue this research investigation with the ultimate goal of developing an advanced clinical decision support tool to alert clinicians with erroneous weight values and subsequently prevent adverse events and patient harm in clinical practice.

Providing Comorbid Decision Support via the Integration of Clinical Practice Guidelines at Execution-Time by Leveraging Medical Linked Open Datasets

[a] *NICHE Research Group, Faculty of Computer Science, Dalhousie University, Halifax, Nova Scotia, Canada,*

Abstract

Clinical Decision Support Systems (CDSS) utilize computerized Clinical Practice Guidelines (CPG) to deliver evidence-based care recommendations. However, when dealing with comorbidity (i.e., patients with multiple conditions), disease-specific CPG often interact in adverse ways (e.g., drug-drug, drug-disease interactions), and may involve redundant elements as well (e.g., repeated care tasks). To avoid adverse interactions and optimize care, current options involve the static, a priori integration of comorbid CPG by replacing or removing therapeutic tasks. Nevertheless, many aspects are relevant to a clinically safe and efficient integration, and these may change over time—task delays, test outcomes, and health profiles—which are not taken into account by static integrations. Moreover, in case of comorbidity, clinical practice often demands nuanced solutions, based on current health profiles. We propose an execution-time approach to safely and efficiently cope with comorbid conditions, leveraging knowledge from medical Linked Open Datasets to aid during CIG integration.

Keywords:

Practice Guideline, Decision Support Systems, Clinical; Comorbidity

Introduction

Clinical Practice Guidelines (CPG) are disease-specific and evidence-based recommendations to guide diagnosis, prognosis, and treatment [1]. By computerizing CPG as *Computer Interpretable Guidelines (CIG)*, they can be utilized by *Clinical Decision Support Systems (CDSS)* to deliver evidence-informed care recommendations. While CDSS can effectively manage a single, complex condition, they often cannot cope with multiple illnesses in a single patient (i.e., comorbidity). Indeed, managing comorbid conditions in a patient is a complex problem, and requires avoiding adverse interactions (e.g., drug-drug or drug-disease), by tailoring or adding new therapeutic interventions; and optimizing care and resource utilization, by eliminating redundant investigations. Hence, the direct, concurrent application of multiple disease-specific CIG is considered neither a safe nor efficient option.

A possible approach for managing comorbidity involves reviewing existing, disease-specific CPG, and manually integrating their workflows to yield a single, clinically safe and resource-optimized clinical workflow. Examples include the England and Wales NICE (National Institute for Health and Care Excellence) CPG [2], which manages kidney disease combined with hypertension, lipids and hepatitis C; and Abidi [3] performed a manual, ontology-based integration of CIG for Congestive Heart Failure (CHF) and Atrial Fibrillation (AF). Nonetheless, this solution is considered impractical, since it is not feasible to apply it to every possible comorbidity. In line with his, a range of computer-based approaches have been proposed to semi-automatically integrate comorbid CIG [3-7]. These approaches tend to focus on the a priori integration of comorbid CIG to realize a single, static clinical workflow. Nevertheless, we observe that execution-time aspects driving *clinical workflow execution*—i.e., lab test outcomes, medical resource availability, care delays, and the dynamic patient's health profile—also affect the clinical safety and efficiency of *comorbid CIG integration*. Due to runtime delays, test outcomes or changes in the patient's health parameters, integration decisions may need to be applied, adapted or reverted. Hence, we argue that a comorbid CIG integration approach should incorporate the *execution-time flexibility to dynamically apply or revise previous integration decisions*, in light of evolving clinical profiles and operational aspects. Below, we introduce 3 running examples (based on illness-specific CPG) which will be used to illustrate our work:

- *OA-Diabetes comorbidity*: both osteoarthritis (OA) and diabetes guidelines recommend Non-Steroidal Anti-Inflammatory Drugs (NSAID), such as aspirin and ibuprofen. Since NSAID increase the risk of bleeding in OA patients, this type of drug should only be described once for a comorbid patient.

- *AF-CHF / COPD-PE*: many illnesses require imaging scans, ECG and other tests (e.g., spirometry) at a point-of-care or healthcare facility. With many of these illnesses often occurring comorbidly, such as AF-CHF and Chronic Obstructive Pulmonary Disease (COPD) – Pulmonary Embolism (PE), grouping these tests into a single visit will improve the patient's quality of life and reduce incurred costs.

- *HTN-Diabetes*: thiazide diuretics such as Methyclothiazide are often prescribed for treating hypertension (HTN). However, they may worsen glycemic control for diabetes patients. In regular cases, the dose of thiazide diuretics should be reduced; when creatinine clearance is low and volume control is needed, it should be replaced by loop diuretics.

We present a knowledge-driven, execution-time approach for integrating comorbid CIG into a clinically safe and efficient comorbid clinical workflow. To cope with execution-time aspects and clinical pragmatics, our approach supports (1) refining or reverting integration decisions as more data becomes available—such the outcomes of medical tests, unforeseeable runtime delays, or limited hospital resources; and (2) defining alternative CIG integration decisions, which are conditional on the patient's health profile and other clinical events. Our approach involves a *CIG Integration Framework*,

which employs a Semantic Web based approach to CIG representation, integration and execution. To support the identification of adverse interactions, we leverage various Linked Open Datasets (LOD), including the SNOMED CT ontology[1], the Drug-Drug Interactions Ontology (DINTO)[2], the Drug Ontology (DrOn)[3] and Bio2RDF DrugBank ontology[4].

Methods

Our approach supports a practitioner in (a) identifying the set of clinical tasks, called *CIG integration points*, which could result in loss of clinical safety or efficiency in comorbid sitations; (b) given these integration points, instantiating appropriate *CIG integration policies* that ensure clinical safety and efficiency of the integrated CIG. In particular, a *CIG integration policy* is instantiated to deal with a particular comorbid patient scenario: e.g., to cope with drug interactions in a HTN-Diabetes comorbidity, a policy is instantiated to adjust dosages of Methyclothiazide.

The CIG Integration Ontology (*CIG-IntO*) defines the core terms for representing, integrating and executing CIG. We note that the SNOMED CT taxonomy is integrated into our CIG-IntO ontology, with an extended mapping to other ontologies (DrOn, DINTO, DrugBank). As we will illustrate in the paper, by leveraging knowledge from these datasets, our CIG framework can aid the practitioner in discovering CIG integration points.

A CIG integration policy is responsible for coordinating the execution-time integration of comorbid CIG; which is done by *operating on a multi-level state machine*. At runtime, these state machines manage the lifecycles for integration points. We elaborate on these lifecycles, and the available integration operations, below. Next, we discuss the high-level semantics of our proposed CIG integration policies.

Clinical task lifecycles

Workflow-related task lifecycle

Fig. 1 shows the workflow-related clinical task lifecycle.

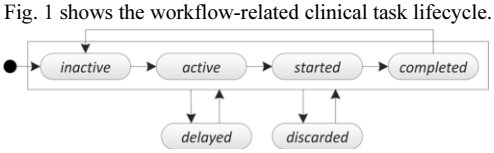

Figure 1– State machine for the CIG task workflow lifecycle.

During regular execution, a CIG task travels from *inactive* to *active* when it is next in line for execution. This may occur when its associated pre-conditions are satisfied and/or the previous task was completed. The practitioner selects an *activated* task for execution at their discretion, thus moving it to the *started* state. Finally, an *activated* task moves to the *completed* state when a practitioner marks it as complete, or when indicated by an external system (e.g., lab information system). Below, we exemplify the *CIG execution semantics* [8] (using OWL2 DL [9]) that move *inactive* tasks to the *active* state:

$$InactiveTask \cap TaskWithSatisfiedCondition \cap \exists hasPrevious.CompletedTask \subset \exists hasNewTaskState.Active \quad (1)$$

An *InactiveTask* with a satisfied pre-condition (*TaskWithSatisfiedCondition* class) and a prior, *completed* workflow task (*hasPrevious* relation), will be assigned the new *Active* state.

To coordinate the integration of comorbid CIG, an integration policy can apply *integration operations*, which move a clinical task to the *delayed* or *discarded* state, or *replace* a task in the CIG workflow. To ensure continuing clinical safety and efficiency in light of changing execution-time circumstances, our approach supports *reverting* these operations as well.

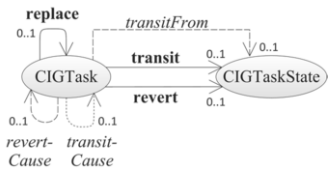

Figure 2– Integration operations on clinical tasks (CIG-IntO).

The *transit* relation indicates a transit operation on a CIG task (*CIGTask*) to a particular state (*CIGTaskState*). To support reverting the operation, the *transitFrom* property keeps the original *from* state. The *revert* operation is represented by the *revert* relation, indicating the state that the CIG task should be reverted to. The *replace* relation indicates the clinical task (subject) to be replaced and the replacement task (object). The causes for *transit* and *revert* operations are kept as well.

Outcome-related task lifecycle

Various outcome-related information, including medical test results or physician/patient choices, will only become available as the clinical workflow progresses. When faced with such new execution-time information, additional integration operations may be needed, while previous operations may need to be adapted or reverted. To that end, CIG tasks additionally feature an outcome-related lifecycle:

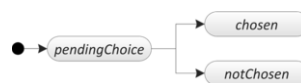

Figure 3– Integration operations on clinical tasks.

A clinical task is in the *pendingChoice* state when no choice has yet been made at the nearest preceding decision node; i.e., it is still unknown whether the task will be executed. After a choice is made, all tasks in the "chosen" branch travel to the *chosen* state, up until the next decision node; and tasks in the non-chosen branch(es) travel to the *notChosen* state. In other words, tasks in the *chosen* state are in line for execution, while *notChosen* tasks will not be executed.

CIG Integration Policies

We present an initial set of CIG integration policies to safely and efficiently integrate comorbid CIG at execution-time. We formalize their high-level semantics in terms of the CIG Integration Ontology (CIG-IntO) and First-Order Logic (FOL) rules. These integration semantics are informed by, and operate on, the multi-level state machine introduced previously.

EquivTasksPolicy

A practitioner creates an *EquivTasksPolicy* instance to cope with equivalent tasks: e.g., both OA and diabetes guidelines recommend NSAID, but this type of drug should only be prescribed once, since it increases risk of bleeding. To that end, the practitioner identifies the integration points and instantiates an *EquivTasksPolicy* as follows (using Turtle syntax[5] with *CIG-IntO* as default namespace):

```
:NSAID_equiv a :EquivTasksPolicy ;                    (2)
   :equivTask :task_OA_NSAID ;
```

[1] http://browser.ihtsdotools.org/
[2] https://bioportal.bioontology.org/ontologies/DINTO
[3] https://bioportal.bioontology.org/ontologies/DRON
[4] http://bio2rdf.org/
[5] https://www.w3.org/TR/turtle/

```
:equivTask :task_Diabetes_NSAID ;
```

Here, the *equivTask* relation indicates the equivalent tasks, i.e., prescribing the NSAID medications, as integration points. Below, we elaborate on how these integration points may be identified, and the concrete integration semantics.

- Finding equivalent tasks

In CIG-IntO, many workflow tasks are attached to SNOMED procedures; which, if applicable, is further linked to the prescribed medication (Turtle syntax, "sno" is the SNOMED namespace). For instance, in the OA CIG:

```
:task_OA_NSAID a :WorkflowTask ;                    (3)
    :involves :presc_OA_NSAID.
:presc_OA_NSAID a sno:Prescription; sno:drugUsed sno:NSAID.
```

Since the relevant workflow tasks from both the OA and diabetes CIG are linked to a *Prescription* (subclass of *Procedure*) of the same drug (*drugUsed*), the system flags the (potential) comorbidity issue to the practitioner, indicating the two clinical tasks as integration points. Based on their medical knowledge and expertise, the practitioner may then proceed by instantiating an appropriate CIG integration policy.

- CIG integration semantics

An informed execution-time choice should be made on which equivalent task will be kept, and which one(s) will be discarded. Simply discarding an arbitrary task at *design-time* may negatively affect CIG execution, as shown in Fig. 4. Here, task T_1 was discarded at design time (Fig. 4.a) since it would have been executed last under normal circumstances. However, due to execution-time delays, task T_1 is executed first; meaning that the following tasks, such as T_2, which rely on task T_1 or its equivalent (i.e., T_A) having been executed, need to be delayed until T_A is executed (Fig. 4.b).

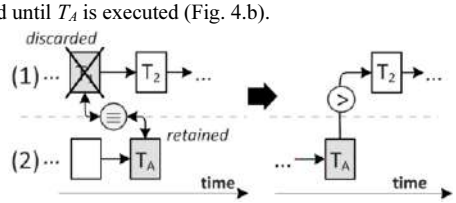

Figure 4– Integration operations on clinical tasks.

Our execution-time approach purposefully introduces a race condition; whichever task is reached first (i.e., *activated*) during execution will be retained. In Fig. 4, this means that T_1 will be retained instead of T_A, meaning that both workflows are able to proceed without delay.

These execution-time integration semantics can be represented using the following state-transition rule:

$$EquivTasksPolicy(p), intPt(p,t_1), intPt(p,t_2), t_1 \neq t_2, \quad (4)$$
$$ActiveTask(t_1), ChosenTask(t_2), NotDiscardedTask(t_2),$$
$$IncompleteTask(t_2), taskState(t_2,s)$$
$$\rightarrow transit(t_2,'discarded'), transitFrom(t_2,s), transitCause(t_2,t_1)$$

Once any integration point (*intPt)* is activated (t_1), any other integration point (t_2) part of a *chosen* branch, i.e., in line for execution, and not yet *discarded* or *completed*, will be moved to the *discarded* state (*transit* operation). The origin state (*transitFrom*) and cause (*transitCause*) are recorded as well. To simplify the formulation of integration semantics, we define complex OWL subclasses of *CIGTask*; e.g., *InactiveTask* class includes tasks with value *inactive* for property *state*.

ReplaceTasksPolicy

A *ReplaceTasksPolicy* instance is created to replace one or more tasks by safer and/or more cost-effective task(s). For instance, the thiazide diuretics prescribed for HTN may worsen glycemic control in case of HTN-Diabetes comorbidity. In clinical practice, solutions for such interactions are often nuanced, and depend on the patient's dynamic health profile. For normal cases, the dosage of thiazide diuretics should be reduced; but when creatinine clearance is low and volume control is needed, loop diuretics should be prescribed instead. This can be formulated as follows:

```
:thiazide_diuretics_diabetes a :ReplacePolicy ;          (5)
   :toReplace :thiazide_diuretics
   :replacement [
     :condition cond:default ;
     :element :low_dose_thiazide_diuretics ] ;
   :replacement [
     :condition [
       cond:operand :low_creatinine_clearance ;
       cond:conn cond:and ;
       cond:operand :volume_control_needed
     ] ;
     :element :loop_diuretics ] .
```

The *toReplace* relation indicates the integration point(s), i.e., the clinical task(s) to be replaced. The *replacement* relation indicates the conditional substitutions for the CIG task, marking (a) the condition (*condition* relation), which refers to the patient profile; and (b) the replacement task (*element* relation). The default substitution, i.e., with "default" condition, prescribes *low dose thiazide diuretics*; the second substitution prescribes *loop diuretics* in case *volume control is needed* and *low creatinine clearance* is observed.

Using our CIG framework, the practitioner can leverage LOD to identify such integration points. To that end, the *:thiazide_diuretics* task is linked to the related medication (e.g., see (3)). Based on this knowledge, there are multiple ways for the CIG framework find potential interactions:

- Finding drug-drug interactions (DDI)

Searching the DINTO and Bio2RDF DrugBank ontologies, the system discovers multiple DDI between Methyclothiazide and different types of insulin—if the patient was prescribed insulin for managing glucose levels, the system will flag these DDI to the practitioner together with the integration points. E.g., DrugBank encodes the DDI in question as follows:

```
drb:DB00232 dcterms:title "Methyclothiazide"@en ;        (6)
    drb:ddi-interactor-in db:DB00030_DB00232 .
drb:DB00030_DB00232 a drb:Drug-Drug-Interaction .
```

- Finding drug-illness interactions (DII)

The system finds that Methyclothiazide is a type of *Thiazide Diuretic* (SNOMED CT), which are categorized as *Hyperglycemia-associated Agents* (DrugBank); whereas Diabetes is a type of *Disorder of Glucose Metabolism* (SNOMED CT). Based on a DII knowledge source, which encodes adverse interactions between agents and disorders of that type, the system flags the DII and integration points to the practitioner.

- CIG integration semantics

When *multiple tasks* need to be replaced, as before, a choice needs to be made on which task to discard (see Fig. 4). In that case, a transition rule similar to (4) will be applied—which additionally ensures that other task(s) (i.e., t_2) are only discarded when a replacement was actually applied (see (7)). When only a *single task* is to be replaced (as in (5)), the *toReplace* task is simply discarded when it becomes active.

Based on the patient's current health profile, a substitution will be selected at execution-time, after which the *toReplace* task will be replaced in the CIG workflow (*NotApplied* ensures that a replacement is applied only once):

$$ReplaceTasksPolicy(p), intPt(p,t_1), ActiveTask(t_1), \quad (7)$$
$$replacement(p,r), condition(r,c), Satisfied(c),$$
$$NotApplied(r), element(r,t_2)$$
$$\rightarrow replace(t_1,t_2), applied(r,'true')$$

SimulTasksPolicy

To simultaneously execute certain clinical tasks, the practitioner creates an instance of *SimulTasksPolicy*. For instance, many comorbid illnesses involve imaging scans, ECG and

other tests (e.g., spirometry) at a point-of-care or healthcare facility; by grouping such medical tests together in time, we may improve the patient's quality of life and reduce healthcare costs. This can be encoded using *SimulTasksPolicy* as follows:

```
:simult_siteofcare_tests a :SimultTasksPolicy ;          (8)
  :simulTask [
    :involves [
      a sno:Evaluation_Procedure ;
      sno:placeOfTesting [ a sno:SiteOfCare ]
] ] .
```

In the above case, the policy aims to group in time any clinical task that *involves* any procedure of type of *Evaluation Procedure*, and with any *placeOfTesting* of type *SiteOfCare*. In SNOMED CT, medical tests such as ECG, MRI scans, spirometry are all subtypes of *Evaluation Procedure*; whereas *SiteOfCare* has subtype *Hospital*, among others. Based on the policy definition, the CIG integration framework identifies concrete integration points for the *SimulTasksPolicy*. Below, we exemplify such an integration point:

```
:task_AF_ECG a :WorkflowTask ;                           (9)
    :involves :proc_ECG_monitor .
:proc_ECG_monitor a sno:ECG_Monitoring ;
   sno:placeOfTesting sno:Hospital .
```

- *CIG integration semantics*

To group the identified integration points at execution-time, a *SimulTasksPolicy* will delay any activated *simulTask* until the other *simulTasks* have "caught up" (i.e., have also been activated)—at least, as long as it is clinically safe to do so.

In particular, the *max. (overall) delay* of the active task shows the max. period *the task may still be delayed* while safeguarding clinical safety. Hence, as long as the *max. delay* exceeds the (estimated) *activation time* of an inactive task, it will make sense, and not violate clinical safety, to delay the active task:

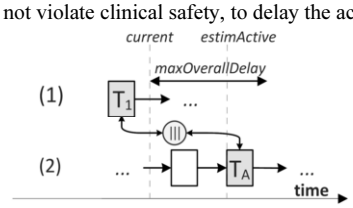

Figure 5– Example workflows for SimulTasksPolicy.

Here, the *max. overall delay* for T_1 exceeds the *estimated activation time* of T_A, meaning that T_1 can be safely delayed until T_A catches up. The following should hold: *current* + $maxOverallDelay_1 \geq estimActive_A$, which is formalized as follows:

$$maxOverallDelay(t_1, d_1), estimActive(t_2, a_2), t_1 \neq t_2, current + d_1 \geq a_2 \rightarrow delayCondition(t_1, t_2) \quad (10)$$

The *maxOverallDelay* property is calculated based on (a) the initial max. period that workflow tasks can be delayed while ensuring patient safety; and (b) any already incurred delays during execution, as well as the impact of discarded and replaced tasks. The *estimActive* property is calculated recursively from the prior task's *estimActive* time and duration.

The integration semantics are represented as follows:

$$SimulTasksPolicy(p), intPt(p, t_1), intPt(p, t_2), t_1 \neq t_2, ActiveTask(t_1), delayCondition(t_1, t_2), taskState(t_1, s), PendingOrChosenTask(t_2), InactiveTask(t_2) \rightarrow transit(t_1, 'delayed'), transitFrom(t_1, s), transitCause(t_1, t_2) \quad (11)$$

In case the *delayCondition* holds for an active task (t_1) and at least one other integration point (t_2), which is part of a branch with a pending decision or a chosen branch (*PendingOrChosenTask*), the active task will be delayed.

As the CIG execution progresses and more information becomes available, integration decisions may need to be adapted or reverted. When the delay condition no longer applies, the delay operation should be reverted:

$$SimulTasksPolicy(p), intPt(p, t_1), DelayedTask(t_1), transitCause(t_1, t_2), \neg(delayCondition(t_1, t_2)) \rightarrow revert(t_1, 'delayed'), revertCause(t_1, t_2) \quad (12)$$

In case the *delayCondition* no longer holds for a *delayed* task and the reason for the delay (*transitCause*), the delay operation will be reverted. Note that, at execution time, the delay condition could become valid again at any point; in that case, the *delayed* state transition (10) would be triggered again.

Secondly, when the operation's *transitCause*, i.e., reason for the delay, eventually becomes part of a non-chosen branch (*NotChosenTask*), it becomes pointless to delay the clinical task any further, and the delay operation will be reverted:

$$SimulTasksPolicy(p), intPt(p, t_1), DelayedTask(t_1), transitCause(t_1, t_2), NotChosenTask(t_2) \rightarrow revert(t_1, 'delayed'), revertCause(t_1, t_2) \quad (13)$$

Once the previously inactive task has caught up (i.e., is *activated*), task t_1 no longer needs to be delayed:

$$SimulTasksPolicy(p), intPt(p, t_1), DelayedTask(t_1), transitCause(t_1, t_2), ActiveTask(t_2) \rightarrow revert(t_1, 'delayed'), revertCause(t_1, t_2) \quad (14)$$

When multiple medical tests need to catch up, an active medical test will be delayed multiple times. By keeping the causes of task operations (*transit*/*revertCause* properties; Fig. 2), the integration algorithm reverts an operation *only once all its causes are reverted*; as discussed in the next section.

CIG Integration Algorithm

In this section, we discuss how the CIG integration algorithm applies the CIG task operations inferred by the integration semantics. We assume an underlying reasoner that is loaded with the rules representing the integration semantics. The CIG integration algorithm is called whenever dataset changes may lead the reasoner to fire one or more rules:

- Any tasks' state changes caused by the CIG execution algorithm (see *Workflow-related task lifecycle*).
- External events indicating execution-time delays (e.g., from scheduling software), which affects the estimated times (e.g., *maxOverallDelay, estimActive*).

The *performIntegration* function iteratively applies task operations and reverts until no more operations are inferred:

```
function performIntegration()                            (15)
  do
    op ← performTaskOperations()
    op ← op ∪ performTaskReverts()
  while (op ≠ ∅)
```

The *performTaskOperations* function calls the *performTransitOperations* and *performReplaceOperations function* (not shown). We show the former function below:

```
function performTransitOperations()                      (16)
  for each inferred transit operation:
    retract current state of task (= origin state)
    assert target state for task
    assert origin state(transitFrom),cause(transitCause)
end function
```

For each inferred *transit* operation, the function retracts the task's current state, and asserts its new state, keeping its origin state and transit cause. Below, we show *performTaskReverts*:

```
function performTaskReverts()                            (17)
  for each inferred revert operation:
    retract reverted cause (revertedCause)
    if all task transit causes ≠ ∅:
      retract current task state
      assert original target state (transitFrom)
end function
```

For each inferred *revert* operation, the "reverted" cause is retracted (e.g., see (11)-(13)). When no more *transit causes* are left, the task's current state is retracted and its original

state is asserted. We note that, by only reverting a *transit* operation once all its causes are reverted, we support scenarios where e.g., a medical test is delayed multiple times (see (10)).

The *CIG Client* (not detailed here) features a UI that visualizes the current state of comorbid CIG as a workflow, and allows clinicians to make decisions on task execution and integration.

Results

When deploying execution-time, comorbid CIG integration at a point-of-care, there is an expectation of timely recommendations. Hence, we evaluate our approach by measuring the performance of the CIG integration algorithm. To that end, we (a) modeled the comorbid CIG; (b) instantiated suitable CIG integration policies; and (c) executed the CIG integration algorithm to perform execution-time integration for a number of comorbidity scenarios.

We executed each experiment 10 times on a PC equipped with 8GB of RAM and an Intel® Core™ i7-3520 CPU. Table I shows the average performance results. Loading the comorbid CIG and integration policies took avg. ca. 270ms; calculating dynamic properties (e.g., *estimActive*) took avg. ca. 180ms.

Table 1 – CIG Integration Performance Results

Comorbid CIG Integration Scenario	performance (s)
EquivTasksPolicy	
(OA-diabetes) discard second NSAID	0.79
ConditionalReplacePolicy	
(HTN-Diabetes) in regular cases, reduce dosage; when creatinine clearance is low and volume control is needed, replace with loop diuretics.	0.94
SimulTasksPolicy	
group tests concurrently at health facility	0.9

Discussion

Table 1 shows that integrating comorbid CIG takes between 0.7 – 0.9s. We note that, since performance is mostly determined by the underlying reasoner (in our case, Apache Jena), selecting a more performant reasoner would improve performance. Nevertheless, we already consider these acceptable performance times for a consumer-grade PC.

To the best of our knowledge, the work by Anselma, Piovesan and Terenziani [4, 10] presents the first approach to focus on the temporal dimension for comorbid CIG integration. Analysis facilities allow a practitioner to analyse CIG for adverse interactions and identify solutions. To emulate our execution-time approach, the practitioner would need to frequently utilize these facilities *for any set of relevant actions*, and manually apply, adapt and revert integrations when needed. Wilk et al. [7] support a form of execution-time integration by repeating the integration process whenever new patient data becomes available. But the authors do not consider reverting integrations, and only supply two temporal revision operators. Zamborlini et al. [11] propose a rule-based approach that identifies repeated, alternative, and contradictory actions, and leverages external sources. In comparison, our work currently includes limited support for identifying adverse interactions by leveraging LOD.

Another aspect of our approach, not elaborated here due to space limitations, involves resolving conflicts between integration policies themselves. In future work, we aim to study more types of integration policies, and look into a global optimization scheme—currently, integration policies focus solely on their integration points, and disregard the global effect of their actions; e.g., a *SimulTasksPolicy* could delay a task that jeopardizes the success of more "important" policies.

Conclusions

We presented an execution-time approach and framework for comorbid CIG integration, which dynamically (a) applies CIG integrations, based on a priori defined integration policies and the latest execution-time data; (b) refines or reverts previous integrations, as more information becomes available at runtime. To provide solutions in line with clinical practice, alternative CIG integration decisions can be defined, which are conditional on the patient's up-to-date health profile. By leveraging knowledge from LOD, our framework helps practitioners in identifying adverse comorbid interactions, and formulating suitable integration policies.

Proactively Guiding Patients Through ADL via Knowledge-Based and Context-Driven Activity Recognition

William Van Woensel, Samina Abidi, Syed Sibte Raza Abidi

NICHE Research Group, Faculty of Computer Science, Dalhousie University, Halifax, Nova Scotia, Canada

Abstract

Assisted Ambient Living (AAL) focuses on self-sufficiency, assisting disabled people to perform activities of daily living (ADL) by automating assistive actions in smart environments. Importantly, AAL provides opportunities for dynamically guiding patients with a cognitive decline through an ADL. Activity recognition is a pivotal task since it allows detecting when an ADL is started by recognizing its constituent activities. When dealing cognitive decline, activity recognition should also be able to detect when activities are performed incorrectly—e.g., performed out-of-order, at the wrong location or time, or with the wrong objects (e.g., utensils)—which is nevertheless not a common goal in activity recognition. Moreover, it should be able to cope with non-uniform ways of performing the ADL that are nevertheless correct. We present a novel knowledge-driven activity recognition approach, which employs semantic reasoning to recognize both correct and incorrect actions, based on the ADL workflow as well as associated environment context.

Keywords:
Artificial Intelligence, Activities of Daily Living

Introduction

Improving the quality of life for cognitively disabled patients, given the current trend of aging populations, reduces the burden on healthcare systems since patients would be allowed to remain self-sufficient as long as possible. Assisted Ambient Living (AAL) that utilizes "smart" environments outfitted with objects with sensing, actuating, computing, and communication features, is a promising solution to assists disabled people in performing daily living activities. "Smart" hardware is available off-the-shelf; whereas software frameworks [1] for interacting with smart environments, and ontologies (e.g., SOUPA [2], DogOnt [3]) for describing a context in smart homes, have been developed. Concurrently, consumer smartphones and smartwatches have become affordable and ubiquitous adding personal sensors (movement, activity, location) and communication capabilities to a smart home.

When dealing with cognitive decline, AAL supplies a unique opportunity to pro-actively assist patients: alerting them about overdue ADL, guiding them through an ADL while they perform it, and correcting their activities if needed. In this setting, accurate, comprehensive, and fault-tolerant activity recognition is paramount, as it enables the detection of ADL by recognizing their constituent activities, in a robust way that copes with incorrect actions performed by cognitively disabled patients. Data-driven and machine-learning based techniques have proven their usefulness in achieving high-accuracy activity recognition, but they require a large training dataset (cold-start problem), and the learned activity model cannot be reused for other individuals or environments. Knowledge-driven methods for activity recognition, using Semantic Web technologies, rely on semantically modeling the AAL environment and the activity's workflow [4]. Although this is initially complex and labor-intensive, knowledge-driven activity recognition is shown to offer greater flexibility and reusability to infer other ADL activities [5].

Research in knowledge-driven activity recognition, especially ADL recognition, has pursued two main issues: the representation of the ADL workflow to support recognition and resolving uncertainty in recognizing an activity due to noisy sensor input and non-uniform individual behavior. Knowledge-driven activity recognition methods typically model high-level ADL in terms of their constituent tasks [6], possibly including their sequential order [7]; or as a qualitative temporal model, based on Allen's temporal logic [8]. For instance, Chen et al. [6] perform activity recognition by utilizing semantic reasoning to classify unknown activities into a known, high-level activity class. Knowledge-based activity recognition methods have dealt with uncertainty by employing variations of ontological reasoning; such as log-linear DL [7], to assign a belief value about activity based on the sensor observations. In contrast, we aim to address uncertainty in the form of flexible, semantics-based ADL representations that, by design, deal with uncertainty caused by non-uniform individual behavior. Indeed, many correct ways typically exist to perform an ADL. An individual should be able to perform an ADL in their idiosyncratic way, as long as it is in line with the general workflow. Moreover, when dealing with cognitive decline, activity recognition should detect when necessary ADL is *not being performed*, or being performed *incorrectly* including actions that are out-of-order, at the wrong time or location, or utilizing the wrong objects (e.g., utensils). To the best of our knowledge, this goal is not addressed by current knowledge-driven approaches, and requires (a) built-in support by the activity recognition method; (b) comprehensive annotation of the ADL workflow with context information, including the needed objects (e.g., utensils, foodstuff), and an appropriate location and time; and (c) comprehensive context awareness in smart homes.

In this paper, we present a novel approach to computerizing complex ADL workflows, using an OWL ontology to represent ADL tasks and their temporal relations; and apply these constructs to perform knowledge-based activity recognition. Important goals include (a) dealing with uncertainty caused by non-uniform behaviors, i.e., idiosyncratic ways of doing things which are nevertheless correct; (b) coping with mistakes while executing ADL, as they are performed by individuals with cognitive decline; and (c) prompting to perform ADL at appropriate times and contexts. To support these goals, we utilize Semantic Web ontologies for annotating ADL workflows, such as the DogOnt Ontology [3]. We formally define the semantics of

our ADL workflow constructs, which are inspired by general (e.g., BPMN) and specialized (e.g., Clinical Practice Guideline) workflow languages. The paper is based on prior work [9], which we extend here with context-awareness, personalization towards the individual, and a more flexible ADL workflow notation and semantics.

Methods

Modeling Workflows for Activities of Daily Living

To model ADL workflows that meet our goals, we drew inspiration from formalisms for general-purpose workflows (e.g., UML activity diagrams, BPMN), computerizing Clinical Practice Guidelines (CPG), as well as high-level UI-design task models. Workflow languages typically include constructs to indicate start- and endpoints, and sequential and parallel (e.g., split and join) relations between tasks. CPG workflow languages typically support grouping multiple sub-tasks into high-level clinical tasks, as well as pre- and post-conditions. Also, tasks may be explicitly assigned to a patient or physician. In the UI design domain, Paterno et al. introduced ConcurTaskTree method for designing high-level UI task models, which similarly employs a hierarchical structuring of tasks and a set of temporal relations, among others [10]. In general, grouping subtasks into high-level or hierarchical tasks and the availability of diverse temporal relations suits our needs. ADLs are often decomposable into multiple levels of tasks, and temporal constraints may bind the correct performance of an ADL. At the same time, to cope with non-uniform behaviors, an ADL needs to encode the multitude of different ways in which activities can be performed ideally, without explicitly including all task permutations. Based on the state of the art, we proposed six workflow relations for modeling ADL:

- *Grouping tasks*: grouping lower-level tasks into a high-level, composite task that is complete once all of its (non-optional) constituent tasks are complete.
- *Order independent*: if no workflow relation is indicated between tasks, they may be executed in any order.
- *Sequential* ($T_1 >> T_2$): ordering the operands; the second task (T_2) cannot be begin before the first (T_1) is completed, where the completion of T_1 enables T_2 to take place. We present the following subtypes:
  - *Timeout-sequential* ($T_1 >>_{<timeout>} T_2$): once T_1 is completed, T_2 only starts once timespan passes.
  - *Conditional-sequential* ($T_1 >>_{[condition]} T_2$): once T_1 is completed, T_2 may only start once the condition is met.
- *Alternative* ($T_1 [] T_2$): either task can be chosen; once a choice is made, the other task can no longer be started. We further introduce the following subtype:
  - *Conditional-alternative* (T_1 [*condition*] T_2): if the condition is satisfied, T_1 is performed; else, T_2 is performed.
- *Iterative* ($T_{\{n, m\}}$): task is fulfilled between *n*, *m* times
  - *Optional* ([T]): task may be skipped (n=0, m=1).

In Figure 1, we show an example of ADL for making tea using a kettle. When a task was assigned to the smart home, it was annotated with "smart home" icon. The *StartFilling* composite task involved the *GetKettle* and *OpenTap* atomic tasks. These might be performed in any order; depending on individual's idiosyncrasies (and wastefulness!). Users might choose first to get the kettle or open the tap. Regardless, both tasks needed to be completed before moving on to *StopFilling*; and only after 3-5 seconds, or until the kettle is half-full (depending on the sensing/actuating capabilities of the smart home). Similarly, *StopFilling* task included the order-independent *PutKettleOnStove* and *CloseTap* atomic tasks. *TurnStoveOnMax* may be performed in any order (e.g., getting the kettle, turning on the stove, opening the tap). Although multiple degrees of freedom were introduced to allow idiosyncratic behavior, the workflow enforced a correct performance of the ADL. For example, an individual cannot get the kettle and put it on the stove without filling it first with water. We noted that *GetCup* and *GetTea* might be performed at any point, and were prerequisites for *PutTeaInCup*.

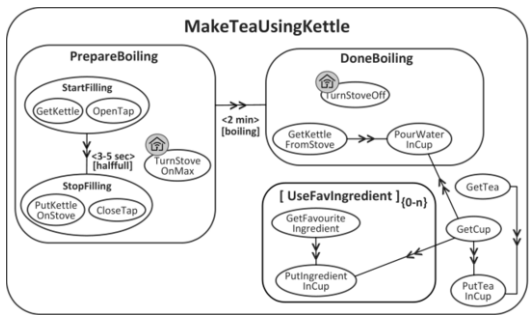

Figure 1– MakeTea ADL.

Once all *PrepareBoiling* subtasks were completed, after 2 minutes or once the water was boiling (depending on sensing capabilities), the individual could proceed with *DoneBoiling* subtasks. The task *GetKettleFromStove* was a prerequisite for *PourWaterInCup*, together with *GetCup* that must be completed first. The *GetTea* and *PutTeaInCup* might be performed at any point in the beginning; while the kettle was boiling; or after the water was poured in the cup. Moreover, individual might perform the optional up to n times that involved *GetFavouriteIngredient* and *PutIngredientInCup*. Finally, *TurnStoveOff* might be performed at any time.

Using our ADL ontology, the *MakeTeaWithKettle* ADL was encoded using RDF. Below, we discuss how this semantic ADL description can be extended with environment context.

Annotating Tasks with Environment Context

By associating ADL tasks with context, such as the required objects (e.g., utensils, foodstuff), and location and time where it should took place, the system can achieve the following:

- Guidance: inform the individual on which objects are needed, and where they are found (e.g., kitchen cupboard), together with the task's location and time.
- Troubleshooting: correlate the specified objects to the utilized objects with their time and location, and highlight mistakes.
- Prompting: based on the current task and time, prompt the individual to perform the (next) task.

Below, we illustrate how tasks from MakeTeaUsingKettle were annotated to support such features (Turtle notation, "do" represents DogOnt[1], "adl" is our custom ADL ontology):

adl:MakeTeaUsingKettle **adl:todoAt** time:around4pm ; **(1)**

[1] Since DogOnt was designed for home automation, we extended it with e.g., support for non-automated devices (e.g., kettle, water tap).

adl:requires [**a** *do:Kitchen*] ;
adl:GetKettle **adl:requires** [**a** *do:Kettle*] .
adl:PutKettleOnStove **adl:requires** [**a** *adl:Kettle*] .
adl:OpenTap **adl:requires** [**a** *do:WaterTap*] .
adl:CloseTap **adl:requires** [**a** *do:WaterTap*] .

These context annotations supported the adaptation to the current context and the individual's profile. Using blank nodes as existential variables, these context annotations represented a query over the environment context, including the location model (i.e., the layout of rooms and their contents), which is collected by the smart home sensors and the profile. Once resolved, these annotations would indicate concrete locations and objects, as well as the latest context state. For instance:

do:ikeaKettle **a** *do:Kettle* ; **(2)**
do:initiallyAt *do:kitchenCupboard1* ;
do:currentlyAt *do:stove1* .
do:kitchenCupboard1 **do:alwaysAt** *do:kitchen* ;
do:image *do:img1927202* .

In our case, the blank node expression in lines 2-3 (code 1) resolved the kettle activity; which specified *do:initiallyAt* in *do:kitchenCupboard1* and provided its latest detected location (*do:currentlyAt*) *do:stove1*. The cupboard was *do:alwaysAt* the kitchen, with an image illustrating its location. The detection of *do:currentlyAt* depended on the smart home's capabilities (e.g., a "smart" kettle with RFID tag that can be read by the stove). Using this concrete context, the system indicated necessity of a kettle for the second and third task (code 1) and the location of the kettle (*guidance*), alerted when the wrong item was used for boiling water (*troubleshooting*), and prompted the individual when tea-time is due (*prompting*).

ADL Workflow Semantics

Figure 2 shows the SmartAssist Ontology. Each *TemporalRelation* (e.g., sequential, alternative) had a left and right operands; whereas a *WorkflowTask* might act as the left or right operand for any number of temporal relations. A *Task* could be either an *AtomicTask* or *CompositeTask*. The former included tasks assigned to individuals (*PatientTask*) and the smart home (*SmartHomeTask*); and the latter included *ADL* themselves. The *TemporalRelation* class included a subclass for each type of temporal relation; with *SequentialRelation* and *AlternativeRelation* including subclasses for their conditional (and timeout) versions. Further, a *Task* could be associated with one or more *Context* (see code 1). To support the formal semantics of ADL workflows, each *Task* had an associated *State (inactive*, *active*, *started*, *completed*, or *error)*. These states and the transitions between them, are shown in the form of a state machine in Figure 3.

Each task was initially in the *inactive* state. A task became *active* when it was next in line for execution, as determined by the ADL workflow (multiple tasks may be *active* at the same time). Inversely, *inactive* meant that the task should not be executed at this time. The *completed* state indicated that the task was successfully executed, and was marked either by the individual or the smart home, depending on its sensing capabilities. In case an error was detected with regards to the task's execution, the state would transition to the *error* state. Orthogonal to these states, a task might also be in the *ready* state, meaning that their required-context had been met; or the *todo* state, meaning that their todo-context was met (i.e., at which the task should be done). For instance, *MakeTeaUsingKettle* (code 1) required the individual to be inside the kitchen (requires-context), and the task should be done at around 4 pm (todo-context); whereas *GetKettle* required first retrieving the kettle from the kitchen cupboard (requires-context). Although a task could be in multiple states, the *inactive* state was retracted once a task moved to the *active* state.

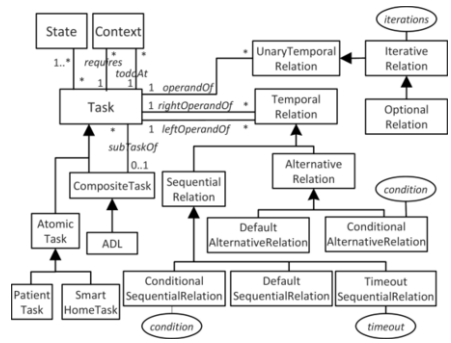

Figure 2– SmartAssist Ontology.

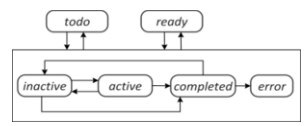

Figure 3– Task states and transitions between them.

The formal semantics of an ADL workflow was defined in terms of state transition rules that governed the transitions between task states. We listed them below using Description Logics (DL). To simplify the DL expressions, we assumed that each *Task* was assigned a type based on its current state. A task in the *completed* state was assigned the *Completed* type; a task in any other state was assigned *Incompleted*; operands for the *optional* relation were members of *Optional*.

(a) Any ↔ Ready

(a.1) $Task \cap \forall requiresContext.(Active) \subseteq Ready$

An ADL task was moved to the *ready* state once all its *required* context was active—e.g., in case the individual retrieved the *ikeaKettle* for making tea (see code 1, 2).

(b) Inactive → Active

Any ADL task for which any higher-level composing task (*subTaskOf* property) was *active,* was considered for transitioning to the *active* state (as indicated in the rules below).

(b.1) $Task \cap \forall subTaskOf.(Active) \cap \neg(\exists rightOperandOf.(TemporalRelation)) \subseteq Active$

Tasks not acting as the right operand for any temporal relation (b.1) were moved to the *active* state. For instance, *GetTea* and *GetCup* would become *active* once the ADL was *active*.

Note that this means that any ADL will always be activated as well, since they are not related to higher-level composing tasks, nor act as operands for temporal relations.

(b.2) $Task \cap \exists subTaskOf.(Active) \cap \forall rightOperandOf.($
$(SequentialRelation \cap \exists leftOperand.(Completed \cup Optional))$
$\cap (DefaultSequentialRelation \cup$
$(ConditionalSequentialRelation \cap \exists condition.(Satisfied))$
$\cup (TimeoutSequentialRelation \cap \exists timeout.(Satisfied)))$
$\subseteq Active$

Regarding the right-hand operands of *sequential* relations, for all incoming sequential relations, the left operand must be either *Completed* or *Optional*, before the task was moved to the *active* state. In case of the *conditional* or *timeout* version, the condition or timeout also needed to be satisfied,

respectively, before moving to *active*. For example, *PutTeaInCup* only moved to *active* once *GetCup* and *GetTea* were *activated*; and *StopFilling* only became *active* once the *StartFilling* task was *completed* and 3-5s had passed or "half-full" was satisfied (depending on the capabilities).

(b.3) $Task \cap \exists subTaskOf.(Active) \cap \exists operandOf.(DefaultAlternativeRelation) \subseteq Active$

Any operand of *default-alternative* directly moves to *active*.

(b.4) $Task \cap \exists subTaskOf.(Active) \cap \exists rightOperandOf.(ConditionalAlternativeRelation \cap \exists condition.(Unsatisfied)) \subseteq Active$

For the *conditional-alternative* version, in case its condition was not met, the right operand would move to *active*. Otherwise, the left operand task would simply remain active, due to the rule in (b.1) that activated all left- (or non-) operands.

(c) Active → Inactive

(c.1) $Task \cap Active \cap \exists leftOperandOf.(ConditionalAlternativeRelation \cap \exists condition.(Unsatisfied)) \subseteq Inactive$

In case the *conditional-alternative* relation's condition was not met, its left operand would move to *inactive*.

(d) Active → Complete

(d.1) $Task \cap Active \cap \forall operandOf(AlternativeRelation \cap \exists operand.(Completed)) \subseteq Completed$

An ADL task acting as operand for an *alternative* relation would be completed once one of the other operands were completed. The user might only execute one alternative task.

(d.2) $CompositeTask \cap \forall hasSubTask.(Completed) \subseteq Completed$

A composite task would be moved to the *completed* state once all its subtasks were *completed*. For instance, the *StopFilling* task would move to *complete* once its subtasks *PutKettleOnStove* and *CloseTap* were *completed*.

(e) Completed → Inactive

(e.1) $Task \cap Completed \cap Active \cap \forall transitiveSubTaskOf.(ADL \cup Completed) \subseteq Inactive$

Any *completed* task that is part of a *completed* ADL (*transitiveSubTaskOf* property) will move back to the *inactive* state.

(f) Completed → Error

(f.1) $Task \cap Inactive \cap Completed \subseteq ErrorTask$

Regarding erroneous performance, a task that was *completed* while *inactive* would move to the error state since it was not executed within ADL workflow. For instance, *CloseTap* task would move to the error state if it was *completed* in the *inactive* state and before completing *StartFilling* composite task.

(f.2) $Task \cap Completed \cap \neg Candidate \subseteq ErrorTask$

In case a *completed* ADL task was not *Ready*, i.e., its *requiredContext* had not yet been reached (a.1), it would be moved to the error state such as completing *GetKettle* with a different item (e.g., glassware).

(g) Active → Todo

(g.1) $Task \cap Active \cap todoAtContext.(Active) \subseteq TodoTask$

An *active* task with active *todoAt* context would move to the *todo* state—e.g., *MakeTeaWithKettle* at around 4 pm.

Note that, for brevity, we did not consider cases where a task acts as the right operand for different types of temporal relations (it is not needed in our example). This required correlating the number of *active* state transitions to the number of types of incoming temporal relations.

Knowledge-Driven Activity Recognition

Based on the ADL workflows and detected user actions (i.e., atomic tasks), a semantic reasoning process applied the proposed task state transition rules to recognize the current states of ADL activities. In doing so, we realized *knowledge-driven activity recognition*, where the start and completion of ADL were recognized, based on the execution of their constituent, lower-level tasks; and erroneously performed tasks were marked (*error* state), based on workflow relations and associated context. Importantly, it supported non-uniform behavior during ADL completion, allowing individuals to perform the ADL in an idiosyncratic way as long as they adhere to the core ADL constraints. Our approach dealt with multiple, simultaneous ADL when the individual perform constituent tasks in any interleaved way that adheres to the individual ADL.

To detect the atomic actions that drove knowledge-driven activity recognition and detected current context, we relied on sensor data processing techniques, as elaborated by Van Woensel et al [9]. Each time an atomic action or new context was detected, the semantic reasoning process was executed. Activity recognition results were passed to any top-level component (e.g., knowledge-driven pro-active assistance).

Knowledge-Driven, Pro-active Assistance

We supplied three features for pro-active assistance:

Guidance

Assistive acts were issued to guide a patient through their daily ADL routines. Once the start of an ADL was recognized, guidance kept the patient apprised of the current progress in the workflow. For example, when a patient performed a cooking activity, assistive acts provided information about the activity's progression (current subtask) and its current state (instructions, location of utensils and ingredients, etc.) on nearby devices (e.g., TV, smartphone, tablet). If the smart home was connected to devices, some tasks could even be performed automatically, such as the *TurnStoveOnMax* and *TurnStoveOff* tasks (Figure 1). The system could offer guidance by leveraging context annotations such as showing that a kettle was needed for a task (code 1) and the location of kettle (code 2).

Troubleshooting

Troubleshooting involved alerting the individual about detected errors during ADL execution and explaining the correct workflow. Our novel activity recognition process detected when a task was inconsistent with the ADL workflow (rule f.1). Further, our system detected when a task was done in the wrong context (e.g., wrong item, location; rule f.2). An error would also be raised when an activated task (e.g., *GetKettle*) was not completed within a reasonable time.

Prompting

When an ADL was overdue, as inferred from its associated context (see code 1; rule g.1), the system would prompt the individual with increased urgency until the ADL is carried out—ensuring their daily routine continues as expected. Corresponding to this increasing urgency, we applied an *evolving* notification lifecycle [11], where interactions (e.g., icons, audio & haptic feedback) increased in obtrusiveness overtime, together with frequency, until the complete.

Results

We implemented a system prototype to evaluate the feasibility of our activity recognition approach. Uutilizing the Hermit

reasoner (v. 1.3.8.4) for reasoning over the DL transition rules:

- Ontology loading: utilizing the Hermit API to load the ontology, state transition rules and ADL workflow.
- Initialization: running semantic reasoning after loading.
- Detected action: performing the semantic reasoning step after detecting an atomic action or new context.

Using this prototype, we performed a preliminary evaluation of our activity recognition method, executing 10 simulated scenarios for the *MakeTeaWithKettle* ADL (Figure 1), where the individual performed different permutations of 13 atomic tasks (5 correct, 5 incorrect performances). We ran the experiments on a Lenovo Think-Pad T530 laptop running Windows 7, with an Intel Core i7-3520M CPU (2.90 GHz) and 8Gb of RAM. We ran each scenario 10 times and retrieved the average performance results of each operation (Table 1). The prototype was able to properly detect each of the incorrectly performed actions in the simulated scenarios.

Table 1– Activity Recognition Performance

Operation	Average processing time (ms)
Ontology loading	31
Initialization	299
Detected action	374

Discussion

Table 1 shows that the semantic reasoning process, which underlies our knowledge-driven activity recognition, takes between 0.3 and 0.4 seconds. While performance is mostly determined by the reasoner (in this case, Hermit), these seem acceptable performance times for a consumer-grade PC.

In contrast to data-driven activity recognition, which train an activity model based on a collected dataset, knowledge-driven activity recognition relies on an a priori designed knowledge artifact. A subset of knowledge-driven works applies logical reasoning to infer high-level activities from detected atomic actions. Chen et al. [5] performed activity recognition by classifying an unknown instance, with sensor observations attached as properties, as an activity class with constraints defined on properties (e.g., *hasContainer*) and values (e.g., cup). This approach is unable to cope with tasks being performed incorrectly, or in the wrong temporal sequence, since this would lead to an incorrect classification. Helaoui et al. [6] represented activity models using log-linear DL, and proceeded similarly to Chen et al. In case of incompatibilities due to noisy sensor observations, the most probable activity is inferred based on confidence values. However, their approach only considers a *sequential* temporal relation. Okeyo et al. [8] incorporates composite, interleaving and concurrent task relations based on Allen's temporal logic. However, the approach does not support conditional, alternative, or optional relations, and does not focus on dealing with incorrect actions.

Future work involves studying how to deal with uncertainty resulting from faulty sensor observations (e.g., utilizing Probabilistic Description Logics [12]). We also aim to investigate automatic generation of ADL using automated planning, based on the required context of tasks. Further, we aim to utilize our method to determine non-compliance to health activities in behavioral self-management.

Conclusions

We proposed a novel approach to knowledge-driven activity recognition, based on a formal semantics in the form of state transition rules. Properties of our method include: (a) coping with uncertainty, caused by non-uniform behaviors; and (b) robustness towards mistakes during ADL performance. Based on recognized activities, a pro-active assistance process provides features such as guidance, i.e., keeping the patient appraised of their progress; troubleshooting, i.e., correcting the patient's actions, if needed; and prompting, i.e., informing the patient when an ADL is required. We further linked ADL with environment context. Future work involves accounting for more types of variation in which people complete their tasks—e.g., heating water using the microwave instead and personalizing the utilized modalities for pro-active assistance.

Abstract

The quality of software is high in medical devices due to the strict regulatory requirements and their implementation in the software development processes through the use of the IEC 62304 standard. The goal of this standard revision project was to extend the scope of the standard to all health software and also to bring the requirements of the 12 year old standard back to the state-of-the-art including provisions for cybersecurity. The joint IEC/SC62A and ISO/TC215 project team revised the standard and adapted its risk management, usability, and security requirements to serve both the medical device industry and the overall health software industry. The resulting second version of the standard has gone through a multistage global voting process to achieve a consensus of the requirements to serve both these communities. The resulting standard has potential to have a major impact on the quality of software used in health care globally.

Keywords:
Standards; Health Care Technology; Software Engineering

Introduction

The quality of software in medical devices is very important because a failure in medical device software can have fatal consequences to the patients in some cases. A classic example of this is the case of the Therac-25 radiation therapy machine in the 1980's [1]. The weaknesses in the production processes of the software to this device resulted in undetected programming errors which led to massive radiation overdoses in at least six accidents and three dead patients. It is a well-known fact in the software engineering field that the testing of the software does not alone ensure sufficient quality of the software, but the production process of the software needs to be of high quality, as well. Few, if any other documents have a greater impact on how the software development processes have been arranged in the medical device industry than the IEC standard 62304 Medical device software – Software life cycle processes [2]. This standard is recognized by the Food and Drug Administration in the USA. It is also on the list of harmonized standards under Directive 93/42/EEC for Medical devices in the European Union; although, it does not necessarily cover all the requirements of the Directive 2007/47/EC for medical devices [3]. The medical device industry applies this standard because it may be the easiest way to demonstrate the conformity of the company's medical device software production process with the regulatory requirements. The regulatory requirements suggest that the standard is typically used in conjunction with the quality system standard ISO 13485 [4], the risk management standard ISO 14971 [5], and the medical device usability standard IEC 62366-1 [6], which are harmonized standards as well. The standard has a three class software safety classification A, B, and C of which class C represents the highest risk class software.

The growing needs to improve the quality of all the software used in health care has led to the idea to extend the scope of the 62304 standard beyond medical devices to all health software. The term health software is defined to include all software used for managing, maintaining, or improving the health of individual persons, or the delivery of care, still also including the software in medical devices. In the regulatory meaning, the medical device software can be embedded to a device or it can be a medical device as such, so-called Software as a Medical Device (SaMD). Software with a health purpose runs as a service, e.g. in a cloud service, could be a medical device if it fulfills the definition of a medical device, but if not, it is still covered by the definition of health software. This independence of the hardware platform means that this definition and the new version of the 62304 standard cover the popular mobile health apps.

After the approval of the revision proposal, the work on the second edition of the 62304 standard was (re)started in October 2014. The revision work was carried out in a project team of the Joint Working Group seven (JWG7), which is a co-operation working group between IEC subcommittee 62 A *Common aspects of electrical equipment used in medical practice* (IEC/SC62A) and ISO technical committee 215 *Health Informatics* (ISO/TC215) because both committees are interested in contributing to this work. The project team consisted of experts nominated by the national standards bodies of the member countries of these standardization committees.

The health informatics standards are not very well-known by the health informatics research community, partly because the standards are relatively expensive. For this reason, it is important to introduce the new version of the 62304 standard here also to the scientific community, because health informatics researchers may later face it anyway if they want to commercialize their research results.

Methods

Design Specification

The work began by defining the target of the second version of the standard. The highlights of the planning were:

- The scope of the standard would be extended from medical device software to cover all health software
- The standard would remain a life cycle standard in contrast to being a product standard
- The software maintenance process requirements would remain in the standard
- The same software safety classification would remain in the standard and the required rigor to the safety class C software would be preserved
- Significant changes to the requirements should be avoided unless there is a compelling motivation for the change
- The new version of the standard should be applicable to fulfill the regulatory requirements of medical device software

The expansion of the scope to all health software expands the user base of the standard significantly to new audiences. The designers of non-medical device health software have often not applied equally strictly controlled processes as the medical device manufacturers and the required level of rigor may come as a surprise to these companies when their customers begin to require the use of 62304 ed. 2 in the software production.

Keeping the standard as a life cycle standard instead of a product standard leaves out two main activities of the standard. A product standard such as the IEC 82304-1 [7] contains also software use requirements and the validation that the use requirements are met but these are out of the scope of this standard.

The need to keep essential changes minimal comes from the high costs that major changes could cause to the industry when they would have to change their processes and train the personnel for the changes. Major changes might also make it more difficult for the regulatory bodies to accept the standard as a way to fulfill the regulatory requirements, particularly if the changes are considered to result in less safe software than before.

Literature Review

When the revision was started, a literature review was carried out as well. For a standardization project, other related standards are the most relevant literature, because a standard can refer to other standards normatively if the other standards contain material that is not feasible to repeat in the current standard. As the list of potentially relevant standards spans a few pages, only a small subset of them is mentioned here. An earlier version of the ISO/IEC/IEEE 12207 [8] standard was used in the drafting the first version of 62304. Its latest developments were checked to maintain a certain level of compatibility to general software development standards. The IEC 60601-1 standard [9] contains requirements for medical device software and they were compared to the requirements in 62304. The risk management subclauses of 62304 were checked against ISO 14971 [5] and its draft versions under development. A similar comparison was carried out with ISO 13485 [4]. ISO 90003 [10] was checked as an alternative to ISO 13485 for health software which is not classified as a medical device. In addition to the harmonized usability standard IEC 62366-1 [6], the corresponding medical device standard IEC 60601-1-6 [11] was also considered.

The IEC 61508-3 functional safety of programmable electronic systems standard [12] was checked for comparison although its field of application is not in the medical domain. The ISO/IEC TR 29110 series [13] was identified to contain recommendations for software life cycle management in small organisations but its requirements were not sufficiently strict for high risk medical device software production. SWEBOK V3 [14] was used as the latest state-of-the-art document for software engineering.

During the course of the work, it became apparent that the cybersecurity issues in medical devices and health software in general became more and more important. A cybersecurity problem in a medical device can develop into a patient safety problem too, if the problem is in a safety critical device. Previously, when medical devices were isolated to their own networks, the cybersecurity issues could be rather safely ignored by the medical device community, but in today's interconnected world, their addressing has become mandatory. Regulatory cybersecurity guidance for manufacturers of medical devices has been published and already revised in the USA [15] and corresponding guidance is expected from the European Commission as well. Moreover, the health software which is not embedded in a medical device is typically at risk of cybersecurity attacks as personal medical data is more valuable to cybercriminals than credit card numbers [16].

A large number of security-related standards have been identified by the project team members. The NIST Cybersecurity Framework [17] can be taken as the starting point for improving security in software development but other alternatives exist too. The project team investigated the applicability of several security standards. The ISO 27799 health informatics security standard [18] refers to the general ISO/IEC 27002 standard [19] but they are not very much related to the software life cycle processes. The IEC/ISO 80001 series of standard documents [20] and particularly TR 80001-2-2 [21] and TR 80001-2-8 [22] are also relevant because they inform the health delivery organizations how to manage security risks with networked medical devices which run software developed according to 62304. These standards introduce security requirements to software which need to be addressed in the software development life cycle. The IEC 62443 series of standards, particularly the IEC 62443-4-1 [23] from the industrial automation field is a good reference source for secure development life cycle requirements. The Microsoft Security Development Lifecycle model [24] is an alternative security-aware software design model from the general software development field. Finally, the ISO/TR 17791 [25] contained a survey of standards for enabling safety in health software; thus, the project team had a good comprehension of the existing literature to be considered.

Working Method

At the outset of the work, the project team had the draft amendment [26] of the 62304 standard in its disposal. It updated parts of the first version of the 62304 without the scope extension to health software. The project team began to introduce changes to the document based on the design specification and also on the feedback received from the field in the application of the 62304.

The work was carried out in a series of meetings. In between the meetings, the core project team members formulated new paragraphs of text to the subsections to be revised. The project team has produced three drafts of the standards, which have been circulated for voting in the both standardization committees IEC/SC62A and ISO/TC215. The national standardization bodies have collected the comments of each member country, and they have been delivered to the project team for handling. The project team is responsible of

addressing each one of the comments and either (partially) approve the comment or reject it with sufficient motivation. For example, the most recent vote resulted in about fifty pages of comments to be considered, indicating great interest in the contents of the standard. The governing working group needs to accept the project team's disposition of comments before the draft standard can proceed to the next stage. When all the comments have been addressed, the standard draft is sent to the Final Draft International Standard (FDIS) vote, which decides the approval of the document as an international standard. This is the normal working method of the international standardization organizations like IEC and ISO.

Results

At the time of writing, the latest draft addresses around 95 per cent of the received comments in agreement of the stakeholders. The scope has been extended to all health software and the necessary changes relating to this change have been implemented to the standard. The draft 62304 second edition standard covers now the following stages for the software development process:

1. Software risk management process
2. Software development planning
3. Software requirement analysis
4. Software architectural design
5. Software detailed design
6. Software unit implementation
7. Software integration and integration testing
8. Software system testing
9. Software release
10. Software configuration management
11. Software problem resolution

The software maintenance process is similar to the development process, but the stages 2 and 3 have been replaced with the establishment of the software maintenance plan and the problem and modification analysis.

Both the old and new versions of the 62304 require the use of a quality management system in the software production. The old version of the standard required that the manufacturer applied a risk management process complying with ISO 14971 [5]. The new version requires the conformity to ISO 14971 only when a software failure can contribute to a hazardous situation, which in turn can lead to injury or damage to the health of people, or damage to property or the environment. The new risk management process must also manage risks associated with security. The new version does not make any security standard mandatory, but it suggests some that can be used.

The new version makes the requirement to apply a usability engineering process explicit. The use of the IEC 62366-1 [6] is not mandatory but it is given as an example of how to demonstrate the conformity to the usability design requirement.

The software safety classification still has the three classes, A, B, and C. The assignment of the software to these classes has be clarified. The procedure can be seen in Figure 1.

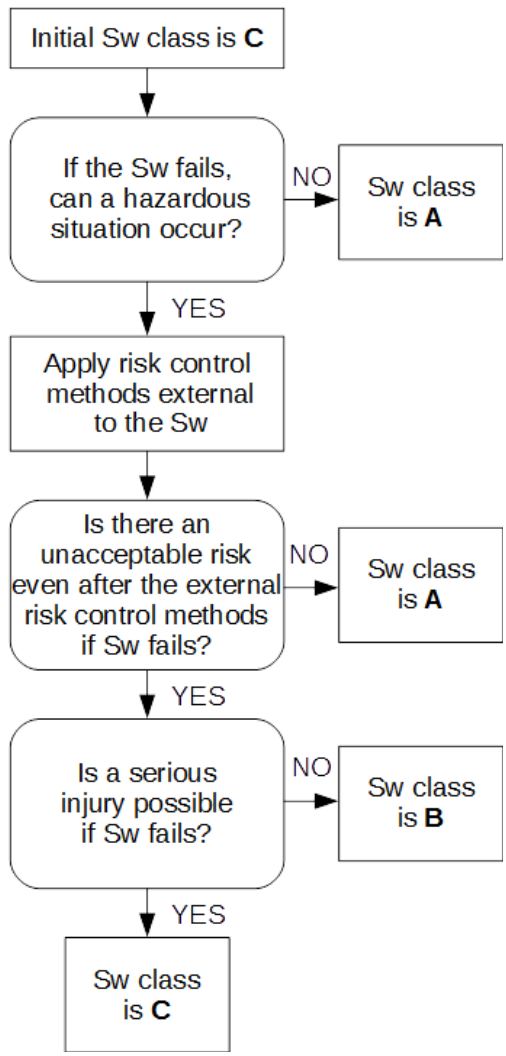

Figure 1. The Procedure to Assign the Safety Class to Software.

Legacy software is software that was produced before the new version of the standard was published, and it was therefore not possible to produce the software according to this standard. The new version has provisions how to demonstrate the compliance of the legacy software with respect to the new version.

The changes in the requirements for the software development process are relatively minor. There are a few additional requirements for the software system test record contents, but otherwise the changes are not very significant.

Similarly, the changes in the requirements for the software maintenance process are few. The new version requires that the change requests are analyzed also with safety class A software, which was not a requirement before.

The software risk management process has new requirements. More potential causes of contributions to hazardous situations must now be identified, including those related to cybersecurity.

The changes to the software configuration management process are again minor. The same applies to the changes in the software problem resolution process.

Over half of the document contains rationale and guidance in the implementation of the standard. Much of the text has remained the same or has been revised for additional clarity. The extended risk management sections now include new material which explains IT risks too. The relationships between the software safety classification and risk management are explained in more detail as well. The risk management of legacy software contains also additional new information.

The informative Annex C about the relationship to other standards has been partially rewritten. New standards are introduced to the table of standards to be considered. Accordingly, the bibliography now contains references to updated sources.

Discussion

The new version of the 62304 software life cycle processes standard extends its scope to all software production for health purposes while maintaining the current user base of medical device software producers. It remains to be seen, how widely the new audiences begin to use the standard voluntarily, because its implementation to the processes of a software company can be a significant effort. This is particularly the case with small software companies that have not produced regulated software before. Larger software companies with established quality systems may have an easier task in adjusting their processes.

The benefits of beginning to apply the revised 62304 standard to a company which has not applied a standard-based process before are the following:

1. The planning, programming, testing, and the documentation of the software becomes more controlled
2. As a result of the above, the final product will have fewer errors
3. The company will have a well-structured process to handle software updates, planned or corrective updates
4. The reputation of the company improves because the audited proof of high-quality software production processes is not so easy to achieve

For the customer, the benefit is that the products produced under the state-of-the-art software production standard are likely to be of higher quality than those produced without this methodology.

When the health software buying organizations hear about the completion of the second edition of the 62304 standard with its extended scope, they may decide to use it in procurement in order to improve the quality of the software they buy. When this happens, software companies wishing to stay competitive need to begin to apply this standard. The national regulators of health software in developed countries may also recognize their opportunity to improve the health software quality in their countries by requiring conformity to this standard. This would ensure the success of this standard in the field.

The additional requirements regarding cybersecurity do not lengthen the standard much, but their inclusion demands changes in the organizations applying the standard. The many publicly well-known cybersecurity incidents have probably triggered most members of the industry to react to the threats even without the requirements from this standard.

As the new standard has not yet passed the final vote, all the details of the standard have not been frozen. There is still discussion about the requirements regarding risk management, but the discussion will converge to a conclusion which the majority of the national standards bodies can approve.

The update of a standard causes consequences in other standards, as well. At least documents like IEC 82304-1 [7] and IEC/TR 80002-1 [27], and IEC/TR 80002-3 [28] need to be partly revised.

It is interesting to note how little direct impact the scientific literature actually has in the final version of this kind of a standard. The standard preparation work needs to consider other closely related standards more than the scientific works. Additionally, comments from the national ISO member country votes need to be considered in order to reach consensus. In this process, new radical ideas from the research community can easily get lost.

Conclusions

This paper presented the goals, methods, and results of the IEC 62304 Software life cycle processes standards for health applications. The revision of the standard brings the standard to the state-of-the-art in software production including provisions to cybersecurity and extends its potential user base to all health software producers. Thus, it has potential to have a major impact to the quality of software used in health care.

Acknowledgements

The authors want to thank all the 62304 edition 2 project team members for their contributions to the work. The support of the Finnish Standards Association (SFS) to the travel expenses to the project team meetings is also acknowledged.

Enhancing Guideline-Based Prescribing and Personalized Medication Scheduling

Charles Wachira, Samuel Osebe, William Ogallo, Aisha Walcott-Bryant

IBM Research - Africa, Nairobi, Kenya

Abstract

Poor communication of medication administration instructions is a preventable cause of medication nonadherence. The Universal Medication Schedule (UMS) framework improves adherence by providing a simplified set of dose timing rules. However, this framework does not readily generalize to individuals with varying daily routines. We propose a point-of-care solution for enhancing guideline-based electronic prescribing and personalizing dose schedules. We describe a JSON-based approach to encode and execute standard treatment guidelines to support electronic prescribing as well as an algorithm for optimizing medication administration schedules based on a patient's daily routine. We evaluated the structure and accuracy of our JavaScript Object Notation (JSON) formalism focusing on Kenya's hypertension treatment guidelines. Our experiments compare the medication schedules generated by our algorithm with those generated by pharmacists. Our findings show that treatment guidelines can be efficiently represented and executed using the JSON formalism, and that different medication administration schedules can be generated automatically and optimized for patients' daily routines.

Keywords:

Drug Administration Schedule, Clinical Decision Support, Medication Adherence

Introduction

Despite the known benefits and advancements in treatments, medication nonadherence remains one of the most significant healthcare challenges. The World Health Organization estimates that 50% of patients on long-term therapies are nonadherent, with direct consequences on patient health outcomes and increased healthcare costs [1]. Although the causes of medication nonadherence are multifactorial, patient misunderstanding of prescription drug label instructions is an important contributor to the situation, and patients who use multiple medications and with lower literacy levels are disproportionally affected [2–4].

Research has shown that the manner in which prescriptions are written and in which medications labeled are important underlying factors responsible for patient misunderstanding of their medication instructions [5–8]. Vagueness and unnecessary complexity of prescriptions result in variability of pharmacy interpretations of the prescriptions and subsequently makes it difficult for patients to know when to take their medications [6], and many dispensing labels emphasize drug characteristics rather than dosing instructions [7]. For example, in a study of 446 United States veterans, only 42% were able to correctly interpret a prescription with the directions "take one tablet daily with meals" [9].

In 2008, the United States' Institute of Medicine (IOM) introduced the Universal Medication Schedule (UMS) concept to simplify medication administration instructions for patients and their caregivers with the goal of improving patient understanding and medication adherence primarily to solid dosage forms used daily [10]. More than 90% of multi-drug regimens are dosed four or fewer times per day [11], and as a result, the UMS standardizes administration instructions to provide explicit timing with four standard dose periods (morning, noon, evening, bedtime). Evidence supporting the use of UMS instructions indicates that patients are 33% more likely to interpret medication instructions correctly when using the UMS [12]. Since the inception of the framework, researchers have investigated its potential for adoption in other settings such as the United Kingdom [13], and have expanded it to non-solid dosage forms [14] with considerable promise. However, there is a scarcity of literature on generalizing the framework to accommodate persons with different routines.

We posit that application of the UMS without the promotion of rational prescribing, and also considering daily routines of patients, may not sufficiently solve the problem of nonadherence and inaccurate use of medications. We believe that interfacing guideline-based prescribing with customized medication schedules based on the UMS would result in better understanding of medication instruction and lead to improved adherence. Our approach supports recent advances in health information technology decision-making aids, which have the potential to transform prescribing and dispensing practices by intelligently incorporating prescribing guidelines and medication scheduling.

We developed a point-of-care solution for enhancing guideline-based electronic prescribing and personalizing dose schedules. This involves generating electronic prescriptions based on patient parameters and existing care guidelines recommendations for some common chronic diseases (Hypertension, Diabetes, and HIV), and subsequently predicting the most appropriate dose periods, given the patient's drug regimen and routine (e.g., meals schedule and sleep schedule). The output of this process is an optimized medication schedule for guideline-recommended drug regimens. The solution can be integrated with a medication adherence reminder system to further enhance the appropriate use of medications.

In this paper, we describe the development of a guideline implementation and execution engine using the JSON formalism as well as an algorithm for dosing schedule optimization. We also provide the preliminary intrinsic evaluation of the accuracy and performance of the solutions and discuss our plan for their extrinsic evaluation.

Methods

Guideline Implementation and Execution

In this sub-section, we describe the approach used to encode and execute treatment guidelines (available as text-based flowcharts) using the JavaScript Object Notation (JSON) data structure format. Clinical practice guidelines are a critical component of care delivery because they standardize care across different settings, making it possible to sustain the quality of care in disparate contexts. Such contexts may be defined by several factors including demographic, diagnostic, environmental, and individual patient-level factors. Standard treatment guidelines provide evidence-based knowledge about treatment regimen options for patients with particular diseases and comorbidities. In personalized medication scheduling, clinical guidelines are critical for reducing variations in prescribing and dispensing of medication, as well as determining medication administration instructions that would be optimized to better fit the patient's daily routine. Furthermore, implementing standard treatment guidelines electronically would help meet the information needs for the care provider at the point-of-care, and also provide a means of data collection for determining guideline deviation in the care delivery process.

Guideline Encoding

The encoding process involves breaking down the guideline into individual steps, determining the data needed to execute the guideline, and writing the logic that consumes the data. First, we began by analyzing the guideline to determine and extract all the data items, referred to as parameters, that are needed to execute the guideline. These were then represented as a JSON data structure that specified the description of each data item (e.g., "age") and the data item's data type (e.g., "integer"). All data items are required upfront before execution begins. We preferred this approach over requesting data from users at every step as the user experience would be affected. Second, we manually extracted the steps in the guideline flowchart and represented these as nodes. Each node contains the following components:

1. Identity: Unique identifier for the node.
2. Description: Human readable information on what the node does.
3. Children: A list of all the child node identifiers, represented by set $N = \{n_0, \ldots, n_n\}$.
4. Type: Node type, represented by set $T = \{t_0, t_1\}$ where t_0 is a condition type and t_1 is a recommendation type. A node can be of type t_0, t_1 or both.
5. Action: A set of procedures that need to be taken by a caregiver, $A = \{a_0, \ldots, a_n\}$, where a_n can be null.
6. Function: A pointer to a machine executable logic. This logic is typically written by the encoding expert using a machine-readable language.
7. Fired: A flag that is set from false to true when the node is visited. Its role is to provide information on the traversal that led to a specific recommendation.

Third, we represented the guideline as a network graph $G = \{N, E\}$ with the set of nodes N, and the edges, E, where an edge $e \in E$ is represented by the relationship $e(n_m, n_n)$ where n_m is the parent and n_n is the child. Each node is a group of key-value pairs represented as JSON objects. We selected the network graph data structure over the tree data structures because it supports connected subgraphs and multiple parents per child node, which is common in flowcharts for treatment guidelines. We do not, however, support traversal from a child to its immediate parent because of the nature of this problem. For example, for nodes $N = \{n_0, n_1, n_2\}$ where n_n is the child of n_{n-1}, the edges $e(n_1, n_0)$ and $e(n_2, n_1)$ would not be allowed while traversing the network.

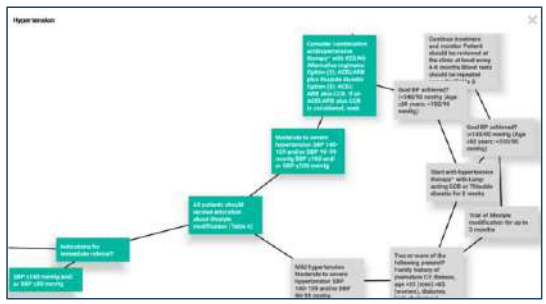

Figure 1 – Guideline snippet showing nodes activated based on input parameters

Guideline Execution

A sample guideline snippet is shown in Figure 1. Guideline execution begins with the root node. Once parameters are fed to the root node, the associated logic is retrieved and executed using a subset of the parameters. The root node function includes skipping logic for procedures that are long term. For example, when monitoring a condition for three months, the execution will skip from the root node to the node corresponding to the third month, all factors held constant. When a node is visited, its logic is retrieved from the logic repository. In this implementation, logic is represented as Java methods whose identifiers are similar to the node identifiers, providing a mapping between a node and the logic functions. Each node has only one logic function. Once the logic is retrieved, it is executed to determine the action to perform. This action can either be a traversal to one of the child nodes or a termination of the execution. If the action is a termination, the node involved returns recommendations which correspond to a procedure to be conducted.

Dose Schedule Optimization

We describe our approach that extends the Universal Medication Schedule (UMS) [10] to enable the provision of customized medication administration instructions to persons with different daily routines. The UMS is crucial in simplifying dose schedules. It is equally critical to consider patient routines in order to improve their medication experiences. However, manually determining the right schedule for the patient may be cognitively tasking and time-consuming. We propose a dose-schedule algorithm to automatically determine and rank dose schedules given patient regimens and routines. This would help dispensing staff develop more suitable medication administration plans for their patients.

Algorithm Description

Our dose-schedule algorithm computes the most optimum dose periods given a patient drug regimen and routine. The output of this algorithm is an optimized schedule for the patient's drug regimen. Each patient has a single optimized dosing schedule that can be integrated with a medication adherence reminder system or a patient health wallet to enhance appropriate use of medications. The inputs to the algorithm are as follows:

1. Prescription Information: The algorithm requires medication administration instructions such as dose frequency, dose quantity, total pills prescribed, recommended time of day, and meal restriction (e.g., "with a meal", "without a meal", "with or without a meal") for each drug in the patient's prescription.
2. Dose Intervals: The algorithm requires the dose intervals for medications given more than once a day. Based on the UMS, we set acceptable dose interval as 8 to 12 hours for medications administered two times a day, 5 to 8 hours for medications administered three times a day, and 5 to 6 hours for medications administered four times a day.
3. Patient's routine: This includes the time to wake up, breakfast time, lunch time, dinner time, and sleep time to the nearest hour.
4. Active Medication Schedule: If the patient has an active medication schedule, the algorithm uses this information along with the patient's new prescription, to generate a new medication schedule.

The dose schedule optimization process consists of several steps. These are described as follows:

1. Compute the total number of hours that the patient is awake based on sleep and wake times inputs.
2. For each drug in the prescription, compute all possible dose periods given the dosing interval and the output of (1).
3. Apply a meal constraint to the output of (2) i.e., for each drug in the prescription, check the meal restriction and constrain dose periods to hours that support this direction of use.
4. For each drug, constrain the output of (3) with any administration instructions that specify a specific time of day for taking a drug. For example, drugs which are recommended to be taken at bedtime will be confined to bedtime hours.
5. Repeat steps (2) to (4) for all drugs in the prescriptions.
6. Compute all possible combinations of the output of (5) along with present active medication schedule. This step is accomplished using recursion.
7. For each combination n in (6), compute scores based on the number of dose periods N_{dp}, number of pills per dose period N_p, and the distribution of interval durations between dose periods T_{int}. In this paper, these scores were obtained as follows:
   - Dose period score: The dose period score $S_{dp,n}$ for each combination n is calculated as the normalization of the number of dose periods $N_{dp,n}$ using the smallest score $N_{dp,min}$ and largest score $N_{dp,max}$. Each $S_{dp,n}$ is between 0 and 1, where larger values are preferable. In this formulation, combination of medications having the higher number of dose periods are more heavily penalized.

     $$S_{dp,n} = \frac{N_{dp,n} - N_{dp,min}}{N_{dp,min} - N_{dp,max}} + 1 \qquad \text{(eq1)}$$

   - Pill score: The pill score $S_{p,n}$ for each combination n is calculated as the normalization of the number of pills $N_{p,n}$ using the smallest score $N_{p,min}$ and the largest score $N_{p,max}$. Each $S_{p,n}$ is between 0 and 1 where larger values are preferable. In this formulation, combination of medications having the higher number of pills are more heavily penalized.

     $$S_{p,n} = \frac{N_{p,n} - N_{p,min}}{N_{p,min} - N_{p,max}} + 1 \qquad \text{(eq2)}$$

   - Interval Score: The coefficient of variation $C_{v,n}$ for the distribution of the duration of intervals between dose periods $T_{int,n} = \{t_{int,n,0}, \dots, t_{int,n,i}\}$ for each combination n is calculated as the ratio of standard deviation and the mean of the distribution. The interval score $S_{cv,n}$ for each combination n is then calculated as the normalization of the coefficient of variation $C_{v,n}$ using the smallest coefficient of variation $C_{v,min}$ and the largest coefficient of variation $C_{v,max}$. Each $S_{cv,n}$ is between 0 and 1, where larger values are preferable. In this formulation, combination of medications having the lower coefficient of variation are more heavily penalized.

     $$S_{cv,n} = \frac{C_{v,n} - C_{v,min}}{C_{v,max} - C_{v,min}} \qquad \text{(eq3)}$$

8. The scores in (7) are weighted by a) minimizing the number of dose periods per day, b) minimizing the number of pills per dose period, c) maximize time intervals between dose periods.

   $$S_n = W_1 * S_{dp,n} + W_2 * S_{p,n} + W_3 * S_{cv,n} \qquad \text{(eq4)}$$

   Where W_n is a weight and $W_1 + W_2 + W_3 = 1$
9. The weighted scores S_n for each combination n from eq4 are ranked and used to select the medication schedule (combination) with the best score.

We implemented the algorithm using Java. The inputs to the algorithms were collected using a mobile app that we built to automate the data entry process, while the prescriptions and existing schedules were queried from the patient's electronic health record. The output of the algorithm is shown in Figure 2.

Experiments and Results

To evaluate the JSON-based guideline system, we encoded a treatment protocol for the management of hypertension among adults in primary care that was endorsed by the Kenya Ministry of Health and the Healthy Heart Africa project [15]. This resulted in a total of 14 nodes covering non-hypertensive, mild hypertension, and chronic hypertension. 50% of the nodes were terminal nodes, meaning they resulted in therapy recommendations. Patients who have been on the therapy get reviewed every 4 to 6 months. Accuracy was determined by selection of a parameter set that covered all the seven terminal nodes. This was then fed into the guideline for execution and both the recommendations and the execution path were evaluated against human results. Lastly, we compared the attributes of the JSON formalism with those of popular guideline encoding platforms.

The guideline execution took 1ms on average. This is accounted by the fact that the guideline logic comprised of simple comparison arithmetic. This execution resulted in the correct execution path and recommendations for all the parameters tested. Table 1 shows the comparison of GLIF 3 [16], PROforma [17], GLIDES [18], and the JSON formalism presented in this paper. The guideline format compares the

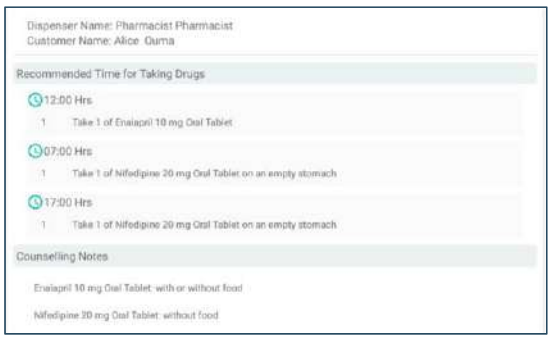

Figure 2 – Example output of a personalized dosing schedule

representations such as XML, RDF, and JSON which can be used interchangeably, and for which there exists parsers for mapping one structure onto another. Both GLIF 3 and PROFORMA have graphical tools for encoding guidelines. This, however, requires an expert such as a knowledge engineer. GLIDES approach consists a hybrid of a graphical tool and natural language approach where a free text guideline is mapped onto an XML structure [19].

To assess the performance of the dose schedule optimization algorithm, we began by generating synthetic prescriptions from existing hypertension and HIV clinical guidelines and drug labels. This process involved specifying the medication instructions for single medications. Each instruction consisted of the clinical drug, dose, frequency, and food restriction tuples e.g., "Amlodipine 10 mg Oral Tablet", "1 tablet (10 mg)", "once daily", "with or without food". Next, using information from the guidelines, we generated all possible combinations of single medications that formed known regimens for the treatment of hypertension or HIV. Examples of this include 1 Calcium Channel Blocker (CCB) + 1 Angiotensin Receptor Blocker (ARB) for the management of hypertension and 2 Nucleotide Reverse Transcriptase Inhibitors (NRTIs) + 1 Non-nucleoside Reverse Transcriptase Inhibitor (NNRTI) for HIV treatment. At the same time, we created random patient routines, each describing different sleep times, wake times, breakfast times, lunch times, and dinner times. These two sets of data (regimens and routines) were used to randomly select 100 regimen-routine combinations that were processed by the algorithm. The output of this process was 100 optimized dose schedules along with the time taken to generate each. We evaluated the average time taken to generate each optimized regimen, and compared the output of the algorithm to the output generated by two pharmacists for a random sub-sample of 23 prescriptions. The two pharmacists worked together and did not make changes to the prescriptions.

The mean dose optimization time was 498.4 ms (IQR: 453 ms to 508 ms). Of the 23 randomly selected prescriptions, the algorithm and the pharmacists had 18 common optimized regimens, implying that the algorithm is approximately 78% accurate against human experts. Inspection of the 46 individual medication instructions in the 23 prescriptions revealed that 43 instructions (93%) were correctly determined by the algorithm. This suggests that the algorithm performs better when optimizing dose schedules for individual drugs but its performance deteriorates when combining information from individual drugs to form a regimen.

Discussion

This study describes an approach for implementing standard treatment guidelines for electronic prescription generation and subsequently personalizing the medication administration instructions, through a dose-schedule optimization algorithm, in the prescription based on the patient's routine. To the best of our knowledge, our study is the first to attempt to formalize standard treatment guidelines as JSON data structures. This study showed that the rate-limiting step, which is the recursive dose scheduling optimization step, takes less than a second for a single prescription optimization process. This implies that the solutions proposed in this study could be adopted at the point-of-care to enhance prescribing and dispensing as well as improve the patient's medication adherence.

Several approaches have been used for creating computerized guidelines for clinical decision support including the Arden Syntax, GLIF, and PROforma [20]. JSON formalism is a programmatic approach where functions containing the guideline logic are written using an object-oriented programming language. Consequently, it can be executed by any system that can interpret the object-oriented language chosen. These factors and the fact that it is available via an application programming interface make it easily scalable once the encoding has been done. The other guideline approaches require specialized execution and sharing platforms.

There is a dearth of literature on using technology to optimize medication administration schedules as a means of promoting medication adherence in the outpatient setting. The review by Choi et. al. [21] reveals that whereas many mobile applications have been developed in an attempt to improve medication adherence, a majority consist of similar alerts and drug information access functions. A similar review by Ahmed et al. [22] found that three strategies utilized by developers of mobile applications for medication adherence include reminders (e.g., alerts and SMS), behavioral approaches (e.g., patient tracking and gamification), and patient education. Interestingly, Stawarz [23] demonstrated that adherence to long-term therapies could be improved by taking into consideration the patient's context such as daily routine events, locations, and objects. However, currently available reminder applications do not support patients in adopting daily routines, while behavioral applications tend to ignore the importance of contextual cues [23]. Accordingly, it is critical that personalized medication scheduling solutions such as the one proposed in this study are developed and studied to complement existing approaches for enhancing medication adherence.

Conclusion and Future Work

We presented a point-of-care solution that combines guideline-based electronic prescribing and personalized medication scheduling. This was achieved through a JSON-based approach for encoding and executing clinical guidelines, and also by extending the Universal Medication Schedule to fit different patient mealtime and sleep routines. The findings of this work suggest potential in the combination of guideline-based prescribing and the customization of drug administration instructions to improve medication adherence.

A key limitation of this work is the lack of adequate evaluation of the proposed solutions, and the lack of real data from a clinical setting for the evaluation. We intend to address these in a pilot study with real patients and care providers. Our plan for the pilot includes rigorous evaluation of the accuracy, acceptability, and completeness in the transformation of clinical care guidelines concepts into the JSON formalism. We will also compare the performance of this approach to existing formalisms. We plan to compare the accuracy and similarity of the dose schedules produced by our algorithm to those produced by a committee of human experts. Furthermore, we would like to extend the functionality of our tool to detect and react to patients who deviate from, or violate, their medication schedules. Natural Language Processing (NLP) techniques can be adapted to make this possible, and this technique can also aide in the processing of guidelines. Finally, we will add checks for drug-drug interactions in the prescription orders to improve prescription safety.

Abstract

Diabetic Retinopathy (DR) is one of the most common microvascular complications presenting by patients diagnosticated with diabetic diseases. Uncontrolled hyperglycemia may manifest as visual impairment and blindness. The early detection of DR is essential to minimize the risk and consequence of visual diminishing. The standard gold diagnoses tool relies on different imaging modalities and requires a judgment of expert photographers, which are not available in most of the primary care centers or remote location. In that scenario, an automate or semiautomated DR screening systems can contribute to improving the accuracy of the diagnostic. Thus, we performed a Systematic Review and Meta-Analysis to evaluate the Decision Support Systems (DSS) in diagnosing DR. The overall Diagnostic Odds Ratio was 73.15 (95%CI: 37.54-142.50), sensitivity was 97.70 (95%CI: 97.50-97.90) and specificity was 90.30 (95%CI: 90.00-90.60). Our results corroborate with the concept of usefulness of DSSs in early diagnosis, screening and preliminary evaluation of suspicious images of DR.

Decision Support Systems, Clinical. Meta-analysis. Diabetic Retinopathy.

Introduction

The World Health Organization (WHO) indicate that Chronic diseases such as Diabetes Mellitus (DM) are experiencing a fast increase in rates worldwide. In 1997, were diagnosticated 124 million people with diabetes, where 97% corresponded to Type 2 [1]. The number of individuals already exceeded 317 million in 2012 and could reach 300 million in 2015. The prevalence of type 2 diabetes mellitus (DM2) increased in the last 25 years [2, 3].

Diabetic Retinopathy (DR) is one of the most common microvascular complications of the diabetic disease and has been responsible for the majority of cases of visual impairment and blindness in adults between 20 and 74 years [4]. The prevalence of patients with complication reaches more than 40% in the age group over 40 years [5]. According to the Center for Disease Control and Prevention, about 4.2 million Americans have Retinopathy In the United States, of which 655,000 have a high risk of vision loss [6].

The symptoms of DR are nonspecific in the early stages and relies on regular and precise screening for early detection. The delayed diagnostic and consequent delayed treatment will be ineffective to avoid the progress of the loss vision [7, 8, 9]. However, the actual standard gold diagnosis tool relies on different imaging modalities and requires a judgment of expert photographers, which are commonly not available in most of the primary care centers or remote location.

Techniques in image processing and segmentation of retinal vasculature are necessary for an accurate interpretation of acquired patient images. In that sense, health Informatics approaches, as Decision Support Systems (DSS), can be defined as an intervention that can offers health professionals with additional clinical knowledge and specific information which has the potential to increase the accuracy of care decisions [10].

In order to reduce the DR numbers, health studies are regularly carried out. Previous studies have investigated methods to support the diagnosis and screening of Diabetic Retinopathy [11, 12].

Some studies have shown that Decision Support Systems, when used as reminders, improve preventive care, increase diagnostic accuracy, clinical performance [13], influence clinical decision-making [14, 15] and significantly improve decision quality [16, 17].

Despite all the investment, the accuracy of Decision Support Systems in diagnosing Diabetic Retinopathy still an unclear matter. Therefore, in this research, we aimed to provide evidence on the subject, which may collaborate in the development of strategies for early detection of peripheral diabetic neuropathy, and contribute to more effective glycemic control. We evaluated the accuracy of Decision Support Systems in diagnosing Diabetic Retinopathy through a Systematic Review and Meta-analysis.

Materials and Methods

The search strategy was carried out by means of an exhaustive search in the following 10 databases, including Medline via

Pubmed, Embase, and Gray Literature, by relevant publications made from 1970 to 2018.

The databases were searched using the descriptors presented in the Medical Subject Headings (MeSH), in the Emtree dictionary provided by Embase, and synonyms, and included the following terms, "Diabetic Retinopathy", and synonyms, which were associated with evaluation technology "Clinical decision support system" (and synonyms).

The "*" symbol was also used, and its syntax presents small differences in the database used to retrieve all variations with suffixes of the source words. The terms above were combined using the Boolean operators "AND," "OR" and "NOT."

The search was limited to studies in humans, but there was no language restriction. Reference lists of all primary studies retrieved were verified. Besides, references cited in relevant studies were also verified. The authors of articles that published studies with incomplete information were contacted.

Four researchers carried out the initial search of the abstracts and titles identified from the research strategy in the databases mentioned above independently. Disagreements on the inclusion or exclusion of each study were resolved by consensus.

Diagnostic accuracy studies were used to support the diagnosis of Diabetic Retinopathy (target condition) through the Decision Support Systems (test under evaluation). Thus, the diagnostic test under evaluation consisted of the result provided by the Decision Support Systems (positive or negative).

We analyzed studies that considered patients with Diabetic Retinopathy and evaluated by the gold standard (fundus examination or funduscopy). And we included patients with type 1 diabetes mellitus or type 2 diabetes mellitus, and were excluded patients with any other specific types of diabetes

Data were extracted from the included studies and the year of publication, country and continent (from the research), type of Diabetes Mellitus, study design, results of the system (and respective diagnostic categories), and demographic data such as age and sex, as well as the number of individuals with Diabetes, number of individuals with Diabetic Retinopathy and number of DSS correct answers.

In addition to the previously mentioned information, it was verified whether the gold standard (fundoscopy) was used as a confirmatory examination, besides the description of the techniques associated to DSS, techniques used in the processing of the images and resolution of the images used. Four reviewers independently abstracted the data cited above. Disagreements were resolved by consensus.

Each reviewer calculated the pre-test probability of Diabetic Retinopathy among subjects with diabetes, sensitivity, and specificity, and Odds Ratio Diagnostic (DOR) [18] of the primary studies. Studies that did not present the necessary data for the construction of the 2 x 2 contingency table were excluded. The 2x2 contingency table was constructed in each selected study, for which all gold standard and DSS results were classified as either positive or negative. Sensitivity, specificity and DOR were calculated.

In the studies in which only one of the cells in the 2 x 2 contingency table presented the value 0 (zero), the value 0.5 was added in all cells in order to do the calculations feasible, however, in those cases where the value 0 (zero) occurred in more than two cells, exclusion of the study was performed in the analysis [19].

The evaluation of the methodological quality was performed according to the Quality Assessment of Diagnostic Accuracy 2 (QUADAS-2) tool [20, 21].

In order to produce a combined pooled estimate of the of the studies, a meta-analysis was developed in R software version 3.6.0 (Comprehensive R Archive Network, http://cran.r-project.org/) [22], and Review Manager (RevMan) version 5.3.5 (developed at The Nordic Cochrane Center, Copenhagen, Denmark) [23].

Bivariate analysis was used to calculate combined estimates of sensitivity, and specificity, with 95% confidence intervals (CI) to estimate the summary values presented in the meta-analysis [24, 25, 26]. The measures were summarized by the DerSimonian and Laird random effect model (which takes into account the presence of heterogeneity in the studies) and we calculated all global means weighted with 95% CI) [27]. The graphical representation of the results was made using forest plots [26].

The heterogeneity in the different studies was analyzed by Cochran Q test, I^2 inconsistency test, and the variation between the studies by τ^2 [28].

Due to the identified heterogeneity, sensitivity analyses were performed to identify the associated co-factors responsible for heterogeneity. Potential cofactors associated with heterogeneity were also analyzed using meta-regression. Thus, as the results showed heterogeneity, it was decided not to elaborate the Summary Receiver Operating Characteristic (SROC) [29]. The Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines were followed in reporting (http://www.prisma-statement.org/). The pilot study with initial results was reported in Medical Informatics Europe Conference (MIE) [30].

Results

Primarily, 581 citations were identified in the databases searched as potentially employed the DSS in diagnosing Diabetic Retinopathy. Based on the titles and abstracts we retrieved 85 complete articles from the initial 581 citations. In the end, 18 primary studies met the meta-analysis inclusion criteria [8, 31-47] and were considered eligible for our Meta-analysis.

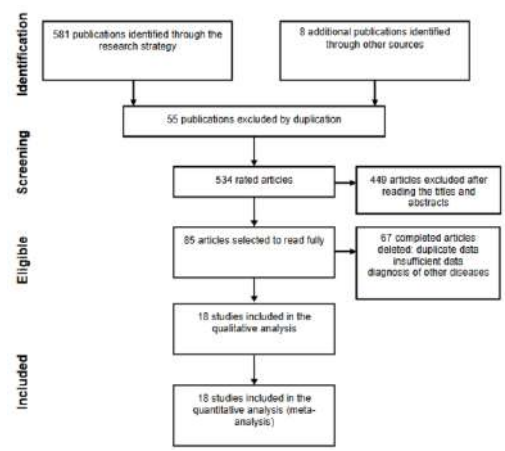

Figure 1– Flowchart of paper selection

Thirteen studies described the image quality used as input to the DSS. We found 2 studies [35, 44] labeled as poor resolution inputs and 11 considered with high resolution inputs [8, 31, 32, 33, 34, 37, 38, 39, 40, 41, 42].

Diabetic Retinopathy was found in 11446 cases (pre-test probability of 24.33%), while 35,608 (75.67%) presented normal images. Table 1 presents the pooled information of all studies

included in the meta-analysis, including True Positive (TP), False Positive (FP), False Negative (FN), True Negative (TN), Sensitivity, Specificity and Diagnostic Odds Ratio (DOR).

Table 1 – Pooled contingency table

Study - Year	DSS				Sensitivity (CI 95%)	Specificity (CI 95%)	DOR (CI 95%)

Sandhu 2018b	38	2	4	36	0.950 (0.831-0.994)	0.900 (0.763-0.972)	124.9 (24.94-625.5)
Total	**11181**	**265**	**3459**	**32149**	**0.977 (0.975-0.979)**	**0.903 (0.900-0.906)**	**73.15 (37.54-142.5)**
					97.7% (97.5%-97.9%)	**90.3% (90.0%-90.6%)**	

The overall sensitivity was 97.7% (95% CI: 97.5%-97.9%) and the specificity was 90.3% (95% CI: 90.0%-90.6%), as shown in the Figure 2 and Figure 3.

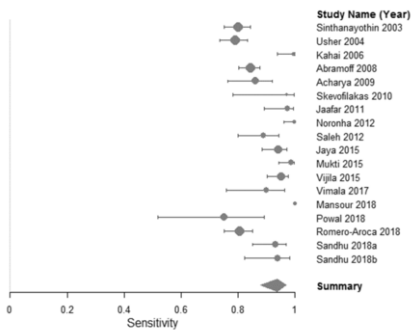

Figure 2 – Forest plot of the sensitivity

The overall DOR showed in Table 1 and Figure 4 (ln(DOR)) was 73.15 (95% CI: 37.54-142.50) which means that considering the use of DSS the probability of a positive result among subjects with Diabetic Retinopathy is 73.15 times greater than the probability of a positive result in individuals with normal retinas images.

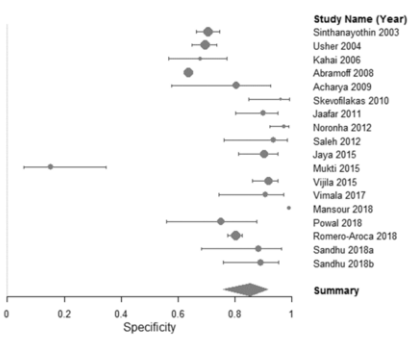

Figure 3 – Forest plot of the specificity

The heterogeneity was medium (I^2=68.53%; P<0.001; τ^2=1.456) [28].

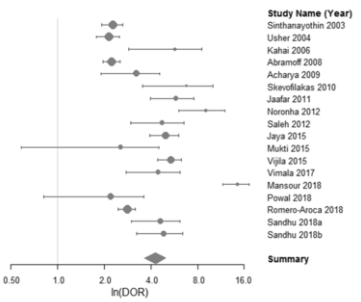

Figure 4 – Forest plot of the DOR

We performed several subgroups and sensitivity analyzes due to the heterogeneity presented. Though, the heterogeneity remained high. Based on our meta-regression analysis including clinical and technological co-factors, we did not observe evidence that any cofactors represented the cause of the observed heterogeneity.

Discussion

The American Diabetes Association along with the American Academy of Ophthalmology formulated Guidelines for Diabetic Retinopathy screening with annual Eye Fund examination for qualify patients [48, 49, 50, 51]. The early detection has the great potential to prevent visual loss since the retinal disease has a pre-symptomatic state [48, 49, 50, 51].

The agreement between ophthalmoscopy and photographs can vary from 61.9% to 86.3%; showing that digital images have the sensitivity of 78% and specificity 86% [52]. When comparing images through the stereoscopic, the ophthalmoscopy presents a sensitivity of 34% and specificity of 100% when compared with the reference standard – stereoscopic [52].

The DSSs based on images may be superior to fundoscopy in the classification of lower levels of Diabetic Retinopathy. It may present as an adjuvant method in diagnosis such as technologies have not been as effective in visualizing other pathologies related to Diabetic Retinopathy, such as cataracts and glaucoma [8].

Despite the limitation of medium heterogeneity, found among the studies included in our meta-analysis, the accuracy of decision support systems was high in support of the diagnosis of diabetic retinopathy. Although, the subgroup analyses and sensitivity revealed that the cofactors presented in the studies could not explain the heterogeneity origin.

Conclusion

The use of Decision Support Systems in diagnosing Diabetic Retinopathy has the potential to noninvasively improve the quality of the management of diabetes patients and contribute to the reduction of cases of visual impairment and blindness. The analysis by QUADAS-2 revealed the high methodological quality of included studies. The high sensitivity and medium specificity points towards to the interpretation of an improvement in the accuracy promote by the DSSs when compared with the high rates of false positives found. The medium heterogeneity observed in the study could not be explained by the cofactors presented. Finally, our results corroborate with the concept of usefulness of DSSs in early diagnosis, screening and preliminary evaluation of suspicious images of Diabetic Retinopathy.

Through the above, we suggest that our findings be interpreted with caution and that future researchs investigate the causes of the presented heterogeneity.

Abstract

Patient safety events (PSEs), or medical errors, are major impediments to healthcare system safety. Health information technology (HIT) is expected to promote quality of care. Nonetheless, HIT also creates unintended consequences that concern patient safety consolidating a high-quality database of HIT events is essential to understanding their nature. Previous studies demonstrated the potential to use FDA Manufacturer and User Facility Device Experience (MAUDE) database to extract HIT events. In this study, we utilized classic and CNN models to extract HIT events from MAUDE. Both individual and combined models were evaluated on the test set, where the best model identified HIT events with ~90% accuracy and achieved a ~.87 f1 score. This model was capable of identifying HIT events in an HIT-exclusive database and serving as a quality and error check tool during event reporting. Moreover, the strategy of HIT event identification may scale in developing other PSE subtype-specific databases.

Keywords:

Patient Safety; Medical Errors; Information Storage and Retrieval

Introduction

Patient safety events (PSEs) are defined as "any event or action that leads to or has the potential to lead to a worsened patient outcome related to the event or action" [1]. Many PSEs can be attributed to medical errors - unintentional and preventable adverse effects due to poor care. Medical errors are the third leading cause of death in the United States, responsible for approximately 251,000 deaths annually [2]. In response, the Institute of Medicine published "*To Err is Human*," a paradigm-shifting report calling on states to provide public, standardized, and mandatory reporting systems [3]. Nonetheless, current practices of incident reporting are imperfect. While report collection has been heavily emphasized, little effort has been directed to analyzing reported events [4]. This is especially troubling because identification of common themes is crucial in identifying relevant issues to improve patient safety.

The adoption of health information technology (HIT) is critical in reducing medical errors [5]. The U.S. Department of Health and Human Services defines HIT as "the electronic systems health care professionals – and increasingly, patients – use to store, share, and analyze health information." HIT includes, but is not limited to, electronic health records (EHRs), personal health records (PHRs), and electronic prescribing systems [5]. HIT-enabled care yields improved data collection, data availability, cost efficiency, coordination of care, and risk analysis, thus reducing extraneous care and medical errors [6]. Hugely beneficial to healthcare, reliance on HIT is not without its faults. HIT unavailability, malfunction, and improper use may increase the likelihood of adverse events. Listed in the top 10 technology-hazards for healthcare by the Emergency Care Research Institute and comprising one sixth of all PSEs, reducing HIT errors will maximize patient safety [7, 8].

Collecting HIT events is the first step in identifying causes and preventing recurrence. The Agency of Healthcare Research and Quality (AHRQ) has spearheaded this task and has standardized PSE reporting, including HIT event reporting, in the Common Formats (CF). However, because the CF includes HIT as a set of contributing factors rather than as an event category, very few HIT event reports were archived [9]. As a result, most HIT events remain uncategorized or insufficiently categorized under only broader categories such as device or medical/surgical supply. In addition, many reporters leave fields blank due to the extensiveness and challenges in knowledge of patient safety reporting. These limitations make data collection on HIT events difficult. Therefore, an HIT-exclusive event database is in an urgent need.

The FDA MAUDE database is an extensive, online, and public resource with great potential for extracting HIT events. Updated once a month, the MAUDE searchable database contains a wealth of information, including manufacturer information, adverse event information, device information, and patient outcomes [10]. Although only an estimated 0.46~0.69% [11] of MAUDE reports are HIT-related, MAUDE contains over 6 million total reports from mandatory reporters (i.e. importers, manufacturers, and device user facilities) and voluntary reporters (i.e. patients and healthcare professionals) as of Aug 2018. This proportion produces challenges in the identification of HIT events [12]. The key problem is that standard classification algorithms are less effective on imbalanced datasets and that data pre-classification is necessary for suitable training [13]. This study expands on our previous study that generated a database containing 97% HIT events by using term frequency-inverse document frequency (TF-IDF), and biterm topic modeling (BTM) [14].

In this study, to improve on the low F1 score of our prior study, we upgraded the identification method by applying four classic classification algorithms (i.e., Logistic Regression, SVM, Bernoulli Naïve Bayes, and Random Forest), and a convolutional neural network (CNN). Both combined models and individual models were assessed to identify HIT events from MAUDE reports for database generation. An HIT specific database, the product of our model, will be helpful in identifying, preventing, and learning from HIT events. The identification strategy may also be scalable to other PSE subtypes.

Methods

Data pre-processing

A pre-filtered dataset of MAUDE reports was expert-reviewed to determine if the reports were HIT-related [11]. We then randomly categorized the reports to achieve a standard 70/10/20 training/validation/test set split.

Tokenization and word embedding

For the CNN model, Keras API with tensorflow backend was used to tokenize the unstructured text fields of each MAUDE report, and tokenized sequences were then padded to a maximum sequence length of 1,000 words [15]. For most deep learning text-classification models, word representation through feature vector classification is essential in maximizing accuracy [16]. Due to the absence of a large unsupervised training set to initialize word vectors, we used publicly available pre-trained word vectors provided by Global Vectors for Word Representation (GloVe). Based on word co-occurrence, GloVe word vectors are highly effective in characterizing word similarity. Our model used trainable GloVe vectors with a dimensionality of 50 [17].

For the classic models, the unstructured text fields of each MAUDE report were interpreted into a TF-IDF matrix using the scikit-learn python package [18]. TF-IDF weights word importance by calculating an inverse proportion of word frequency in a particular document and the percentage of all documents in which the word appears. TF-IDF is calculated through the following formula where $w_{i,j}$ is the TF-IDF weight, $tf_{i,j}$ is the number of occurrence of term i in document j, and N is the total number of documents.

$$w_{i,j} = tf_{i,j} * log(\frac{N}{df_i})$$

The words with higher TF-IDF weights are rarer, signifying greater importance in the document [19].

Classic model architecture

Following TF-IDF word embedding, four popular machine learning algorithms –SVM, Bernoulli naïve Bayes (BNB), random forest (RF), and logistic regression (LR) – were constructed using the sci-kit learn python package to classify the weighted text [18].

CNN model architecture

The CNN architecture was inspired by Kim's work [20]. We used Keras API with tensorflow backend to build our model [15]. After GloVe word embedding, we applied three 1D convolutional layers with kernel size 2, 3, and 4 respectively. Each 1D convolutional layer has 256 filters and was followed by a max-pooling layer to produce 256 features. To minimize overfitting, we applied 30% dropout to the max-pooled layer. The three outputs were then concatenated and flattened into a single layer that was fed to a dense layer of 1024 units with rectified linear units (relu) activation followed by 50% dropout. The output layer had one unit and was activated by a sigmoid function. Hyperparameters were tuned according to the model performance on the validation set.

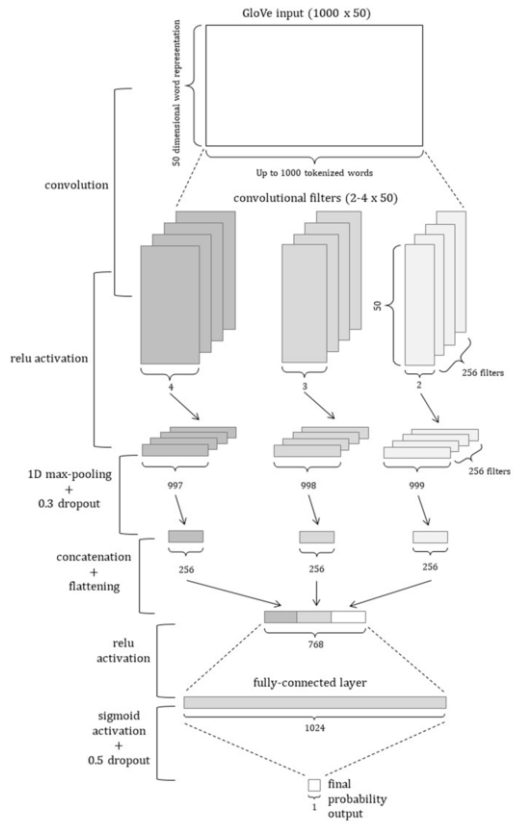

Figure 1: Illustration of CNN architecture for text classification. The figure depicts the three convolutional filter sizes (2, 3, and 4), max-pooling, concatenation, and final output layers used to classify a single document.

Combined model architecture

Among the five individual models, three with the best performance were applied to produce combined models. In each combined model, the probabilities of individual model were averaged to compute the probabilities of the combined model. If the averaged probability that the event is an HIT event equals or exceeds 50%, the combined model guesses 1 (HIT event), and if not, the model guesses 0 (non-HIT event).

Results

Dataset statistics

The dataset, containing 5,588 MAUDE reports, was generated by applying a keyword filter to recent nine-year MAUDE data (2008-2016) [11]. The dataset was relatively balanced between HIT - 2,192 (39.2%) and non-HIT – 3,396 (60.8%) PSEs. For model training, this balanced proportion is preferable to the 0.46~0.69% HIT event proportion in the MAUDE database as a whole [11]. In addition, we extracted 18,132 individual tokens from the 5,588 total reports.

CNN hyperparameter tuning

We tuned numerous CNN hyperparameters including batch size, learning rate, dropout, kernel size, max-pooling pool size, embedding dimensions, maximum token number, and

maximum sequence length. Increasing maximum token number and sequence length improved model accuracy. Thus, a maximum sequence length of 1,000 and maximum token number of 20,000 were used to incorporate as much training data as possible. Multiple dropout layers of 30-50% performed optimally, and max-pooling the product of each convolutional filter to an output of length 1 outperformed smaller max-pooling pool sizes. We found that batch size and learning rate had a negligible effect on model performance. Increasing embedding dimensions beyond 50 failed to improve model performance while increasing training time as well.

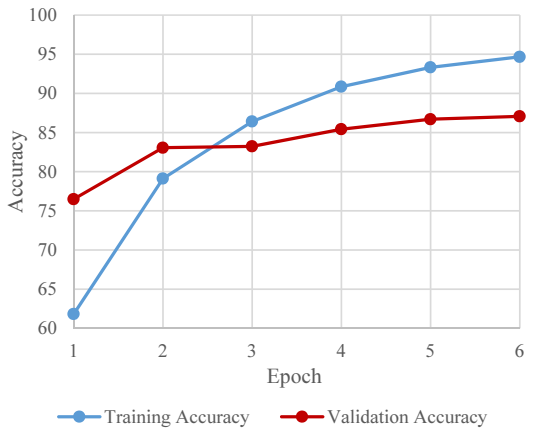

Figure 2: Training and validation accuracy of the CNN model over 6 epochs

While training the CNN model, we found that the rate at which validation accuracy improves decreases significantly around the 2th epoch, and fails to improve consistently past the 6th epoch (Figure 2). Moreover, training accuracy continues to improve past the 6th epoch, signifying overfitting of the training data. We found that the CNN model performed best on the test set when trained for 6 epochs.

Individual and combined model performance

Table 1: Accuracy, Precision, Recall, and F1-score of each individual and combined model on test set

Methods	Accuracy	Precision	Recall	F1
SVM+LR+CNN	.9012	.8796	.8606	.8700
SVM+LR	.8965	.8838	.8413	.8621
SVM+CNN	.8901	.8595	.8534	.8564
LR	.8895	.8828	.8366	.8591
LR+CNN	.8864	.8582	.8438	.8509
SVM	.8860	.8584	.8584	.8584
CNN	.8836	.8463	.8522	.8493
BNB	.8529	.8033	.8440	.8232
RF	.8467	.8690	.7186	.7885

*SVM = support vector machine, LR = logistic regression, CNN = convolutional neural network, BNB = Bernoulli naïve Bayes, RF = random forest

As shown in Table 1, combined models generally outperformed individual models by all metrics. LR+CNN was an exception to this trend. LR, the best performing individual model, outperformed LR+CNN. Among the other three combined models, SVM+LR+CNN outperformed SVM+CNN by all metrics and outperformed SVM+LR on all metrics except precision. Differences in the classification algorithms behind individual models may explain why the combined models performed better. One model may misclassify reports accurately classified by another model. Thus, averaging probability predictions can help mitigate the erroneous predictions of individual models by factoring in other models as well.

Effect of data size on model performance

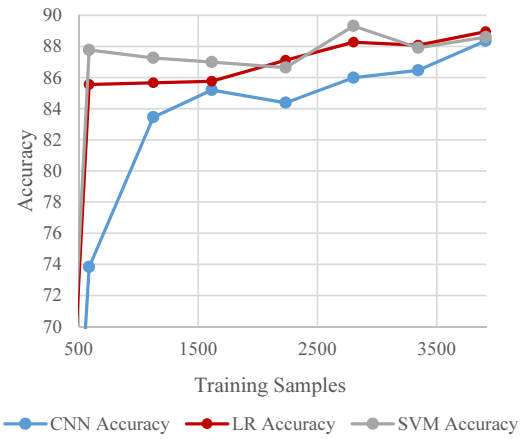

Figure 3: Improvement in test accuracy as number of training samples increases

Given a larger dataset, we believe that the CNN model and combined models involving the CNN will improve. Shown in Figure 3, CNN test accuracy improves steadily as the number of training samples increases. In contrast, classic machine learning methods such as logistic regression and SVM are less sensitive to training sample count

Discussion

Related work

Beyond the FDA MAUDE database, analysis of 48 PSE databases revealed significant technological limitations (i.e. insufficient interoperability, lack of report quality validation) that limit data entry quality. Providing embedded validators, enabling feedback review, and improving interoperability are areas of potential database improvement [21].

Substantial precedent exists in the using machine learning models to extract PSE subcategories. A hybrid CNN and bidirectional long short-term memory (LSTM) autoencoder model has been used in the detection of bleeding events from electronic health record notes with an overall F-score of 0.938 [22], and an artificial neural network (ANN) was used to identify variables which were analyzed via logistic regression to classify fall events from a nursing PSE database from a Taiwan medical center [23].

Growing and using an HIT event database

In our previous study, the models were trained on a small dataset with 490 MAUDE reports (312 HIT, 178 Non-HIT), and reached up to 88.6% accuracy, performing similarly to the classic models in this study [14]. However, we did not have an individual test set in the previous study due to the limited data size, which made the model suffer from severe overfitting. In addition, to obtain high precision, we traded off recall in the previous models. In this study, we used an upgraded dataset

from 9 years (2008-2016) of keyword-filtered MAUDE reports while the previous study only used reports from 2015 [11, 14]. We also upgraded the classifiers and proposed the SVM+LR model for HIT event identification. With an accuracy of ~90% and f1-score of ~.87, the SVM+LR+CNN model outperforms previous models and holds promise in growing an HIT event database.

To extract contextually relevant themes and topics regarding HIT events, we can use the database to process a high quantity of HIT reports at a time. Natural language processing (NLP) techniques may be the best method for identifying connections between HIT events. Such connections will provide experts with the information necessary to address the root causes of HIT events. Developing effective solutions to prevent future HIT events is the final step of this process. As HIT becomes increasingly influential in healthcare, utilization of the constantly updated HIT database will help ensure that HIT functions accordingly to ensure patient safety.

Importance of an HIT event database

The inappropriate use, design, and implementation of HIT are profoundly detrimental to patient safety. However, identifying and fixing relevant HIT issues is challenging without an organized database of HIT events. Many seemingly insignificant events may signify deeper issues, which, without a broader database, are difficult to identify. A database will allow for the detection of broader trends indiscernible from individual documents. Identifying such trends is crucial to fixing HIT issues and preventing future accidents. The fact that the nature of HIT events differs from PSEs as a whole further necessitates the accumulation of an HIT event database. For instance, contributing factors to HIT events such as equipment/device function and data availability do not exist for non-HIT events. The prevalence of certain contributing factors differs between PSE subtypes as well. While poor staff communication is a contributing factor in an estimated 40.0% of HIT events, it only factors into 24.8% of non-HIT events [24]. The uniqueness and impact of HIT mandates the HIT event database construction.

Probability outputs as a reporting aid

Screening the quality of new entries into PSE databases is another means of improving event reporting. Our model can interpret the unstructured text of PSE reports during reporting and continually update the reporter on the probability that the report is HIT or non-HIT. This yields numerous benefits. First, if the reporter writes a report description but has difficulty categorizing the report, our model can help inform their decision on whether or not to check the HIT-related box. Conversely, if the reporter erroneously labels a report, probability predictions may better inform the reporter on what label the report should be. This functionality will help reporters avoid labeling/entry mistakes. Finally, if the reporter is certain that the PSE is clearly HIT or non-HIT but unsure of how to write the report, the model's probability prediction could help guide the reporter into writing narrative text that best coincides with the report category. The overarching benefits of improved report descriptions, fewer mistakes, and more accurate labeling are that HIT-event extraction will be easier in the future, and more high-quality data will be available for analysis.

Tracking HIT changes

In 2015 alone, the U.S. Patent and Trademark Office granted 17,596 patents for new medical devices [25]. HIT is constantly changing, and we must adjust our model to captures such changes. As new PSE and HIT events are added to the MAUDE database, we can update our model. Alternatively, we could completely retrain our model on new data each year to avoid incorporating out of date HIT events. Meticulously choosing a training set that balances the inclusion new HIT events and exclusion of irrelevant, old HIT events is key to constructing a model reflective of the present nature of HIT.

Challenges of identifying HIT events with machine learning

NLP is limited in its capability to account for word context, sentence meaning, and typographical errors [26]. Generalized NLP and GloVe word embedding provide substantial information on individual word frequency and meaning, but cannot discern differences due to word context. Numerous factors such as individual writing style, interactions between different document sections, and accidental errors cannot be accounted for by NLP and machine learning models. Manual review may remain a useful supplement in the classification of reports poorly identified by NLP and machine learning.

Limitations

Missing, duplicated, and non-standardized entries were common in the MAUDE database. Out of 1,103 medical device reports, 64 reports with duplicated information and 6 reports referring to multiple patients were found. The investigation also identified the varying quality and completeness of reports is another issue [27]. Despite its flaws, the MAUDE database is the only publicly accessible database suitable for the extraction of HIT events.

Future work

Optimizing and improving our model

Deducing the quantity and precision of HIT reports desired for database construction is crucial. Because our database must be HIT-exclusive, false positives are more unfavorable than false negatives. Precision takes precedence over recall, and increasing the threshold needed to label an event as HIT beyond 50% without significantly reducing recall would be optimal.

Other deep learning models may perform better than classic models or the CNN. We will apply a recurrent neural network (RNN) for HIT event classification. Bidirection, hierarchical models, and attention may also improve RNN performance [28]. Recurrent CNN (RCNN) also offers potential for HIT event classification [29].

Application to other categories of PSEs

While PSE databases already exist for certain PSE subtypes such as medication error, two additional PSE subtypes that lack a specific database are patient falls and administrative error [30]. Applying a keyword filter to the MAUDE database can help isolate training data for database generation and probability outputs with the proposed SVM+LR+CNN model.

Conclusion

Our strategy to extract HIT events from MAUDE reports for an HIT event database construction bests prior models by all significant performance metrics. Database generation is an essential first step in identifying themes, causes, and solutions to HIT events. Moreover, our model has great potential in improving the quality and accuracy of HIT event reporting.

Abstract

Postpartum depression (PPD) is one of the most frequent maternal morbidities after delivery with serious implications. Currently, there is a lack of effective screening strategies and high-quality clinical trials. The ability to leverage a large amount of detailed patient data from electronic health records (EHRs) to predict PPD could enable the implementation of effective clinical decision support interventions. To develop a PPD prediction model, using EHRs from Weill Cornell Medicine and NewYork-Presbyterian Hospital between 2015-17, 9,980 episodes of pregnancy were identified. Six machine learning algorithms, including L2-regularized Logistic Regression, Support Vector Machine, Decision Tree, Naïve Bayes, XGBoost, and Random forest were constructed. Our model's best prediction performance achieved an AUC of 0.79. Race, obesity, anxiety, depression, different types of pain, antidepressants, and anti-inflammatory drugs during pregnancy were among the significant predictors. Our results suggest a potential for applying machine learning to EHR data to predict PPD and inform healthcare delivery.

Keywords:

Depression, Postpartum; Electronic Health Records; Machine Learning

Introduction

Postpartum depression (PPD) is a nonpsychotic depressive episode that begins one year within childbirth[7]. The prevalence of PPD is reported to be 13% in high-income countries [21] and 15% in low and middle-income countries[9]. PPD is one of the most frequent and serious maternal morbidities after delivery [26]. It not only interferes with mothers' emotional wellbeing [5], but is also associated with infant morbidity, and children's poorer cognitive and behavioral skills later in life [28].

Despite the serious adverse consequences of PPD, there is a lack of consensus and evidence on PPD screening and treatment from high-quality clinical trials [22]. A number of key predictors have been identified from previous meta-analysis studies, including a history of psychiatric illness, prenatal depression, stressors and illness during pregnancy, poor social support, poor self-esteem, and lower socioeconomic status [1, 23]. Few studies found a significant association between prescription drug use during pregnancy with PPD [20].

Although risk factors were reported from previous studies, effective interventions against them and identification of at-risk women still need further evaluations [22]. A number of screening and preventative measures were proposed previous studies with varying outcomes [22]. For example, prior PPD prediction studies were prospective studies conducted with small sizes [14,26]. Features used in these predictive models often included questionnaires measuring psychological statuses such as demographics, education level, self-esteem, and social support, but not current diagnoses and medications. A commonly used questionnaire for perinatal depression screening is the Edinburgh Postnatal Depression Scale (EPDS) [10,26], although its effectiveness in screening has been questioned in previous studies [27].

The current knowledge gap on PPD contributes to substantial variations across clinical practices in screening and information collection [22]. Addressing these challenges, it has been pointed out by the US Preventive Services Task Force (USPSTF) that electronic health records (EHRs)-based tools may be considered in implementing PPD-related interventions [22]. EHR data are routinely collected and contain a detailed history of health and health services utilization [8]. Moreover, models developed using EHR data can be potentially integrated within the EHR system as clinical decision support (CDS), allowing effective screening for expectant mothers at risk of developing PPD.

In this study, we propose that machine learning algorithms can be applied to EHR data, containing information from the full three trimesters of pregnancy period to delivery, to construct a predictive model for PPD outcome. We performed a pilot study using six machine learning algorithms featuring longitudinal clinical information and patients' socio-demographic characteristics. The overarching goal of this study is to demonstrate that machine learning models can be used to predict PPD, and to carefully evaluate the risk factors identified from EHR data.

Methods

Data

In this study, we used EHRs from Weill Cornell Medicine and NewYork-Presbyterian Hospital from 2015 to 2017 as the data source. The study data are represented using Observational Medical Outcomes Partnership (OMOP) common data model [19] and include patient socio-demographics, timestamped outpatient and inpatient diagnoses, and timestamped medication prescriptions.

Study population

Pregnant women with a fully completed antenatal care procedure at the hospital and with a singleton birth were included in the study. The exclusion criteria were: (1) those with unknown pregnancy length of gestational weeks, (2) those

with missing information from at least one trimester during pregnancy.

Outcomes and Predictors

Clinical assessment of PPD was used as the outcome in this study. The main outcome was defined based on the Statistics Canada [3] and International Classification of Diseases, 10th Revision (ICD-10-CM) codes O99.3 and O99.34 as well as their ICD-9-CM equivalents for a diagnosis of PPD within 12 months after childbirth. We considered patients' birthdate, race, maternal status, average body mass index (BMI), gestational week, and delivery type as time-independent predictors, and medication prescriptions and diagnoses at each clinical visit as the time-dependent predictors.

Age was calculated as baseline age at the first visit of prenatal care. Marital status was extracted from unstructured clinical notes and categorized as single (unmarried, divorced and windowed), married, and unknown. Race groups included White, Asian, American Indian or Alaska Nation, Black or African American, Other combinations not described, and Unknown. We included Native Hawaiian, Other Pacific Islander, and other racial combinations as "Other combinations not described." Gestational weeks were computed using the delivery dates and gestational checkup weeks. The specific trimester of medication prescription and diagnoses were identified by the time interval between each event and delivery. We defined trimester of pregnancy as follows: first trimester (0-12 weeks), second trimester (13-28 weeks), and third trimester (29 weeks- gestation). All diagnoses were represented as Systematized Nomenclature of Medicine-Clinical Terms (SNOMED-CT) codes. Medication and dosage were standardized by Anatomical Therapeutic Chemical (ATC) Classification System.

In order to perform variable selection for the prediction model, we first selected the variables above the median frequency for all variables. Then, univariate logistic regression (LR) analyses were performed, in which factors with p-values below 0.05 were assigned as potential predictive factors.

Prediction model

In this study, six machine learning models, including Support Vector Machine (SVM), Random Forest (RF), Naïve Bayes, L2-regularized LR, Extreme Gradient Boosting (XGBoost) and Decision Tree were used to build PPD prediction models. We evaluated each model's performance using the area under the receiver-operator curve (AUC) in 10-fold cross validation. All machine learning and statistical analyses were performed with R version 3.4.3 (R Foundation for Statistical Computing, Vienna, Austria).

SVM is a classifier which transforms input data into a multidimensional hyperplane using kernels to discriminate two classes [12]. RF is an ensemble learning method that operates by constructing a multitude of decision trees and outputting the class that is voted by a majority of the trees [4]. Naïve Bayes classifier uses the Bayes Theorem to predict membership probabilities for each class by assigning a class with the highest probability as the most likely class [33]. LR is a regression model with a binary dependent variable [2]. L2-regularized LR tunes and generalizes the model in order to balance the bias-variance trade off [32]. XGBoost is a scalable tree boosting algorithm which trains a sequence of models to minimize errors made by existing models [24]. Lastly, Decision Tree predicts class membership by inferring decision rules from the training data. For all models, we applied an oversampling method to the training data as our outcome was imbalanced (see Table 1). Oversampling is a popular method in dealing with class imbalance problems, which changes the training sets by repeating instances in the minority training set [17].

Feature Importance

In order to provide more interpretability to our model, we examined the association of predictors categorically with PPD. We compared models with different feature compositions (see Table 3). First, we examined the temporality of the features by grouping medication prescribed by trimesters. Then, we examined feature categories by building models with socio-demographic information only, medication information only, diagnostic information only, and medication combined diagnostic information. Lastly, we built a model with only variables selected using the univariate LR. The Pearson correlation of variables was tested to prevent multicollinearity. If the correlation coefficients were greater than 0.8, variables were combined. Only variables whose associations with PPD were statistically significant were selected. Odds ratios with 95% confidence intervals (CI) and p-values are presented in Table 4.

Results

Demographics

Table 1 shows the characteristics of pregnant women with and without PPD. Results are presented as the mean ± standard deviation for continuous variables and N (%) for categorical variables. A p-value less than 0.05 is considered statistically significant in statistical analyses. Among the studied population, 9,980 episodes of pregnancy were identified. There was a significant difference in age between two groups using a student t-test. The mean age was 33.92 (SD 4.51) years old in non-PPD group and was 34.36 (SD 4.61) years old in the PPD group. The pre-pregnancy average BMI in PPD group is higher than that in non-PPD group. There were significant differences in race between the PPD and non-PPD groups using a Fisher exact test. The number of single mothers is higher in the PPD group than non-PPD group (23.15% vs. 15.96%).

Table 1- Baseline Characteristics of Pregnant Women.

Variables	Non-PPD	PPD
N	9211	769
Age, years*	33.92 ± 4.51	34.36 ± 4.61
Pre-pregnancy BMI, kg/m^2*	23.61 ± 4.41	23.93 ± 4.99
Race*		
White	4801(52.12)	478(62.16)
Asian	1455(15.80)	62(8.06)
American Indian or Alaska Nation	30(0.33)	3(0.39)
Black or African American	492(5.34)	45(5.85)
Other combinations not described	1067(11.58)	90(11.70)

Prediction Model Performance

Table 2– Prediction Results.

Machine learning technique	AUC	Sensitivity	Specificity
SVM	0.79	0.894	0.580
L2 LR	0.78	0.887	0.594
RF	0.78	0.959	0.391
Naïve Bayes	0.78	0.867	0.616
XGBoost	0.77	0.915	0.527
Decision Tree	0.69	0.986	0.386

In this study, prior to variable selection, 256 variables were extracted including socio-demographic characteristics, disease diagnoses, and medications across 3 trimesters. We then identified 98 potential predictors using univariate LR analyses. Among the selected variables, 71 variables were diagnoses and 22 were medications. Results from the 6 machine learning models using all 98 predictors are shown in Table 2. AUC for different classifier was the highest with SVM (0.79), followed by L2-regularized LR (0.78), RF (0.78), Naïve Bayes (0.78), XGBoost (0.77), and the lowest was 0.69 for the Decision Tree. We further computed the sensitivity of different models. The Decision Tree had the highest sensitivity (98.6%), followed by the RF (95.9%), XGBoost (91.5%), SVM (89.4%), LR (88.7%) and naïve Bayes (86.7%). The specificity was highest for naïve Bayes (61.6%), followed by L2-regularized LR (59.4%), SVM (58.0%), XGBoost (52.7%) and Decision Tree (38.6%).

Feature Importance

Using SVM, the best performing model, we investigated model performance using different feature compositions, presented in Table 3. The AUC for the model using only 1st, 2nd and 3rd trimester information was 0.66, 0.64, and 0.65, respectively. The AUC for the model with variables in both 1st trimester and 2nd trimester, 2nd trimester and 3rd trimester was 0.69 and 0.72, respectively, both of which lower than the complete feature set. In addition, the AUC for the model with only demographic variables was 0.60. The AUCs for the diagnoses model or medication classes model were 0.72 and 0.65, respectively. When we combined medications and diagnoses together, the AUC increased to 0.76.

Table 3– Prediction Results in Different Variable Combinations.

Predictors	AUC	Sensitivity	Specificity
Trimesters			
1st	0.66	0.855	0.428
2nd	0.64	0.831	0.424
3rd	0.65	0.867	0.424
1st +2nd	0.69	0.908	0.307
2nd +3rd	0.72	0.854	0.524
Categories			
Demographic	0.60	0.551	0.609
Diagnose	0.72	0.850	0.560
Medication	0.65	0.882	0.389
Diagnose+ Medication	0.76	0.875	0.577
Logistic-selected	0.76	0.892	0.588

The univariate LR identified 26 predictors out of the 98 predictors whose associations with PPD have significant and meaningful odds ratios for PPD (Table 4). The AUC using 26 important features were lower than using the whole features. None of the reduced models performed as well as the full model (Table 3).

(70747007/36923009/79298009/15639000/251000119105/43085200 1/76441001), palpitations (80313002).

In Table 4, amongst factors related to diagnoses during pregnancy, obesity, anxiety, depressive disorder, and mental disorder, threatened miscarriage in 1st trimester; abnormal weight gain, anxiety, depressive disorder, diarrhea, mental disorder, premature labor, muscle pain, vomiting in 2nd trimester; and anxiety, abdominal pain, backache, hypertensive disorder, mental disorder, palpitations, major depression, and single episode in 3rd trimester were found to be associated with increased odds of PPD. Among medications, the use of antidepressants during pregnancy, and anti-inflammatory agents in 2nd trimester were associated with increased odds of PPD. Among the predictors, hormone use had no associations with PPD, despite their mention in previous literature [30].

Discussion

In this study, we employed 6 machine learning models to predict PPD using EHR data. Experimental results demonstrated the feasibility of our approach for PPD risk prediction based on information available during prenatal care in an EHR. We found several disease diagnoses and medications during pregnancy that potentially contribute to the prediction of PPD.

The performances of the model using variables in one specific trimester only, both 1st and 2nd trimesters or both in 2nd and 3rd trimesters were not as good as using variables in whole prenatal care. Thus, our findings potentially suggest that screening should consider health and health service utilization throughout the pregnancy period. When we separated the variables into demographic variables, diagnoses variables, and medication variables, disease diagnoses had the best performance in predicting PPD. Although, using the combination of disease diagnoses with medication improved the performance in predicting PPD than using disease diagnoses alone. Again, more comprehensive information provides more improved prediction performance.

Our data set included multiple features in EHR data. Although SVM had the best performance, the difference across the performance of SVM, L2-regularized LR, RF, Naïve Bayes, and XGBoost was minimal, although differences existed with respect to sensitivity and specificity. The AUC of the decision tree model was the lowest compared with the other five models. This may be explained by the tendency of the decision tree to depend on single variables in generating decision rules [13].

Several associations found in our study are consistent with previous studies. These include race [16] as demographics and threatened abortion [6], prenatal mental disorder [15], in particular, diagnoses such as depression disorder, anxiety, and single episode major depression, backache in the 3rd trimester, and muscle pain in 2nd trimester [6]. Pain is often expressed as symptoms of depressive disorder [6]. Thus, our results indicate that there is a strong need for perinatal interventions to focus on expectant mothers' mental health as prevention for PPD.

Correspondingly, we found that antidepressant use across three trimesters is a strong predictor of PPD. The treatment of women with depression or other psychiatric diseases during pregnancy or postpartum is a complex clinical challenge [25]. A previous study reported that women who had antidepressant treatment during pregnancy were less likely to report postnatal depressive symptoms, compared with the nonmedicated counterpart [18]; however, discontinued antidepressant medications during pregnancy was a risk factor for PPD [11]. On the other hand, antidepressants used during pregnancy might be associated with gestational hypertension and preeclampsia [31]. We did not find analgesic as an independent risk factor for PPD, although its association was reported in previous literature [29].

We recognize that this is a pilot study and there are certain limitations in our current work. First, since we combined medications by ATC classes, we were not able to differentiate drug use by specific dosage levels. In future studies using larger data sets, we will identify and combine different sources of disease diagnoses, and consider the dose-response relationship with medications and PPD. Second, the machine learning methods used in this study are standard methods, and the oversampling method used to handle our imbalance data may have contributed to overfitting and impacted model performance [17]. More advanced machine learning methods such as the neural network models will be used to improve AUC in future work. Third, since we used EHRs from a single health system, our data may miss mothers diagnosed with PPD outside of our health system, as well as information on those who were seen by clinicians outside of our health system before their pregnancy. Future studies will try to leverage multi-site dataset to minimize missing and erroneous data points. Lastly, in this study, we aimed to predict PPD rather than evaluating the causal relationships between variables in the pregnancy period and PPD. Future studies will use causal inference methods to control for potential and time-dependent confounders.

Conclusions

In this pilot study, we demonstrate promising PPD prediction results using a machine learning approach with information on patient demographics, diagnoses, and medications available from EHRs. Our goal is to create an accurate PPD prediction model to identify risk factors for PPD and facilitate effective screening of mothers who may require early intervention for PPD using an EHR. We envision that the model may be integrated with the EHR system for a provider-facing CDS or with a mobile or web platform to be used as a patient-facing CDS in a future phase of the study.

Expanding Virtual Reality to Teach Ultrasound Skills to Nurse Practitioner Students

Elizabeth Weiner[a], Jeffry Gordon[a], Susanna Rudy[b], Ryan McNew[a]

Abstract

This team has had prior successful production efforts in the use of Second Life to implement a virtual reality world into both nursing education and practice. Our current efforts center around a virtual reality application that provides learners with the opportunity to master competencies in the use of ultrasound technologies, which have surfaced in many nurse practitioner certifications as a necessary skill. Using the authoring tool of CenarioVR™, and capturing video footage of a nurse practitioner using the ultrasound equipment, students can don a VR headset for an immersive experience. This ultrasound equipment is expensive, and allowing learners to learn skills in a virtual environment poses less risk to both the equipment and the patients.Future production efforts in augmented and mixed reality applications are described to engage others in cutting edge use of VR.

Keywords:

Virtual reality; education, nursing; ultrasonography

Introduction

Healthcare educators, both in academic and practice settings, continue to seek the most realistic simulations for their students. With the rising cost of healthcare equipment, along with an increased attention to patient safety, these simulations have taken on even more importance. Clinical placement sites do not always have the opportunities to practice certain skills, and have become more difficult to obtain along with seasoned preceptors.

In this article we will describe the development of an immersive virtual reality simulation to teach nurse practitioner students how to effectively use ultrasound equipment. This competency has recently been added for certification in many of the nurse practitioner specialties in the United States.

Simulation is an educational technique which aims to mimic elements of the real world to help achieve specific goals related to learning [1]. When using the term "simulation," most nursing faculty and students think of the typical simulation environment comprised of lower level task trainers to high fidelity simulators. This type of simulation has been around for the last 40 years, but is expensive, difficult to schedule, and takes up physical space [2]. Simulation teaching methods have expanded to include peer-to-peer learning, standardized patients, screen-based computer simulations, and virtual reality.

Virtual reality (VR) is a high-level computer-based interactive and multimedia technology that offers virtual objects and environments that represent actual environments [3]. Virtual simulations have been used to train users in various skills such as bronchoscopy, colonoscopy, laparoscopy, and endoscopic procedures, and in disaster triage [4]. It is fully immersive, which tricks your senses into thinking you are in a different environment or world apart from the real world [5]. The unique contribution of VR is its ability to provide spherical full motion video. The user is placed in the center of a sphere with the capability to look up, down, right, and/or left. This is in contrast to 360° video where the user can only look left and right. VR can also be contrasted to 3D video, typically on a flat plane, which gives a stereoscopic view with depth perception of the scene.

Three of the authors of this article have completed projects using the VR world of Second Life (SL). SL is a 3D virtual world, created by its residents. The world is driven by the interactions of real-world individuals and their avatars. Thus, for every avatar one encounters in SL, there is a live person somewhere in the world who is directing that avatar's actions, emotions, words, dress, etc.

The SL environment was built as part of prior funded grants from the U.S. Department of Health and Human Services Administration (Grants #D80HP11271 and #U1KHP1296). These grant activities have been reported in prior international informatics conferences [6,7,8]. The purposes of these grants were to provide nursing faculty the opportunity to manage clinical simulations while advancing in their own competency and proficiency levels of simulation management while in the SL virtual world. Synchronous sessions were provided by master teachers, after an orientation to SL had been completed by the users. Initial findings demonstrated that faculty participants thought that the programs met or exceeded their learning needs and would be directly applicable to their teaching. Project barriers were the time spent in development of this complex environment and the technology support needed to successfully run the developed scenarios. Those users who were technophobic had difficulties in learning to move their avatars as needed, which distracted them from the overall learning experience. On a more positive note, the replicated Eskind Diabetes Center created in SL was used as the basis for nurse practitioners to provide care to diabetes patients while both were avatars. Finally, this patient care example was presented as a method to better engage patients in their own care.

SL has been used by other nursing educators over the last decade. Trangenstein, Weiner, Gordon and McNew completed a literature search that reviewed 29 nursing educational virtual environments and discovered that nursing educators used SL as explorers and developers [9]. Explorers used SL for a support group, networking,and uncovering health-related sites. The developers were associated with land ownership and were involved in distance learning and simulation activities. Seven unique simulations for nursing education were identified. This type of virtual simulation environment has been generally well received and evaluations of its used in educational settings has been positive [10].

Augmented reality overlays digital information on real-world elements [5]. Pokémon Go is a widely known example. In augmented reality applications, the real world is central but enhanced with other digital details, thus supplementing your reality or environment. Mixed reality brings together real world and digital elements [5]. Mixed reality allows the user to see and immerse oneself in the world around the user while interacting with a virtual environment. It combines the ability to be in a real world enhanced by an imaginary place or image therefore offering an experience that is not possible in the real world alone.

The purpose of this article is to describe the development process used in an immersive VR simulation aimed to teach ultrasound skills to nurse practitioner students. While evaluation data will not be available until the actual presentation, the structure of the evaluation will be discussed. In addition, future applications using both augmented reality and mixed reality will be described.

Methods

Ultrasound has been described as the stethoscope of the 21st century. Evans and Evans demonstrated that with some training, health care professionals can successfully use the ultrasound machine to identify common pathologies [11]. They also claim it can shorten patient waiting time, lower costs, improve diagnoses, and reduce the pressure on other radiography lists.

Portable ultrasound technology is increasingly used in the diagnosis and management of critically ill patients (See Figure 1). As an easily accessible and frequently used bedside tool, ultrasound has the potential to improve patient safety; however if untrained providers use the equipment, the result could be harmful [12].

Figure 1 – Ultrasound Machinee

The charge then becomes to educate large numbers of students on how to successfully setup and use the ultrasound machine on various pathologies. This project was selected for several reasons. First, the typical ultrasound machine demonstration works best for the few students in the front and poorly for those in the back unable to see everything that is transpiring. Such an approach is not scalable to the numbers who need the training. Secondly, many of our nursing specialties want to teach how to use the device but because of the expense, we only have two machines to split among all of the specialties. Each machine was purchased with university discounts but with accessories averaged $85,000 US. These machines have sensitive electrodes, so moving the equipment around the building is also not a desirable option. By simulating the machine and watching an expert complete the ultra sound examination, the students save valuable time when using the actual machine because they will have already been taught how to use it. A seasoned nurse practitioner who has mastered these skills and uses them frequently becomes their expert role model. Students receive consistent quality controlled instruction and learn how to use the machine effectively and safely without risk to patient. Finally, the topic itself is highly visual, making Immersive VR a highly appropriate tool to teach how to setup and use the ultrasound machine.

Format of the Project

The ultrasound application lends itself to VR video development. It is very visual and the technology supports training users how to use the ultrasound device.

The application was divided into two components. The first component simulates the setup and configuration of the machine. The student can select their phenomena of interest, identify the correct probe to use, set the depth, brightness, contrast, and color desired for the correct exposure (see Figure 2). Finally, the student can enter in the patient information and have that stored in a database just as it is on the real device.

Figure 2 – Positioning the Probe

Data elements are entered in the simulation on a standard computer screen, identical to the screens of the actual device itself.

Once the ultrasound machine is configured properly and the appropriate data entered, the student enters the second component. They are told to download the Immersive VR application, launch it on their cell phone, and insert the phone into the VR headset. When the student puts on the headset, he or she is positioned in the middle of the sphere, called a scene, directly in the room looking over the patient so that the student can see everything the clinician is doing in a virtual 3dimensional experience. By looking around, the student can see where and how the clinician is placing the probe.

The student can view actual output of the ultrasound projected above the patient's head simply by looking up above the patient's head. This technique also amplifies the output for easier viewing (see Figure 3).

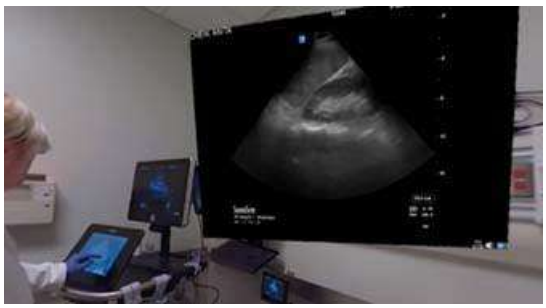

Figure 3 – Ultrasound Output

The student can also view the facial expressions and non-verbal communication of the patient and clinician. The student has the illusion of actually being in the room with only the clinician and the patient. Unlike group viewing situations where views might be obstructed by other students and the output too small to see by everyone, this method provides for a quality-controlled experience.

The student can pause the scene, rewind it, and turn his or her head to view the actual ultrasound output in real time corresponding to the probe positioning and movement (see Figure 4).. At various points in the exam, the instructor can pause and ask a question or even ask the student the next position for the probe.

Figure 4 – Identifying Probe Position

Student responses can be recorded and stored in a learning management system (LMS) for later review and performance evaluation. Feedback to the student can be textual, oral, or video branched to another sphere.

Development Tools Selected

A software authoring environment needed to be chosen. CenarioVR is an easy to use immersive VR development SaaS (Software as a Service) tool, developed by the Trivantis Corporation, that allows the developer to create photo and video spheres and incorporate them into a learning environment. The product can be played on a computer screen in HTML5 using mouse controls for movement or placed on a small mobile device that is inserted into a VR headset (such as Google cardboard, Daydream, or Oculus Go) for the full immersive experience (see Figure 5). When used immersively, the student has the sense of actually being in the room participating directly with the activities. The video can be paused, rewound, or branched to other spheres, called "scenes". Artifacts such as the actual ultrasound output can be inserted anywhere in the sphere and reflect the output of the actual exam in real time on the video sphere. Questions can be asked, and answers recorded and shared to the learning management system (LMS) through xAPI or SCORM. The students can then be graded on the quality of their work in the environment.

Figure 5 – VR Headsets

The video was collected using a spherical camera. The GoPro Fusion camera was selected along with Fusion Studio software on the PC (see Figure 6). Control of the camera was initiated through the GoPro phone application. The camera was positioned close to the patient, opposite from the clinician. Care was taken to make sure the clinician's hand positioning was fully visible to the camera and not eclipsed by the patient's body. A portable DVR was attached via HDMI to the ultrasound device to capture the video output from the ultrasound device.

Figure 6 – The DVR Video Capture Device and GoPro Fusion Camera

The spheres were assembled into equirectangular format and downloaded through the Fusion studio application, then compressed in the software application, Handbrake. The resulting scenes were brought into Adobe Premiere on the main track. The video of the output of the ultrasound was downloaded onto the PC and placed into a separate track in Premiere. It was aligned so that the video of the output matched with what the clinician was doing on the patient.

Using the VR tools in Premiere, the ultrasound output video was sized large to view and positioned over the head of the patient. It was as if a very large screen monitor was displaying the output over the head of the patient. It should be noted that placing video inside a sphere in Premiere requires a minimum of 1GB of video ram. We selected an Alienware 15 i7 laptop with 32GB of memory for its graphics processing capabilities (see Figure 7).

Figure 7 – Video Processing Using Alienware 15 i7

At specific points the video of the sphere was paused and questions asked. Successful selection of the answer started the video again.

Results

The project will be implemented with acute care nurse practitioner students during the 2019 spring semester. A short video of the use of the project will be shown during the conference as a video.

Evaluation results will also be presented. Participating students will be asked to complete the National League for Nursing's Simulation Design Scale and the Student Satisfaction and Self –Confidence in Learning [13]. Both tools have had prior testing with Chronback's alpha measures of .92 for presence of features, .96 for the importance of features, .94 for satisfaction, and .87 for self-confidence [13].

In addition, an evaluation checklist will be developed based on the Ultrasound Guidelines developed by the American College of Emergency Physicians [14]. The checklist created by Patrawall et al., [12] will be consulted in evaluating competencies for critical care ultrasound.

Discussion

This work is original due to the fact that ultrasound training is not available in a format that offers a scalable solution. Academic and practice settings suffer in their ability to be able to provide enough training equipment that can be used for the amount of time needed for skills mastery in an area that is becoming more important for nurses to administer correctly. Once students or practitioners have passed the competencies using the VR solution, the time to use an actual machine to demonstrate mastery should be substantially reduced.

It is anticipated that there will be positive results from the evaluation data submitted by students. It has been difficult due to the number of students needing to use the machine to have such an opportunity. In addition, one-on-one faculty supervision is not always available, and group teaching lends itself to situations where viewing is not feasible by all in the room, and students may miss important details such as placement of the probes. An ultrasound simulation allows for both individual use, but also allows for the repetition that might be needed for some students.

Additional innovations now seem feasible to implement within our facility. The Vanderbilt University School of Nursing has just completed a $23.6 million building expansion. The result is a new five-story building; an atrium connecting all School of Nursing building; a state-of-the-art simulation lab; student service office;, a virtual classroom; technology advanced classrooms, conference, offices, and seminar rooms; a green roof terrace; and outdoor green space.

An augmented reality way-finding application is currently being developed. Once users see the interactive maps on the large video walls in the atrium, additional wayfinding graphics can be transferred to their smartphones so that they can follow directions to their destinations. Rather than having to record directory details, the directions will be transferred directly to their phones.

A second planned application will be for a mixed reality project using the Microsoft HoloLens. Authoring with Unity, we plan to build holographic images of hearts so that various cardiac abnormalities and treatments can be explored among faculty and students as they engage with this digital content and the world around them.

Conclusions

VR offers one solution to expand the teaching-learning environment. Any strategy that allows learners to practice without added stress and with increased confidence can only lead to increased quality outcomes. In a time when clinical placements are becoming more difficult, the chance to practice skills in a safe environment that leads to skill mastery is an added plus. This ultrasound application has the potential to meet all of these requirements. As other clinical specialties require the use of these skills, this VR application will become even more popular.

The development team has also been able to extrapolate two other augmented and mixed reality applications that could benefit our programs. Innovation has become an expected requirement for our students, so faculty and staff must continue to think of useful innovations.

Acknowledgements

The authors wish to thank Allie Saxon for her willingness to be the patient for this demonstration. In addition, JoEllen Holt (Skills and Simulation Lab Director) and Diana Kelley (Simulation Lab Nurse) were most helpful in preparing and participating in the project. Recordings were made in the new Simulation Lab Facility which opened in January of 2019.

Evaluating the Validity of a Knowledge-Based System for Proactive Knowledge Transfer for Caregiving Relatives

[a] *Peter L. Reichertz Institute for Medical Informatics of TU Braunschweig and Hannover Medical School, Hannover, Germany*

Abstract

The evaluation of the validity of a knowledge-based system is of great importance during its development. It determines whether the system represents the experts' knowledge correctly. This is highly important, but also particularly difficult, if the expert knowledge is not explicit, but only implicit and tacit. In the following the validity's evaluation of a system for education of caregiving relatives is presented. To evaluate the system's knowledge delivery strategy against the experts' opinion, several fictious characters were created. The evaluation revealed inconsistencies in the knowledge base. After resolving these, the experts' opinion is represented to a large extent by the system. Nevertheless, the used evaluation approach is not capable of detecting all inconsistencies. Therefore, a strong need of a system's learning capacity to integrate feedback from a larger group of real caregiving relatives exists. In addition, a rule-based component, representing disease specific knowledge, should be implemented.

Knowledge Bases, Nursing Informatics, Evaluation Studies

Introduction

Approaches in the field of artificial intelligence divide into two main fields: soft computing and symbolic approaches. While the data driven soft computing approaches use existent data to learn how to solve a problem, the implementation of knowledge driven symbolic artificial intelligence systems involves the explicit formalization of the subject-specific experts' knowledge. This enables artificial intelligence engineers to model the knowledge in a machine interpretable representation language. The necessary cooperation within an interdisciplinary team during the explication and formalization process is a challenging task for multiple reasons. One reason is, that the practitioners of interdisciplinary studies lack a coherent, defensible sense of their purpose [1]. This often manifests itself in communication problems. Even more, the experts' knowledge ordinarily is not explicit, but implicit and tacit. "Compared to explicit knowledge, tacit knowledge is subjective, personal, and context-specific. It is difficult to describe, examine, and use" [2], which results in an even harder explication and formalization process. To ensure that the developed knowledge-based system represents the experts' knowledge and behaves in the intentional way, a sophisticated evaluation must be performed. Therefore, the evaluation of the validity of a knowledge-based system is of great importance during its development, because it determines whether the system represents the experts' knowledge correctly [3].

In [4], a wider methodology for the evaluation of knowledge-based systems is introduced. Here, a comprehensive approach is presented, which covers not only the validity of the system used, but also the functionality and impact of the complete system. The approach structures into four phases. In the first phase, early prototypes are created using rapid prototyping or requirements specifications. The second evaluation phase estimates the systems validity. Therefore, the inference mechanism, as well as the knowledge base must be evaluated. The knowledge base can be analyzed in a static or dynamic way. Static analysis refers to procedures where no system execution is required, such as internal consistency checks. On the other hand, dynamic analysis incorporates system execution to detect incorrect parts and presents them to the experts. Furthermore, the knowledge base needs to be evaluated against a set of cases different from those used during the system's development, which act as a kind of gold standard. Here, multiple methods like traditional error rate, top down correlation or receiver operated characteristics could be used. The third phase evaluates the system's functionality, which incorporates user interaction, user interface and reasoning efficiency, but is not limited to these. In the last phase, the systems impact is evaluated. Therefore, the outcome of the system's application is compared to the current state. Depending on the system's purpose, various measures can be applied, such as benefits of the expenses.

This approach is used to evaluate a knowledge-based system for education of informal caregivers, which are mostly caregiving relatives. For many relatives the care situation involves extensive burden [5], which is caused, among other things, by a lack of knowledge. Against this background, a system for personalized education of caregiving relatives is developed. The methodology of the system was introduced and three prototypes were evaluated in [6]. Here, statistical approaches are utilized to calculate scores for each knowledge resource to be delivered, based on experts' weighting of profile items. The aim of our research work for this paper was the evaluation of our system's validity. Therefore, the results of the second evaluation phase, which covers the validity of the system, will be presented and discussed. Since the third approach from [6], which utilizes dynamic weights, performed best during prototype testing, it is only further evaluated.

Methods

Before testing with real human users, the system's knowledge delivery strategy on which the validity depends must be evaluated. As stated above, the validity evaluation involves two steps: the evaluation of the inference mechanism and the evaluation of the knowledge base. In particular, the inference mechanism consists of the mathematical formula for calculating the score, while the knowledge base consists of the experts' weightings of profile items for all 82 knowledge resources. Typically, the inference algorithm could be evaluated using software

validation techniques [7]. But these limit the evaluation process to models, where an explicitly expressed requirement or gold standard can be formulated and are not applicable to validate the expatiating process itself. The method described in [6] was created to expatiate the tacit experts' knowledge and therefore cannot be evaluated against an explicit formalization alone. Here, the validity of both, inference mechanism and knowledge base, depend on each other and can hardly be observed individually. In consequence, good validity can only be achieved by good results in both components. Considering that a completely new statistical approach was used to formalize the tacit knowledge and not a representation language, an automated static evaluation of the knowledge base is not possible. Hence, a dynamic analysis was performed. In a first step, a selection of 21 knowledge resources, including important and unimportant knowledge resources, are evaluated against an expert's ordering. For evaluating the entire knowledge base, the total number of 82 knowledge resources must be considered. In this setting, experts are not able to order all knowledge resources for multiple test settings. Accordingly, the calculated orderings were submitted to the experts for evaluation.

Evaluation against experts ordering

A fictious character was created by the experts in nursing science. Johanna is 74 years old and intensively cares for her 76 years old husband Peter. Peter has been suffering from the consequences of a stroke for 2 years and is hemiplegic. Due to hemiplegia, he can no longer walk without support, cannot dress alone and needs support in tasks of daily living. He is already fallen several times. For Johanna it is a matter of course to take care of her relatives. She supports intuitively and has little information about the disease progression, possible "care techniques" and possible support services. She feels overwhelmed in many things and therefore suffers from sleep deprivation. Johanna has become increasingly isolated and receives no support from third parties, such as outpatient nursing services. For the evaluation, the experts selected a subset of 21 knowledge resources, divided into five highly important, three less important and 9 unimportant knowledge resources. The ordering of the system is compared with the order obtained by the experts. For the system's ordering knowledge resources with a score greater than 0.5 are regarded as important. All others are considered as unimportant.

Evaluation of the complete knowledge base

For the evaluation of the knowledge base, it is not sufficient to regard only a subset of knowledge resources. However, ordering the total amount of 82 knowledge resources by the experts is a very time-consuming task and cannot be performed for multiple test settings. Therefore, a dynamic evaluation process is performed in which the experts judge a given ordering calculated by the system. Thus, the authors created 7 fictious caregivers by regarding the weighting of one or multiple thematically very proximal knowledge resources as the caregiver's profile. As a result, the used knowledge resources will be top ranked in the system's ordering. The system's ordering was cut at a threshold of 0.5. Everything below was excluded for a simulation of the later system behavior, in order to not disturb the later real users with unimportant knowledge resources. Additionally, resources not fitting the disease of the care recipient were excluded as well. In order to qualify, whether the experts are just marking everything as correct, unimportant knowledge resources were interspersed to the correct orderings (without the experts' awareness). This results in three completely important orderings, two completely unimportant ones and two of mixed importance. These orderings were evaluated by the experts for a second time approximately four weeks later, yet with the knowledge, that unimportant resources were interspersed. In the following, the descriptions and orderings to be evaluated by the experts are presented. The unimportant resources are marked.

Klaus and Gerda

Klaus cares for his 75 years old mother Gerda. He himself is 53 years old and works as an architect. Gerda suffered a stroke one year ago. Since then, she is partly aggressive towards him and insults him very harshly. Such behavior has never occurred before the stroke. Furthermore, Gerda is frequently sad and depressed. This imposes a great burden on Klaus. Due to the burden he is commonly exhausted. Klaus wishes to be able to withdraw from the care situation but feels ashamed for such thoughts.

1. Changes in personality after a stroke
2. Detecting and preventing depression
3. How does the sense of taste change with age?

Charlotte and John

John (67) cares for his demented partner Charlotte. She is 70 years old. Charlotte needs help with dressing and other activities. She is overextended with everyday decisions, but concurrently cannot admit that she is dependent on help. This makes John sorrowful and enraged. When her children come to visit, John is embarrassed about the way Charlotte is dressed. This often leads to an argument.

1. Clothing
2. Bladder training (unimportant)
3. Psychological changes in dementia
4. Restlessness - sources and handling (unimportant)

Mareike and Matthias

Mareike is 60 years old and works as an office clerk. She takes care of her demented spouse Matthias. Due to Matthias disorientation at night, Mareike sleeps poorly. Matthias is capable of changing his position in bed independently, which frequently awakens Mareike. She feels emotionally and physically exhausted due to the care.

1. How does sleep behavior change with age?
2. Suggestions for a restful sleep
3. Sources of sleeping problems
4. Coping with stress
5. Restlessness in the evenings
6. Dealing with nocturia
7. Detecting and preventing depression
8. Kinaesthetic - definition and relief in care
9. Exhaustion

Hannes and Jana

The pensioner Hannes takes care of his partner Jana. He does not get enough sleep because he must take care of Jana constantly, even at night. Jana is temporally and locally disoriented and frequently walks through the apartment without a destination. Two months ago, Jana was diagnosed with dementia.

1. Physical activity (unimportant)
2. Course of dementia (unimportant)

3. Kinaesthetic - definition and relief in care (unimportant)
4. Financial relief for day and night care (unimportant)
5. Structuring the toilet calls (unimportant)
6. Finger food (unimportant)

Alina and Charlie

The 42 years old Charlie has the feeling that his mother is increasingly dependent on support due to problems in communicating her needs. He also has to cut her food into small pieces. Recently, Alina accidentally caused a grease fire while cooking. Charlie was barely able to prevent the worst. His mother is unaware of this incident's severity.

1. Drinking – when, how much and what?
2. How does the sense of taste change with age?
3. Changes in motion patterns (unimportant)
4. Biography work used correctly (unimportant)
5. Swallowing and swallowing disorders

Anton and Marie

Anton is cared by his 40-year-old daughter Marie, as he needs help with basic everyday tasks. Anton is demented, often disoriented and struggles with multi-step actions. Additionally, he has difficulties communicating his needs. Marie supports him with his meals.

1. Handling incontinence material (unimportant)
2. Changes in motion patterns (unimportant)
3. Dealing with nocturia (unimportant)
4. Assistive devices - everyday relief (unimportant)

Dieter and Helga

55-year-old Dieter cares for his mother Helga. Helga needs assistance with everyday tasks such as washing, positioning, dressing and undressing. She is able to take meals herself, yet has become urinary incontinent and has been increasingly dependent on help since the last six months. Dieter wishes for support.

1. Assistive devices - everyday relief
2. Constructional changes
3. What is fecal incontinence?
4. Handling incontinence material

Results

Evaluation against experts ordering

Comparing the orderings obtained by the experts and by the system (Table 1), seven knowledge resources were assigned to different levels of importance. Five unimportant knowledge resources in the experts' ordering are rated with a score above 0.5 and therefore are regarded as important by the system. These are *What is a tendency to run?*, *Dealing with refusal to eat*, *Finger food*, *Tips for washing demented persons* and *Dealing with nocturia*. One important knowledge resource from the experts ordering (*Communication with people after a stroke*) is regarded as unimportant by the system and *Fall prevention* actually is not within the systems ordering, since it is not represented in the knowledge base. The ordering of unimportant knowledge resources is meaningless, since these knowledge resources are not displayed to the user. Regarding this, the two orderings have a Kendall rank correlation coefficient of 0.31, where the missing knowledge resource *Fall prevention* was excluded to obtain orderings of the same length. This indicates a weak positive correlation between the two orderings.

Table 1 - Orderings by importance obtained by the experts and by the system

Experts' ordering	Systems ordering
Fall prevention	Kinaesthetic - definition and relief in care (1.0)
Kinaesthetic - definition and relief in care	The concept of Bobath (1.0)
The concept of Bobath	Restriction of movement after a stroke (1.0)
Restriction of movement after a stroke	Tips for washing demented persons (1.0)
What is urinary incontinence?	Kitchen aids after a stroke (0.833)
Structuring the toilet calls	What is fecal incontinence? (0.833)
What is fecal incontinence?	Drinking – when, how much and what? (0.833)
Drinking – when, how much and what?	Constructional changes (0.833)
Communication with people after a stroke	Dealing with nocturia (0.75)
Detecting and preventing depression	Dealing with refusal to eat (0.722)
Kitchen aids after a stroke	Structuring the toilet calls (0.685)
Constructional changes	What is urinary incontinence? (0.667)
What is a tendency to run?	Finger food (0.633)
Wandering of demented persons	Detecting and preventing depression (0.567)
Dealing with refusal to eat	What is a tendency to run? (0.561)
Finger food	Restlessness in the evenings (0.25)
Tips for washing demented persons	Changes in motion patterns (0.21)
Biography work used correctly	Wandering of demented persons (0.167)
Restlessness in the evenings	Biography work used correctly (0.0)
Dealing with nocturia	Communication with people after a stroke (0.0)
Changes in motion patterns	

Note: Borderlines inside the table mark changes in the importance and numbers in brackets show the system's calculated scores

Evaluation of the complete knowledge base

Table 2 shows the evaluation results of the complete knowledge base. A knowledge resource is identified as critical and therefore requires further investigation if at least two out of three experts reviewed it not as supposed (false positives and false negatives) in the same evaluation cycle. For Klaus and Gerda this applies to *How does the sense of taste change with age?* in both evaluations. For Mareike and Matthias in both evaluations, it is *Kinaesthetic - definition and relief in care* and *Detecting and preventing depression*. For the characters Hannes and Jana *Course of dementia* and *Financial relief for day and night care*

are the critical knowledge resources in both evaluations and *Finger food* is critical in the first evaluation. *Biography work used correctly* is critical in the first evaluation, *Drinking – when, how much and what?* and *Swallowing and swallowing disorders* in the second evaluation of the characters Alina and Charlie. For Anton and Marie *Changes in motion patterns* and *Assistive devices - everyday relief* are critical in both evaluations. The knowledge resource *What is fecal incontinence?* is critical in both evaluation cycles for the personas Dieter and Helga. Furthermore, the knowledge resource *Constructional changes* needs to be regarded as critical in the second evaluation. Especially critical are the knowledge resources *Course of dementia* (Hannes and Jana) and *What is fecal incontinence?* (Dieter and Helga), as they are reviewed the opposite way by all three experts in both evaluation cycles. Moreover, *How does the sense of taste change with age?* (Klaus and Gerda) and *Financial relief for day and night care* (Hannes and Jana) are reviewed the opposite way by all three experts in one evaluation cycle and by two experts in the other evaluation cycle. The knowledge resource *Biography work used correctly* from the characters Alina and Charlie, which is unimportant from the systems point of view, is noticeable. In the first evaluation cycle, all three experts assessed it as important. While in the second evaluation cycle, all experts rated it as unimportant.

Table 2 – Experts' review of the characters. The sign + stands for reviewed as important and the sign - stands for reviewed as unimportant

	3.	-	-	-	-	-	-
	4.	+	+	+	+	+	+

For characterizing the experts, table 3 shows important metrics. No ordering was reviewed perfectly by the experts. The high sensitivity (0.905) and lower specificity (0.5) of expert #1 shows, that she reviews overly positive. She detects the majority of the important knowledge resources but misses the unimportant ones. The opposite occurs for expert #2. She reviews in a more negative way, as the sensitivity (0.619) is smaller and the specificity (0.714) is higher. Expert #3 reviews in a positive way, but not as positive as expert #1 (sensitivity: 0.81, specificity: 0.571).

Table 3 - Metrics for the experts' overall results from the first evaluation cycle

	Expert #1	**Expert #2**	**Expert #3**
Sensitivity/recall	0.905	0.619	0.81
Specificity	0.5	0.714	0.571
Precision	0.731	0.765	0.739
F1-Score	0.809	0.684	0.773

The metrics' results for the second evaluation cycle, where the experts were informed about the existence of interspersed unimportant knowledge resources, are presented in Table 4. Expert #1 shows approximately the same sensitivity and precision, but a better specificity. For expert #2, almost the same results can be observed in both evaluation cycles. The largest difference between the two cycles occurs for expert #3. The sensitivity drops from 0.81 to 0.476 and the specificity rises from 0.571 to 0.714. This indicates that expert #3 identifies fewer important knowledge resources, but more unimportant ones and therefore reviews in a more negative way.

Table 4 - Metrics for the experts' overall results from the second evaluation cycle

	Expert #1	**Expert #2**	**Expert #3**
Sensitivity/recall	0.857	0.667	0.476
Specificity	0.643	0.714	0.714
Precision	0.783	0.778	0.714
F1-Score	0.818	0.718	0.571

Discussion

Knowledge resources with different classifications of importance were identified by the evaluation against the experts' ordering. These were handed to and examined by the expert group. They revised every knowledge resource with the exception of *Communication with people after a stroke*. As this resource includes basic knowledge, which is important for all caregivers caring for someone suffering from a stroke, it was excluded from this provision strategy and included in a group of basic knowledge. This ensures that all affected caregivers are provided with this basic knowledge. Changes in the weighting haven been made to *Dealing with refusal to eat* and *Dealing with nocturia*. The remaining resources were classified as unimportant by the experts, as they are merely of interest to people with dementia and the disease is not part of the profile data used. The experts' knowledge about the delivery of disease specific knowledge resources is explicit. For that reason, inclusion of the disease in this profile data set is not target-oriented. Yet, it should be implemented as a rule-based system. The entire knowledge base was reviewed by the experts with regard to disease specific knowledge delivery. The order after revision and excluding resources that are not relevant due to the disease is shown in Table 5. By the revision process and excluding resources by disease, the knowledge provision is improved and thus the Kendall rank correlation coefficient increases to 0.53. Even more, the unimportant knowledge resources are filtered out by the score's threshold of 0.5.

Table 5 - Orderings by importance after revision and excluding by disease

Experts ordering	Systems ordering
Fall prevention	Kinaesthetic - definition and relief in care (1.0)
Kinaesthetic - definition and relief in care	The concept of Bobath (1.0)
The concept of Bobath	Restriction of movement after a stroke (1.0)
Restriction of movement after a stroke	Fall prevention (0.833)
What is urinary incontinence?	Kitchen aids after a stroke (0.833)
Structuring the toilet calls	Constructional changes (0.833)
What is fecal incontinence?	Drinking – when, how much and what? (0.833)

Kitchen aids after a stroke	Structuring the toilet calls (0.685)
Constructional changes	Detecting and preventing depression (0.567)
Dealing with refusal to eat	Dealing with nocturia (0.455)
Dealing with nocturia	Dealing with refusal to eat (0.388)

The small amount of knowledge resources regarded as important by the system for the seven fictious characters indicates that the weightings of the different knowledge resources are quite disjunctive. The approach for the evaluation of the complete knowledge base revealed further inconsistencies, which are examined by the experts. Particularly critical are resources that have been incorrectly evaluated by all three experts in both evaluation cycles. Until now, all inconsistencies were resolvable by revising the knowledge base and it can therefore be assumed that the inference mechanism, more precisely the mathematical formula, works convincingly. With the shown approaches many inconsistencies were found. Nevertheless, even the second approach cannot completely validate whether the knowledge base corresponds to the experts' tacit and implicit knowledge. This would require a much larger and more heterogeneous selection of characters. Even more, tables 2, 3 and 4 exhibit that the experts' opinion is not completely stable over time. For these reasons, an evaluation against the experts' opinion is only expedient up to a certain point. To tackle this problem, the system should be extended with a learning capability and then be trained with data derived from a large group of real caregiving relatives. Furthermore, the system needs to be extended by a rule-based component, representing explicit knowledge about disease specific knowledge transfer.

Conclusions

The evaluation process described has shown some inconsistencies in the knowledge base. After resolving these, it can be assumed that both the inference mechanism and the knowledge base represent the implicit and tacit experts' knowledge to a good extent. Nevertheless, not all inconsistencies could be found in the knowledge base. Therefore, a strong need for a learning capability exits. Additionally, disease specific knowledge transfer could improve the system.

Acknowledgements

The evaluated knowledge-based system is part of the project "Mobile Care Backup" (MoCaB)[1], which is funded by the German Federal Ministry of Education and Research (grant number 16SV7472).

Decision Support Tools for Drugs Prescription Process in a Hospital in Argentina

Valeria Zapico, Luciana Rubin, Soledad Díaz, Laura Gambarte, Romina Rebrij, Carlos Otero, Daniel Luna

Department of Health Informatics, Hospital Italiano de Buenos Aires, Ciudad de Buenos Aires, Argentina

Abstract

While medications can improve the health of patients, the prescription process is complex and prone to errors.

The structured medical order entry systems (CPOE) with clinical decision support (CDS) are increasingly implemented to improve patient safety, however the organizations that decide to implement them will have several challenges: understanding which classes of CDS can admit their systems, ensure that clinical knowledge is adequate and design tools for proper monitoring.

We share our experience of over ten years of development and implementation of clinical decision support tools during drugs prescription process and tools that have allowed us to monitor them correctly.

Keywords:

Decision Support Systems, Clinical; Knowledge Bases; Computerized Physician Order Entry

Introduction

A key process to improve drug safety is to implement computerized physician order entry systems (CPOE) that enable the incorporation of clinical decision support systems (CDS). With the implementation of electronic health records (EHR) throughout the world, the use of these CDS is increasing and enables the access to relevant patient information[1,2]. Health information technologies associated with a reduction in medication errors and adverse events[3-5] , improved patient care[6] and improved profitability for organizations[7] are considered potentially transformative and are being increasingly implemented [8,9].

When incorporating CDS into the drug prescription process, organizations should choose whether to develop knowledge bases (KB) or use commercial databases. Given that the resources and experience necessary for its development and implementation are available only to some large academic centers, most organizations choose to purchase KB from commercial suppliers [10].This action poses some challenges: a) high variability among the KB [11,12] for which some authors suggest that more than one should be used [13] b) the commercial KB tends to be very inclusive and place more emphasis on the amplitude of the coverage than on the clinical relevance or severity of the adverse events [7] and c) in some cases KB are not customizable and even when they are, most organizations lack the resources to do so effectively [14].

Many of the CDS that have shown utility are those that have been developed by the same institutions that use them, they have the capacity to elaborate knowledge, test interventions before implementing them and monitor its effectiveness over time [15].

In Argentina, the lack of infrastructure and the digital immaturity of health institutions are factors that have determined that CPOEs have not yet reached a sufficient degree of maturity and even the institutions that have it have not implemented CDS.

The aim of this work is to describe the components of a CDS fully developed in Hospital Italiano de Buenos Aires as well as the monitoring tools used to monitor them.

Methods

Hospital Italiano de Buenos Aires (HIBA) is a teaching hospital founded in 1853 in Buenos Aires, Argentina that works as a health network with 25 ambulatory centers, and 150 medical offices distributed along Buenos Aires city and its suburbs. HIBA has 750 beds and admits 45000 patients annually. The hospital handles 3 million outpatients each year. Since 1998 the Department of Health Informatics has designed, developed, and implemented a hospital information system (HIS) that manages health and administrative information from data capture to analysis. The HIS includes a web based, problem oriented, and patient centered EHR with a CPOE that allows the electronic prescription of drugs, connected with the pharmacy system, and integrated with the nurse care process.

The first CDS that were incorporated into the CPOE were: 1) duplicate prescription alert and 2) drug-drug interaction alert. In this case, in addition to considering the prescribed drug and those already existing in the pharmacological indications module, the CDS needs to access a KB, and since at that time there were no companies in the Argentine market that provided them in the Hospital, the decision was made to create a source of knowledge structured and controlled by international standards.

As a result of the validation of different sources of information, a reliable, up-to-date and Spanish-language KB was created with the main purpose of providing classified, structured and evaluated information on drug interactions to nourish the CDS and improve the safety of the drugs prescription process. After 6 years of implementation of the CDS, a process of analysis and redesign of the KB was initiated (see drug-drug interaction alert), followed by a redesign of the alerts using user-centered design techniques (UCD)[16]. At the same time, it was decided to add pharmacological alerts for drugs - allergy, teratogenic risk, maximum dose, etc., so adaptations and improvements were done in the KB to support and in some cases increase the specificity of the alerts (see Monitoring tools).

Currently a multidisciplinary team works to give continuity to this CDS project, conformed by a physician specialist in Health Informatics responsible for the coordination of the team, pharmacologists responsible for gathering the evidence and defining the content that is loaded in the KB, medical career students in charge of the data entry, pharmacists that create the functional requirements, test and authorize the

deployment of the necessary changes in the KB and two developers, one in charge of the maintenance of the BCF and another one of the pharmacological alerts that the CDS generates.

Results

A description of the CDS (chronologically ordered) implemented in the HIBA's EHR and the tools used for its monitoring are named below.

Alert for Duplicate Indication

This alert informs the physician that he is prescribing a drug that was already prescribed, a situation that generally occurs when several physicians provide care to the same patient or when prescriptions coexist for a drug to be administered in different ways. These unintentional duplications are the cause of toxicity adverse events that can be prevented [15]. However, since there are also situations in which duplication is intentional and valid (such as the indications of analgesics at regular intervals and additional doses in the presence of pain), when the HIBA implemented CPOE it did so with an interruptive alert that appears as a window emergent in the center of the prescription screen on which the prescriber must click "Accept" without having to justify continuing with the prescription.

Drug-Drug Interaction Alert

The frequent commercialization of new medicines, increasingly older populations with multiple comorbidities and polypharmacy with different specialists treating the same patient and where each of them may not be familiar with all the medications that their patients receive [16,17] are cited as factors that contribute to the frequency of interactions between drugs. These represent, not only a common cause of adverse reactions to medications but also of therapeutic failures. Regardless of the outcome, an important feature of drug interactions is that they are often preventable [17] in this way information systems that could retrieve all of the medications a patient is using to detect and remind doctors of IDDs are believed increasingly necessary to improve patient safety [18].

The redesign of HIBA's KB in 2006 allowed the creation of new functionalities that would later be taken into account when displaying alerts as: the categorization of active or passive according to whether they would manifest themselves actively interrupting the prescription workflow or not, requires monitoring feature to inform the prescribing physician about the clinical or laboratory parameters to be controlled when deciding to continue with the indication of the drugs and to evaluate the use of alternative drugs so that the alert promotes action through recommendations for alternative treatment [19].

With these changes implemented in the KB and after the redesign of the alerts mentioned above, it was determined that only drug-drug interactions with severity C, D or X, according to Lexicomp classification[20], would generate alerts: for drug-drug interactions severity C, the alerts would be non-disruptive blue light, for drug-drug interaction severity D, alerts would be disruptive orange and for interactions drug drug severity X, alerts would be non-disruptive red (see Figure 1).

Drug allergy alert

The verification of drug allergy is a very important feature in terms of patient safety. This type of intervention presents an alert when a physician prescribes a medication for which the patient has an allergy documented in their EHR [21]. It is very important that the patient's allergy data is stored in their EHR before prescribing medications. However, in some cases, it is not possible to know the allergic status of the patient at the time he enters the hospital. For this reason and in order to increase the number of registered allergic patients in the EHR, a circuit has been designed with the pharmacy service that reminds the physicians to register the allergic state of every patient who contacts the hospital.

When a physician prescribes a drug that matches the allergic patient status, an irruptive alert appears. The user has the option of cancelling the prescription and accept the alert or continuing the indication and ignore the alert, in the latter case they are requested to select a structured justification or enter one in free text (see monitoring tools).

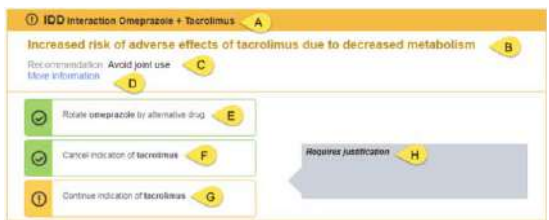

Figure 1 – IDD Alert Interface. (A) Interaction between Omeprazole and Tacrolimus severity D (B) risk of interaction; (C) main recommendation for the prescribing physician; (D) link to more information; (E) suggestion to rotate Omeprazole, already indicated, by Pantoprazole or Ranitidine that do not interact with Tacrolimus; (F) "cancel indication of Tacrolimus"; (G) "continue indication of Tacrolimus"; (H) required justification

Alert for Maximum Dose

Many preventable adverse drug reactions (ADRs) are caused by dosage errors in the prescription process. For this reason, it is proposed that CDSS linked to KB that contain the maximum recommended therapeutic doses (MRTD) can prevent the prescription of excessive doses and their consequences [22]. A particularity of the MRTD is that they can vary according to the route of administration [23], the age of the patients [24] and the unit of time (dose, day or accumulated) and these characteristics must be registered in the KB. It is important to note about this alert, that the selection of the generic is not enough to trigger it; the physician must select the dose so that it is contrasted with the KB record. Figure 2 shows the interface of an alert for an exceeded dose of Acetaminophen for an adult patient, which includes an action-oriented button to adjust posology.

Teratogenic Drug Alert in Pregnancy

There are drugs that are highly teratogenic and should never be administered to a woman who is or may be pregnant; many others who are relatively contraindicated to a greater or lesser extent[15]. Since 2015 when a physician prescribes a teratogenic risk drug in the HIBA's CPOE to a pregnant woman, an alert is triggered. The alert's input are: a) the existence of a pregnancy problem registered in the patient's EHR and b) the teratogenic risk of the prescribed drug documented in the KB. As in the case of the drug-allergy alert, this CDS also depends on elements present in the EHR problems' list[25] that are usually incomplete or have outdated information [26]. To solve the lack of pregnancy status registration, it was decided that the opening of an obstetric chart would automatically load the problem "Pregnancy" in the EHR of the patients. A set of controlled terms (derived

from delivery, caesarean section, abortion or puerperium) generates the automatic resolution of the problem when they are created in the system by physicians, increasing the specificity of this alert.

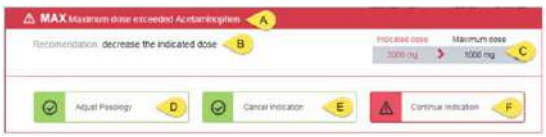

Figure 2 – Alert Interface for Maximum Dose (A) Maximum exceeded dose of Acetaminophen; (B) recommendation to reduce the dose; (C) comparison between indicated dose, 2000 mg, and maximum dose, 1000 mg; (D) adjust posology leads the user to modify the prescribed dose (E) "cancel indication of Acetaminophen"; (F) "continue indication of Acetaminophen" in this case the user must justify choosing between structured options or free text.

Pharmacogenomic Alerts

Since 2014 when the physician prescribes a drug, the execution of the process begins, the inference engine, which retrieves the genetic information from the EHR, infers if there is any risk to the patient in case the drug that is being prescribed is supplied. If there is a risk, the inference engine issues an alert that informs the user about the risk, allowing him to cancel or continue with the prescription and also allows him to send a query through an email to the Clinical Pharmacology section [27].

Frequent Posologies

Frequent posologies are defined as complete orders of pre-written medications that include dosage, route and frequency of administration. The supply of these lists of posologies improve the users system acceptance and reduces errors [15,28,29].

For the development of frequent posologies implemented in the CPOE of the HIBA in 2015, an analysis of all the medications that had been prescribed during the previous year and had a rate of use greater than 80%. This group defined the posologies that would later be reviewed by a group of pharmacists. Each generic could have more than one recommended dose but not more than 3 and the physician always has the opportunity to create his own posology if he considered, or even use a recommended one and edit it. The information on each drug is contained in the KB discriminated by generic and by age group.

Drug-Food Interaction Alert

It is important not to forget the interactions between drugs and foods that can inadvertently modify the effect of drugs. Most clinically relevant interactions are caused by food-induced changes in the bioavailability of the drug (changes in absorption or metabolism) that correlates with the clinical effect of most drugs[30,31].

In 2016, this CDS was implemented to warn physicians about these interactions. The alert is generated when a medicine that is being indicated has a record of contraindication with some food in the KB. The alert it is not interruptive, and it was designed only to raise awareness of the possible interaction in prescribers.

Drug-Laboratory Test Interaction Alert

To minimize the risk that certain medications may have, it is recommended to perform laboratory tests before their administration and in many cases also at regular intervals during a treatment. It is known that not taking into account these physiological parameters can result in morbidity and even mortality for the patients [32,33]. For this reason in 2016 it was decided to develop and implement this CDS (see monitoring tools).

The first laboratory results contemplated for the creation of the alert were potassium and calcium, due to their relevance.

The drug-laboratory interaction (DLI) alert inputs are: a) a result of serum measurement out of range; or b) a blood calcium measurement result out of range, and b) the prescription of a drug that can decrease more these electrolytes, in the case of values lower than the minimum (see Figure 3) or increase them (in the case of values greater than maximum) or that without having the potential to affect the results, its pharmacological effect can be modified (for example, the case of patient with a result of measurement of Potassium less than 3.5 millimole / liter and prescription of Digoxin).

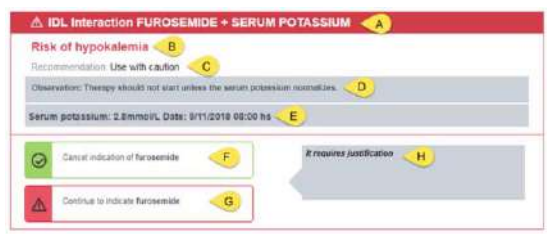

Figure 3 – Alert Interface by DLI. (A) DLI between Furosemide and the test Serum potassium measurement; (B) risk of interaction; (C) (D) recommendation and observation for the prescribing physician; (E) result of serum potassium measurement and date of it (F) "cancel indication of furosemide"; (G) "continue indication of furosemide"; (H) required justification

Tools Developed for CDS Monitoring

Monitoring is often included as a success factor for CDS [6] because it permits to iteratively refine the interventions implemented and thus improve their use and impact. In the HIBA the process of monitoring is covered through boards, reports and review of RME.

Dashboards

Dashboards enable a global view of what happens with the alerts. A general dashboard shows users the distribution of alerts by type, behavior of the prescribers (continue, cancel, etc) and justifications to continue. Also, five specific dashboards (one for each alert) are used to represent the singularities, so, for example, the alerts for allergy-drug show the most frequent allergens that have generated alerts; and the IDD dashboard shows the drug drug pairs that have been prescribed.

Reports

Although the dashboards shows what is happening in a given domain, it is not within their scope to show what happens in each specific situation. Specific reports enable the team to identify, for each alert activated, the prescribing user, their medical specialty, the drug with the intention of being indicated, the action taken after the appearance of the alert, the reason why it was ignored and the patient in which the drug was prescribed. Also for IDD alerts, the reports show the drugs that form each pair and for DLI the result of the value of Potassium or Calcium at the moment the alert was generated.

Revision of Electronic Medical Records

Based on the information provided by the reports, the review of medical records helps the team to search for adverse effects (in ignored alerts), false positives, patterns of use by specialty, and unintended consequences. From these monitoring actions the team was able to realize that in the development of the alert by DLI it had not been accounted for the route of administration of the indicated drug, reason that generated many false positives and for which there was the need to add a field in the KB to record this data. And from the analysis of free text justifications for the allergy alert we noticed that 30% of the cases were due to indications from the Allergy service to submit the patients to desensitization tests, which is why this reason was added as a structures option.

Discussion

This paper describes the pharmacological CDS embedded in HIBA's homegrown HIS.

Undoubtedly, the decision to incorporate CDS during prescription is a strategy used by organizations that seek to increase safety in the quality of care. Being able to have a full integration between the CPOE, the EHR and CDS is the best scenario that allows a comprehensive approach to improve the quality of care provided [34,35]. The biggest challenge when implementing CDS is to achieve and maintain a correct balance between useful alerts and overexposure [36] and a good way to achieve this is to keep the KB updated to ensure that the records contained in them are correct, consistent, complete and current [37]. The commitment is not trivial and requires substantial resources [38], in our case it has taken many years of a great team work to achieve a truly multidisciplinary approach. However, even when the clinical content is adequate, the lack of completeness and / or updating of the data in the medical records does not allow for the specificity that we expect from the CDS.

On the other hand, the only way to make decisions is through the use of information, which is why the data provided by our monitoring tools are essential to know if the interventions are accepted by users, if their actions are modified and finally, if our interventions are impacting the quality of care and the health of our patients.

Conclusions

Healthcare organizations wishing to implement integrated CDS to CPOE and HCEs should be prepared to take on three major challenges: understand what kinds of CDS their systems can support, manage knowledge and design tools that allow them to know how it works.

Abstract

A key trend in current medical research is a shift from a one-size-fit-all to precision treatment strategies, where the focus is on identifying narrow subgroups of the population that would benefit from a given intervention. Precision medicine will greatly benefit from accessible tools that clinicians can use to identify such subgroups, and to generate novel inferences about the patient population they are treating. We present a novel dashboard app that enables clinician users to explore patient subgroups with varying longitudinal treatment response, using latent class mixed modeling. The dashboard was developed in R Shiny. We present results of our approach applied to an observational study of patients with moderate to severe rheumatoid arthritis (RA) on first-line biologic treatment.

Keywords:

Precision Medicine, Medical Informatics Applications, Rheumatoid Arthritis

Introduction

Complexity and variability of patients' trajectories in response to treatment poses significant challenges in many medical fields, especially in those requiring long-term care [1-4]. While it is possible to define high-level clinical phenotypes, the prediction of outcomes with respect to interventions is complicated by the high variability in responses [5-7]. One of the main trends in current medical research is a shift from a one-size-fit-all to precision approaches, where the focus is on identifying narrow subgroups of the population who would benefit from a given intervention. In order to achieve this goal of precision medicine, the analysis of longitudinal data in clinical research is becoming increasingly important. Longitudinal analytics methods, their exploitation in the context of clinical decisions, and their translation into clinical practice through accessible tools, represents a potential for enabling precision healthcare [8].

The plethora of rich data routinely collected in clinical practice and in clinical trials captures underlying information that could allow for identification of specific subgroups of patients that may in turn predict if these will benefit from specific treatments. Despite this rapid growth in available data, and advancement in machine learning methods, the application of these in medical research and routine clinical practice is still very difficult and impeded by several factors. One of these issues revolves around the limited involvement of clinicians in the discovery process and a missed link between data-driven discovery and their application in real environments. The development of informatics applications that can introduce data-driven discoveries directly into clinical practice is a current unmet necessity in medical informatics. Precision medicine will greatly benefit from accessible tools that clinicians can use to identify groups of patients that respond differently to therapies, and to generate novel inferences about the patient population they are treating. Source data and visual analytics can improve diseases' management by enacting the implementation of the learning health care system cycle: the introduction of clinical data in outcomes research, together with the translation of research findings into care, can support decision-making with the realization of precision medicine [6].

In rheumatoid arthritis, clinicians already have some classification criteria but are developed using subjective thresholds and typically applied to one or two follow-up time-points. Our approach aims at removing subjectivity and making use of all available data. One approach for subgroup discovery in longitudinal data is latent class mixed modeling (LCMM), a type of latent class analysis that is increasing in popularity as a powerful method for discovering meaningful and differing subgroups with homogeneous patterns of change over time [9-11]. Here we revise the LCMM analysis framework proposed in [12], where authors detail the methodological steps for off-line analysis, adding the necessary steps to allow on-the-fly analysis by clinicians. More specifically, we developed a dashboard tool that allows clinicians to perform several key steps of an LCMM analysis themselves; for example, the clinician can refine and redefine data-driven models, identify which of these models are clinically plausible and relevant, test specific hypotheses, and ultimately translate the results into clinical practice.

We present results of our approach applied to an observational study of moderate to severe rheumatoid arthritis (RA) patients about to commence treatment with a biologic drug. RA is a chronic, systematic inflammatory joint disease of autoimmune nature [13]. RA is a heterogeneous disease that is classified using a set of clinical factors. Patients with similar clinical features in early disease may go on to experience a very different disease course or response to medication [14]. Recently, the treatment of RA was improved by the introduction of biologic disease-modifying antirheumatic drugs which target elements of the immune system, these are typically reserved for those with an inadequate response to non-biologic disease modifying antirheumatic drugs (DMARDs) [13,15]. Clinical responses and efficacy of biologics vary largely among different individuals. Based on experience and observations made in clinic, although defined in a non-methodical fashion, response criteria are accepted (EULAR classification in non/intermediate/poor-response) [16], and clinicians agree on stratifying patients with respect to the response to the therapy as: primary non-responders which never responded or failed to respond within the first 3 months, secondary non-responders who are patients that initially responded but then loose response after 3 months, and good responders. Secondary noon-response

is seen in a significant minority of primary responders. Reasons for this could include: patients stop taking drug (i.e. feel better and are less motivated), patients develop anti-body against the therapeutic (immunogenicity), as the TNF/TNF pathway is brought under control a second inflammatory pathway may kick in and cause the disease to flare. In RA, a precision medicine approach will allow better understanding of which patients respond to specific therapies within a given time window, as well as improved disease monitoring. In order to understand the underlying mechanisms of response, well powered biomarker discovery studies are needed. A first step is to this process is to better define the phenotype so that biomarkers can be contrast across meaningful patient groupings and include all patients across multiple time-points.

Here we describe an accessible tool to perform LCMM analysis in RA. The goal is to provide clinicians and medical researchers with the possibility to automatically identify different responders to biological treatments over time. The tool relies on a dashboard-based approach to translate the data-driven retrieved models into medical inference and practice [17,18].

Methods

Latent Class Trajectory Modeling

We applied LCMM with the goal of identifying subgroups of RA patients with distinct responses to different types of biological treatment over time. The implementation of the dashboard is based on the framework proposed in [12], which includes eight steps: 1: definition of a scoping model; 2: refinement of the number of classes; 3: refinement of the model structure on the basis of fixed-effects through random-effect specification; 4: model adequacy assessment; 5: graphical presentations; 6: classes discrimination; 7: clinical characterisation and plausibility; and, 8: sensitivity analysis. Our developed dashboard implements the framework as an interactive tool aimed to give the possibility to clinicians to carry out, independently, each step of the analysis. In particular, clinicians can perform steps related to graphical representation, classes' discrimination and clinical plausibility, independently from the first steps of the analysis. Indeed, for this application we initially performed steps 1 through 4 to retrieve a *favoured model*, which we used as the default model in the dashboard. Dashboard's users can exploit this favoured model to perform the last steps of the analysis (i.e. visualize classes trajectories and compare clinical characterises in the classes), but they can also change the model parameters (e.g. the number of classes, fixed-effects) and re-run the whole analysis. Below we describe in detail the steps that we implemented in the dashboard.

Step 1: Scoping Model

We used a maximum likelihood approach to fit the model through the 'lcmm' function from the R package lcmm [19]. The function estimates mixed-effect models and latent class mixed-effect models for different types of longitudinal outcomes. We built models for the entire cohort, using all the possible combination of the available variables. While the scoping model is based on the entire cohort, the dashboard provides the option to stratifying patients on the basis of the class of treatments and perform the analysis on these subsets separately.

Step 2: Number of Classes

We tested the scoping model to determine the optimal number of classes K: 1-10 number of classes. The lcmm function provides Akaike (AIC) and Bayesian information criterion (BIC) as model fit indices. The K number of classes chosen was primarily based on BIC as suggested in [12]. AIC was considered to confirm or clarify the empirical solution. The dashboard presents as a default parameter the number of classes with the lowest BIC and gives the option of changing this number from a fixed range (1-10 classes).

Step 3 Model Refinement

We further refined the model using the model with the lowest BIC derived in step 2, considering the possibility of using linear or quadratic specification of time (days) as the random-effect, logarithm transformed values of our outcome measure, and linear or quadratic link functions to model the longitudinal outcome. The dashboard allows to perform the LCMM analysis with linear or quadric time, transforming or not the outcome and with different link functions.

Step 4 Model Adequacy Assessment

For each subject, we calculated the posterior probability of being assigned to each trajectory class and exclusively assigned the individual to the class with the highest probability. Average maximum posterior probability of assignments above 70% in all classes was considered acceptable. We ensure that each class includes at least 10% of the initial population, otherwise the model is discharged.

Steps 1-4 allow a favoured model structure to be selected using the lowest BIC value and satisfactory values from the model adequacy assessments. The favoured model is used to set the default parameters. Although, as already specified, the dashboard allows to modify the parameters and perform the analysis from scratch.

Step 5 Graphical Presentations and Class Separation

We assessed the design choices according to the clinical relevance for the specific application in RA. Severity RA is estimated using the Disease Activity Score in 28 joints (DAS28). It is an index which combines different scores: the count of the 28 swollen joints and 28 tender joints, the C-reactive protein (CRP) which levels rise in blood in response to inflammation, and the Visual Analog Scale (VAS) of patient's general health. The results of the model are visualized with the DAS28 trajectories of classes over time as well as with all four DAS28 components' individual trajectories. Differently from the original LCMM framework, where classes' discrimination was assessed by degrees of separation, this step is embedded in the graphical representation of the trajectories to simplify the tool usability by final users. The trajectories of the subjects belonging to each discovered latent class are represented with locally weighted scatter plot smoothing method (LOESS) and include confidence intervals. This step allows clinicians to independently clarify the meaning of the presented solutions and to revise the assumptions in performing latent class mixed modeling that might be context dependent.

Step 6 Clinical Characterisation and Plausibility

To assess the clinical meaningfulness of the resulting trajectories/classes, the dashboard allows for comparison of relevant clinical characteristics in the discovered latent classes through a graphical representation with violin plots (for continuous variables) and bar plot (for categorical variables).

Cohort and variable description

The data we used to perform the analysis were derived from a prospective cohort study, BRAGGSS (Biologics in Rheumatoid Arthritis Genetics and Genomics Study Syndicate). BRAGGSS is a UK based study including over 50 recruiting centres. Patients participate in the BRAGGSS study are followed for 12 months, during which they are assessed at baseline and three follow-up visits, at 3, 6 and 12 months [20]. From the entire cohort, we selected 1,531 patients with at least one measure of DAS28 recorded. The baseline characteristics of the total patient population are shown in Table 1. Considering the

different types of treatment, patients are stratified to three groups: biological drugs, biological drugs plus DMARDs (excluding Methotrexate), and finally biological drugs plus DMARDs (including Methotrexate). Methotrexate (MTX) is the first-line therapy for RA.

Table 1 – Cohort characteristics

Treatment group	Only Bio	Bio and DMARD	Bio and MTX
Number of subjects	275	248	1006
Gender (%)			
Male	21	21	26
Female	79	79	73
Age at baseline	65,5	65,2	62,7
(Mean and SD)	12,6	11,2	12,6
DAS 28 at baseline	4,19	4,38	4,18
(Mean and SD)	1,22	1,23	1,24
BMI at baseline	29,8	29,2	30,0
(Mean and SD)	19,7	10,8	15,2

Dashboard Implementation

The dashboard was built in response to the interest of clinicians and medical researchers for having a tool that they can independently use to identify different response trajectories of DAS28 during the first 12 months of treatment with biological drugs. To assess the usability of the tool and the clarity of the analysis to end-point users, we organized biweekly meetings with RA specialist clinicians, during which we discussed each step of the analysis and design of the dashboard according to clinicians' needs.

Dashboard Architecture

We implemented the dashboard using Shiny [https://shiny.rstudio.com]. Shiny is an open source R package to build interactive web application on the basis of R scripts. Shiny applications have two components, a user interface (UI) object and a server function, which are passed as arguments to the shinyApp function that creates a Shiny app object from this UI/server pair. The user interface object controls the layout and appearance of the application (in our case the Dashboard graphical user interface (GUI)). The server function contains the instructions to run the analyses (The Analysis Engine that performs the LCMM analysis). Finally, the shinyApp function creates Shiny objects from an explicit UI/server pair.

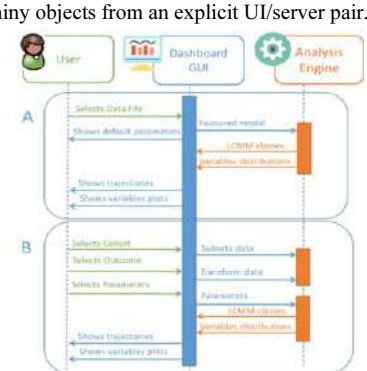

Figure 1 – UML Sequence Diagram.

Dashboard Functionalities

Figure 1 describes the system's functionalities along with the main actions of a user, dashboard GUI and analysis engine. Panel A shows the actions needed to run the favoured model, panel B depicts the actions needed to refine and re-run the model. The first user's action is to select a properly formatted text file (see Supplementary), the default parameters shown in the dashboard GUI are the ones used to run and present the favoured model. The analysis engine perform the LCMM on the basis of these parameter, assign each subject to the most probable class and sends back the results to the dashboard as DAS28 trajectories and variables values in the classes. The dashboard GUI shows the graphs of the trajectories and variables distributions. The user can re-run the whole analysis selecting a different cohort of patients (i.e. only patients treated with a specific drug regiment), outcome (i.e. log transformed DAS28) and different parameters, for example a different number of classes, as shown in Figure 1, panel B. The last set of actions to needed perform the analysis and present the results are then identical as in the approach in presented in panel A.

Results

LCMM model

In RA, clinicians expect to encounter three types of patients: primary non-responders (flat trajectories), secondary non-responders (trajectories with decreasing trends followed by increasing trends), and good responders (trajectories with decreasing trends). The favoured model selected within the first four steps of the analysis identified four classes. This is the default model shown by the dashboard, which has been discussed by clinicians on the basis of different clinical characteristics and DAS28 components. Our LCMM analysis was able to recognize a fourth group of responders: secondary good responders (trajectories with increasing trends followed by decreasing trends)

Dashboard Interface

Figures 2 and 3 depict the Dashboard GUI's results pane: DAS28 trajectories and their components in Figure 1, and demographic and clinical values distributions in Figure 2.

The main page of the Dashboard contains a panel where the user can choose the input dataset. The "View Data" button allows to visualize the dataset on which we are going to run the analysis. If the user doesn't modify any parameter, the favourite model parameters are set by default. The user starts the analysis by pressing the "Best model" button and receives a message when the analysis is complete. The same panel allows users to select a different subset of the dataset with the dropdown menus "Choose the outcome" and "Choose the treatment group", and to preview the filtered and transformed dataset. The rest of the dropdown menus and check boxes allow to set the lcmm parameters: covariates of the model, time effect, number of classes and link function. Pressing the "Start the analyses" button, the lcmm analysis starts. If all the required variables have been correctly selected, the user receives feedback that the analysis has started, otherwise he/she receives an error message which advises to complete the form in the correct way.

The first panel (Figure 2) visualizes the trajectories of the Das28, and their components. The second panel is accessible via the "Compare classes" tab and shows the variables distributions. Continuous variables: age, BMI and the health assessment questionnaire disability index (HAQ score), are presented with violin plots; categorical ones are presented with bar plots. By clicking the "Reset form" button, the user can reset the dashboard to the initial state and restart the analysis.

Qualitative Assessment of the Tool

The qualitative assessment of the dashboard's functionalities and usability has been carried out through 13 meetings where we discussed the analyses, functionalities and interface of the dashboard. We organised bi-weekly meetings with clinicians and separately, 4 meetings with a technical group composed of

experts in medical informatics. The first bi-weekly meetings consisted in preliminary sessions where we defined the key functionalities for the dashboard. First of all, we clarified the interest of clinicians in having a tool to perform this type of analysis. Secondly, we discussed expectations from the dashboard. Over several weeks, we refined the dashboard according to the feedback we received. For example, one request was to be able to visualize the trajectories of DAS28 and its components, especially for VAS and the count of tender joints. This is because RA has significant implications for patient quality-of life and increased psychological symptoms. Depression and anxiety have implications for disease activity primarily due to their influence on tender joints and patient global assessment. In addition, the capability to visualize the distribution of the type of biological drugs in each sub-group was also requested. This is because anti–tumor necrosis factor (anti-TNF) is the most common biologic therapy, but sometimes patients fail to respond on this initial anti-TNF therapy. For clinicians it is important to visualize the distribution of the type of biologic drug in each subgroup, in order to better assess the trajectories of DAS28. When we finalized the tool, we presented it at our internal meeting. We received positive feedback in terms of usability and the results of the lcmm analysis. The main refinement suggested was to add the option of visualizing the number of patients for each class, in order to create awareness in the classification that we obtained from the analysis; this has now been implemented within the dashboard.

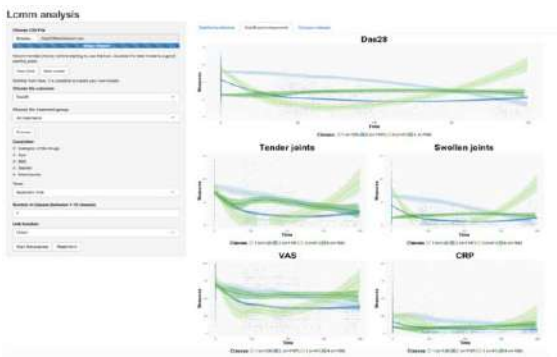

Figure 2 – Latent Classes' Trajectories: Das28 and its Components

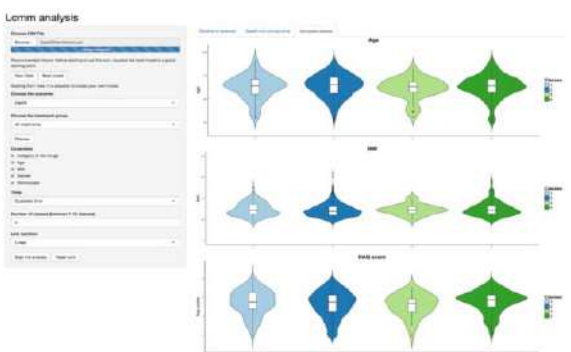

Figure 3 – Variable Distribution in the Latent Classes

Discussion

We present here a dashboard for performing latent class mixed-modeling analysis in the context of RA. The presented results and application case study are based on data from the BRAGGS multi-center study. To the best of our knowledge, this the first example of an accessible tool that enables lcmm analyses to be carried out, along with graphical representation of the results, specifically intended for a clinician and medical research user base. The dashboard provides clinicians the possibility of generating novel hypotheses regarding treatments responses, identify subgroups of patients that respond differently over time, and to assess results by comparing the mined groups with demographic and clinical features. The dashboard presents an initial, but crucial step towards enabling the translation of data-driven approaches into medical practice bettering the definition of phenotypes and supporting precision medicine.

Alongside the aforementioned contributions, several limitations of the study need to be recognised. While the graphical comparison of clinical characteristics and covariate serves to assess the clinical plausibility of the discovered classes, they might be biased. Additional methods like multinomial regression or corrections for measurement error in the classification of individuals to reduce bias could reduce potential biases. The dashboard has been evaluated by qualitative assessments through meetings with clinicians and medical informatics experts. While this approach contributes to implement a tool that responds to real-world and practical needs, a structured and quantitative usability validation is likely to further benefit the development and implementation of such a tool. Once the usability of the tool is assessed, further technical and methodological enhancements can be applied. In future versions, it may be beneficial to create a direct link between the dashboard and the BRAGGS database. Discriminative and sensitivity analysis can also be added as final steps for analyses. The BRAGGS dataset includes data on adherence to treatments and proteomics analysis performed on a subset of the cohort. Future work could focus on including these and other data, as an additional approach for subgroup validation and biomarker discovery.

Conclusions

While the initial goal of developing a tool to perform lcmm for precision medicine is situated within the scope of the current dashboard, the functionality scope can be extended. The application of lcmm analyses has shown promising results in several medical fields [9,10], and the system can be extended, generalised, and applied in any of these. Furthermore, this approach would also facilitate public and patient involvement/engagement in medical research. Accessible results will encourage involvement in study design and interpretation/dissemination of study findings through various patient groups. While more work is needed to determine the real impact of the use of such systems in medical practice, dashboard frameworks [17,18] can work as a bridge between different clinical fields, machine learning approaches and precision medicine, creating the possibility of real improvement in clinical research and practice.

Abstract

The habits and lifestyles are the fundamental factors in the control of cardiovascular risk. Patients who have had a cerebrovascular accident (CVA) have a high risk of having a new event with similar characteristics. The exponentially growing success, penetration and adherence of the new communication technologies, based on applications (APPs), allows to use them to obtain information and influence the risk factors. We propose that empowering patients in their disease can make a more efficient management of it. For this reason, we designed and developed a system which integrates a mobile application and a web application. This system also makes use of peripheral devices to monitor patients and allow the automatic acquisition of information to enable the characterization of this kind of patients in relation to habits and lifestyle. At the same time, the system can also empower these patients with their disease to do secondary prevention.

Keywords:
Stroke; Secondary Prevention; Medical Informatics Applications.

Introduction

The modifiable cardiovascular risk factors (CVRF) are determinants of the major scourge in morbidity/mortality and global disability that generates cardio and cerebrovascular disease [1]. Globally, it is known that patients with ischemic stroke have a high risk of recurrence or the appearance of other cardiovascular events [2]. Keeping the CVRF controlled is essential for reducing the risk of having a cerebrovascular event delaying and even preventing the onset [3]. After an ischemic stroke, the risk of recurrence during the first year is approximately 10% and subsequently, 5% annually. In addition, the risk of presenting a coronary disease is estimated at 6% during the first year and then at an annual 4.6% after a first episode of stroke [4, 5]. The exponentially growing success, penetration and adherence that new mHealth communication technologies, based on applications (APPs) and devices such as wearables and others, allows us to use them as a means to obtain information and influence cardiovascular risk factors. Several studies have been published to demonstrate efficacy in promoting small but important changes in patient behavior and improvements in health status [6, 7]. In addition, the potential benefit for public health is very great given the ubiquity of such devices [8].

We propose in our hypotheses that it is possible to prevent stroke-related events by empowering patients to make more efficient management of their disease. At the same time, we think that we can better know this type of patients by means of knowing their habits and lifestyles better, through a data model that characterizes them and applying new technologies.

To achieve these objectives, we have designed and developed a system composed of two applications, an APP for patients and a Web Application for researchers and clinicians. In addition, we have also integrated some peripheral devices to monitor patient activity and improve the data visualization and follow-up. All peripheral devices used are available in the market at low cost. On the other hand, we have also improved the access to information material and patient training.

The main objective of this paper is to present the technological results prepared for the study focused on the secondary prevention of cerebrovascular events.

Methods

The methodology to achieve technological developments is based on formal software engineering techniques that ensure the suitability of the tools developed to meet the established requirements. In this sense, an iterative and incremental agile project methodology will be used, differentiating the following phases:

a) Requirements analysis: the technical requirements of the project are identified and defined through bidding techniques applied to the health area. The objective is to have a system requirements document with the specifications of the all proposed technological solutions. A working group consisting of a doctor and an engineer gather the functional requirements of the system. These requirements will be analyzed by a multidisciplinary group (clinicians and technologists) of 20 researchers. In the last phases, patients will be included in the process to validate the requirements.

b) Design: the user-centered design paradigm will be applied during this phase. The use of co-design techniques involves the end users in the development process and guarantees the adequacy and acceptance of the product to the end user.

c) Implementation: After the analysis and design phases, the implementation of the system will begin, using an agile methodology based on the development of prototypes and the establishment of goals. Since it is a very long and complex phase, we focus on the technologies used in each module to meet the requirements established above.

d) Testing: the evaluation of the prototypes mentioned above makes it possible to identify new requirements and correcting or improving the possible deficiencies in the design of the solution. To achieve this, unit tests of the created software will be performed. After checking the correct functioning of each component, integration tests will be carried out, where the correct flow of information between the components of the proposed infrastructure will be checked. In addition, in the

next phase the developed tools will be made available to the end users to check if the tools work correctly.

The next phase is the pre-pilot. In this phase, patients will be recruited into the examination room. These patients must have recently had a stroke. The objective of this phase is to make the last adjustments and checks.

Afterwards, a pilot phase will be carried out. The study we are doing in this project is a prospective study. There will be two groups of patients, a control group and an intervention group. At recruitment, they will be provided with the devices and the designed protocol will be applied to them. Patients will be assigned to the groups randomly.

Finally, we will analyze the collected data using the developed system.

Results

All the phases of the described methodology have been carried out including the developments and the tests. In the following sections we explain the results in more detail.

a) Requirements analysis: the technical requirements of the project were identified and defined. The required solution was based on (1) a distributed platform formed by a backend, with 2 differentiated front-ends (the clinician's website and the patient's application), (2) integrated with the Hospital Information System (HIS) (to authenticate healthcare personnel or to get clinical constants) and (3) with other external devices used by the patient; such as a quantifier wristband (to measure his physical activity) and a bluetooth blood pressure meter. (4) The web had to be modular, scalable to the estimated number of users and allow the patient monitoring through the collection of data, scales and constants. Regarding the app, (5) it had to be responsive (accessible from any device) and multiplatform (used in android and iOS mobiles), (6) accessibility adapted to patients who have suffered from stroke , (7) it should alert about the next patient consultation, (8) generate personalized notifications, (9) collect patient behavior constants through forms, and (10) allow the clinician to modify the multimedia content of the app through a web interface in order to achieve patient empowerment. Using this data, (11) the web interface should allow an analysis of the patient's stored data for the extraction of the healthcare professional conclusions. (12) As well as, it should be available from the professional's computer of the recruitment and patient follow-up centers. Furthermore, (13) physicians had not to intervene in the review of patients with the aim of not influencing their decisions.

b) Design: The result of applying the techniques mentioned in this section of the methodology is described in the following figure (figure 1).

Figure 1: Infrastructure design

In this figure, the following modules are differentiated:

- Healthcare web application: application used by clinicians. This application will allow the patient recruitment, information registration and follow-up through scheduled reviews, thanks to the integration with the patient's social and medical history (BDU, in Spanish, demographics user database). In addition, this application stores the patient's records and allow to see the patient's evolution and to carry out the subsequent analysis of the information. Finally, it has been developed and implemented under the regulations established by the Information and communication technologies service of the Virgen del Rocío Hospital in Seville.
- Remote devices: set of peripheral or wearable devices that allow the patient to be tracked. A Fitbit quantifier wristband (from which physical activity, step and arterial frequency are obtained) and a blood pressure monitor are used to store patient data and incorporate them into the study through the use of web services based on their respective clouds. A chromecast is also used to facilitate the visualization of audiovisual content on the patient's television, allowing access to education and risk factors information associated with suffering a new stroke.
- Mobile app: application used by patients at home, to track the disease and improve knowledge about stroke in order to prevent a new cardiovascular event. The patients can visualize their profile, see and add the cardiovascular risk factors associated with the stroke they have, access educational content on the CVRF associated with the patient, make weekly forms for monitoring their disease, visualize their evolution through graphs and visual color codes, and manage their next reviews through alarms. In addition, the application uses artificial intelligence algorithms to give personalized recommendations and advice to the patient. These advices are about the key elements of your illness and are shown using intelligence notifications or when the forms are made.

c) Implementation: The results obtained after applying the techniques mentioned in methodology section and after developing prototypes have been the following.

- Healthcare professional web application: a clinical trials and research studies management platform known as ITC-Bio has been used for the development of this interface. This platform is developed through a framework based on MEAN STACK, which includes the following technologies: MongoDB, Express, AngularJS and Node.js. The platform makes use of a service gateway developed using the Mirth Connect service bus for communications between its components. This bus is a free software initiative, whose objective is to allow the electronic registration of clinical information of patients or the advanced analysis of information, among others. For the storage of clinical information, a PostgreSQL database is used (relational and also based on free code). In addition, within the framework of the PrevenCer project, a module has been developed within the ITC-Bio platform for alarm management, as well as for the analysis and monitoring of the information recorded by patients through their mobile applications.

- Remote devices: a module has been developed that allows the integration of the data collected by the FitBit® wristbands. To do this, the Mirth Connect communications bus has been used to obtain the patient's desired variables from the Fitbit Cloud (through its native APIs). For example, pulse, physical activity, etc.
- Patient mobile application: the IONIC framework has been used for the development of the mobile application. This framework allows generate multiplatform hybrid applications (they can be used in both iOS and Android). For this purpose, the following technologies are used: HTML/CSS/JS, TypeScript, Angular 4 Framework and Apache Cordova (to access the native capabilities of the mobile phone). In addition, it has been designed using styles and libraries such as Bootstrap, which allow the application to be responsive (adapted to other devices such as tablets). For the integration of the mobile application with the health professional's web application, the service platform has been used, developed with the Mirth Connect integration bus, through the JSON information exchange and interoperability standard. Finally, for patient monitoring, several devices (wearables) have been used that are activated by Bluetooth from the application (e.g. the Fitbit® wristband), or use external services to integrate (e.g., Youtube for Chromecast®).

All the information is stored in the Hospital databases within a secure network. Secure communication protocols are used for the exchange of information based on standards.

d) Testing: unit tests of the created software have been carried out. After checking the correct functioning of each component, integration tests have been carried out, where the correct flow of information between the components has been checked.

All the components of the system have been designed for the target population with special emphasis on communication techniques, vocabulary, graphic interface and dynamics adapted to this type of group. The technology infrastructure, the APP and desktop application is set up. The devices are available and ready to start the study. The maximum market price for all devices is approximately € 200 per patient, according to the CVRF and the conditions of each patient. Then, the pre-piloting phase is beginning with patients recruited in consultation.

Figure 2: Patient application screenshot

In Figure 2, it is possible to see how the developments have been focused on the end users, elderly Spanish-speaking patients with motor and cognitive sequelae. We show two screenshots. One of them shows the main menu with six buttons: (1) My profile: it contains the data of the patients. (2) Education: it contains the information about the risk factors customized for the patient, (3) My evolution: it contains the evolutions of the risk factors for the patient, (4) Registry: it is where the patient can register their information. (5) My calendar: it picks up the patient's appointments. (6) Information: it contains the information of the project. The other screenshot in about the evolution. It is possible to visualize the evolution of risk factors.

Discussion

We present the project that we are running between January 2017 and December 2020. The objective is to perform the secondary prevention of stroke and obtain a data model that helps to better understand patients who have had a stroke. We have made the design and development of a system that supports this study through low cost devices and available for most of the public or for health services.

We believe that by obtaining the data model of this type of patients, it is possible to design more efficient secondary prevention measures and improve adherence to treatment.

We have found a few limitations of the study. Patients can obtain training and uncontrolled information through the apps of the devices delivered in the study.

These patients should not install the wristbands or the APP tension meter in order not to use other means of training and information not controlled in the study.

Perspectives

Afterwards, the pilot phase will begin. A total of 160 patients will be recruited and monitored for one year. We will provide the APP for the patients from the intervention group, as well as, the FitBit® wristbands, the iHealth® tensiometer and the chromecast®. For the patients from the control group we will provide only the FitBit® wristbands, iHealth® tensiometer. These patients should not install the bracelets or the APP tension meter in order not to use other means of training and information not controlled in the study.

Once the pilot phase is over, we will analyze the collected data using the developed system (ITC-Bio) which includes a data analysis module.

Once the study is finished, if the behavior of the patients is modified and adherence to healthy lifestyles and medication improves with the training and information introduced in the patients through the means of support. This will help better control modifiable risk factors and will delay the onset of new cardio and cerebrovascular events.

We will publish the conclusions obtained from the study.

Conclusions

We have built a system consisting of an APP, a desktop application and some devices adapted to the end users. We have created an infrastructure capable of integrating the whole system. In this way, we will support a research on secondary prevention of personalized stroke through the monitoring of patients, creating at the same time a data model and allowing the final analysis of the study. The tests carried out on the entire system have been satisfactory. We are currently starting

the study. We hope that by the end of 2020 we can present the results of the study.

Abstract

Understanding the progression of chronic diseases, such as chronic obstructive pulmonary disease (COPD), is important to inform early diagnosis, personalized care, and health system management. Data from clinical and administrative systems have the potential to advance this understanding, but traditional methods for modelling disease progression are not well-suited to analyzing data collected at irregular intervals, such as when a patient interacts with a healthcare system. We applied a continuous-time hidden Markov model to irregularly-spaced healthcare utilization events and patient-level characteristics in order to analyze the progression through discrete states of 76,888 patients with COPD. A 4-state model allowed classification of patients into interpretable states of disease progression and generated insights about the role of comorbidities, such as cardiovascular diseases, in accelerating severe trajectories. These results can improve the understanding of the evolution of COPD and point to new hypotheses about chronic disease management and comorbidity.

Keywords:

Latent multi-state models, chronic obstructive pulmonary disease, disease progression.

Introduction

Chronic diseases typically progress slowly over many years. For example, patients with chronic obstructive pulmonary disease (COPD) may progress from mild to very severe disease over the span of more than a decade [1]. Understanding how, and to the extent possible why, patients progress through their disease is crucial for improving disease detection, management and prognosis. For example, inappropriate care at early stages of the disease can accelerate progression to more severe stages.[2,3] At a clinical level, the GOLD criteria define stages of COPD disease (based on lung function assessments) and identify appropriate care by disease stage.[4] However, in the absence of accessible clinical and physiological data for the whole COPD population, health system managers are unaware of the distribution of disease severity and cannot tailor interventions to alter their trajectories.

Fortunately, the data needed to model disease progression exist in the form of the vast amount of individual patient data stored in longitudinal health records, such as healthcare administrative databases. Despite their value, these data are not direct observations of the underlying processes that drives disease progression, but instead they record indirect measures such as healthcare encouters, diagnositc codes and drugs. As a result, inferential methods are needed to model disease progression as a function of these observeables.

Several factors complicate the modeling of disease progression. First, patient data are recorded only when services are delivered, resuling in irregularly-spaced observations that differ in granularity between patients or across one patient's course of illness. Disease trajectories, in terms of the rate of progression and the profile of health service used, will also vary widely across patients, further creating challenges in modeling progression for groups of patients. Moreover, for large segments of patient trajectories, records may be sparse due to infrequent visits, or records may be incomplete (e.g., censored data or care provided outside the health system). Finally, the comorbid conditions experienced by most patients are an important driver of both observed healthcare use and progression in the underlying disease of focus.

Research that has used data from electronical health records to model chronic diseases such as COPD has tended to simplify or collapse the data over time (e.g. 30-day readmission [5]). Other researchers have opted to use regularly spaced data from relatively small and selected clinical cohorts, allowing them to model disease progression as time-to-event [6,7]. In modeling the heterogeneity in COPD progession, researchers have clustered clinical measures cross-sectionally [8] or over-time as latent trajectories from smaller regularly-spaced trial data [9].

Previous disease progression research using mutli-state modeling has typically made use of known disease status or known transition rates [10–13] rather than modeling the latent disease progression as a stochastic process. Recent research by Wang et al. [14] has developed a novel approach to modeling COPD progression using a hidden Markov model (HMM), which assumes a latent Markov process governing an evolution of observed events. These events are defined by latent groupings of COPD-related and comorbidity diagnostic codes (ICD-9) measured in 90-day bins.

To model the heterogeneous, sparse, non-equidistant, and incomplete longitudinal observations in a large cohort of COPD patients we propose using a continuous-time hidden Markov model (CTHMM) under a generalized linear modeling framework with patient-level covariates of comorbidities [15]. Such multi-state models can describe patient status over time as a discrete-time realization of a continuous-time Markov process, while accommodating irregular spacing of observations [16]. We are interested in understanding how a CTHMM can be used to infer latent disease progression from an observed evolution in complex healthcare utilization data.

We use a CTHMM on data from a large cohort of COPD patients to model trajectories of the chronic disease and

examine the role comorbid conditions in the progression. Our objective is to generate hypotheses about the evolution of the illness and how the management of COPD may be improved.

Methods

Data

A cohort of COPD patients was selected from an open, dynamic cohort sampled in 1998 as a 25% random sample drawn from people registered with the provincial health insurance agency (*Régie de l'assurance maladie du Québec*) in the census metropolitan area of Montreal[17]. At the start of every following year, 25% of births and new residents arrived to the area in the past year were sampled to maintain a representative cohort. Patients were followed until they died or moved out of the region. The administrative records included outpatient diagnoses and procedures submitted through billing claims, and procedures and diagnoses from hospital records.

Using established case-definitions based on diagnostic codes [18,19], we enrolled 76,888 COPD patients with an incident event (ICD-9 491x, 492x, 496x; ICD-10 J41-J44) occurring after a minimum of two years at risk and followed patients until December 2014. Comorbid diseases were determined at baseline (upon entry in the larger dynamic cohort) using established case-definitions for 9 diseases: acute myocardial infarction (AMI), asthma, cancer, congestive heart failure (CHF), diabetes, hypertension, ischemic heart disease (IHD), mental illness, and stroke). Patient age and sex were also retained for model covariates.

When a patient has an ecounter with the health system, the data recorded are indirect measures of their underlying disease state. For this study, we used data captured during an outpatient visit with a general practitioner (GP), an outpatient visit with a specialist (SPEC) (coded as respirologist or internist), visits to an emergency department (ED), and hospitalizations (HOSP). Health services used prior to the incident COPD event were not considered.

Model description

To model disease progression within the COPD cohort, we used a continuous-time hidden Markov model (CTHMM). Our model assumes the observed events are generated from hidden states that we interpret as belonging to states of disease severity, by computing the probability of different healthcare utilization events with known levels of severity.[20] The observable data in this CTHMM were healthcare utilization events, which were classifed into four mutually exclusive types (GP, SPEC, ED, HOSP). If two events occured on the same day, then we used the most severe event, where HOSP was the most severe, follwed by ED, SPEC, and GP.

Given an observed event, the probability of each of the four observables was determined by a multinomial model, using GP as the reference event. For each state, there was a set of parameters β that specified the multinomial model of the four healthcare utilization outcomes. Each state's multinomial model was specified as a set of three logistic regression models of the probability of specialist, ED, or hospital visit versus the probability of a GP visit. Each logistic regression model was an intercept-only model, meaning that the probability of each healthcare utilization outcome was the same for any patient in the same state. Fixing the utilization probability within states facilitates the interpretion (or labeling) of different states, strictly based on differences in the severity of patient need across states.

Because the observed values (healthcare utilization events) were irregularly-spaced in time, we modeled the transitions between hidden states in continuous time. Also, as patients may have extended periods without any healthcare visits, we allowed for transitions between states even if there were no observed healthcare utilization events. The transition rate between states was specified by the transition rate matrix Q, whose parameters were fit as part of the model, where each row and column corresponded to a hidden state. If X_t is the state membership at time t, then $q_{ij} = \lim_{\Delta t \to 0} \frac{P(X_{t+\Delta t}=j|X_t=i)}{\Delta t}$ where $i \neq j$. The diagonal entries of Q are computed so that the rows of Q sum to zero. Q was calculated separately for each patient using the vector of their baseline covariates $\mathbf{W}$, such that $\log(q_{ij}) = \mathbf{W}^{\mathrm{T}}\xi_{ij}$ where $i \neq j$.

We fixed the transition matrix to allow transitions only to one adjacent subsequent state (a Markov chain), except in one branching state with two transitions. The parameter set ξ_{ij} for all other state pairs were fixed to zero. By restricting the transitions in this manner we aimed to model a set of alternative disease progression trajectories following an earlier Markov chain progression. We compared the goodness-of-fit of a 4-state model (as an initial state transitioning to a state that branches to two absorbing states) to three models with similar topologies but additional states: 5-states (one state before the branching state), 6-states (one state before each absorbing state), and 7-states (a combination of the 5- and 6-state additions). We compared models using the Bayesian information criteria (BIC), mean posterior probabilities of predicted states, as well as criteria from guidelines on model fitting in HMM concerning the interpretability and usefulness of additional states. [21]

Model fit

Our model required us to fit three sets of parameters. π specified the probability of starting in each state, ξ specified the relationship of the patient's baseline covariates to the transition rate matrix, and β specified the probability of each observable (healthcare utilization) for each state.

To fit our model, we used expectation-maximization (EM) [22], an iterative algorithm in which previous parameter values are used to compute new values. The EM algorihm requires starting values for the model parameters. For π, we specified equal probability of starting in any state, the β parameters were randomly drawn from a normal distribution with a mean of 0 and a standard deviation of 1, and the ξ parameters were drawn from a uniform distribution between 0 and 1, except for the parameter for age, which was scaled by the maximum age in the data. We scaled Δt to be expressed in years.

At each iteration of EM, we used the forward-backward algorithm [23,24], along with the current parameter values for π, β, and ξ, to compute, for each consecutive pair of observations within each patient, the probability of starting and ending in each state pair. From these state pair membership probabilities, we computed the probability of state membership at all observed times for all patients.

We then computed new estimates for each of our parameters. We computed a new value for π using the mean probability of state membership at the first observed time point across all patients, and computed new values for β by fitting a multinomial model for each state, weighting each observation by the probability of state membership at that time. Finally, we computed new values for ξ by using a nested EM procedure [25,26]. We stopped the algorithm when the sum of the

difference in norms between the previous and new parameter values was below 0.05.

Results

Figure 1 (A) describes the β and 5-year, non-diagonal Q coefficients of a 4-state model. A 4-state model was chosen over 5-, 6-, and 7-state Markov chain models despite decreases in BIC in latter models (4-state, 5853716; 5-state, 5767363; 6-state, 5721712; 7-state, 5668360). This decision was based on the 4-state model's higher mean posterior probabilities of predicted states (0.93 vs 5-state, 0.91; 6-state, 0.90; 7-state, 0.87) and its better interpretability of distinct states, allowing for better understanding of predictors of transition in disease progression modeling and for the aim of hypothesis generation. We interpreted state 1 as representing a controlled state with high probability of GP visits (86%). Patients in state 2, interpreted as a state of higher disease severity, had a higher probability of ED visits (51%) and hospitalizations (22%). State 3 was interpreted as a stage of more specialized disease management (40% specialist visits and 41% GP services), compared to state 4 in which patients have a combination of higher GP use (65%) but also higher ED visits (23%).

Patients typically transitioned slowly (16% over 5 years) from state 1 to state 2, while transitions away from state 2 were more accelerated (57% to state 3 and 29% to state 4 over 5 years). The complements of these rates represent the probability of remaining in states 1 (84%) and 2 (14%) over 5 years. Transitions from state 1 to 3 or 4 only occurred through state 2.

Figure 1 (B) shows four illustrative patients trajectories of observed health service use along with predicted states at observation time based on patients' posterior probability. .

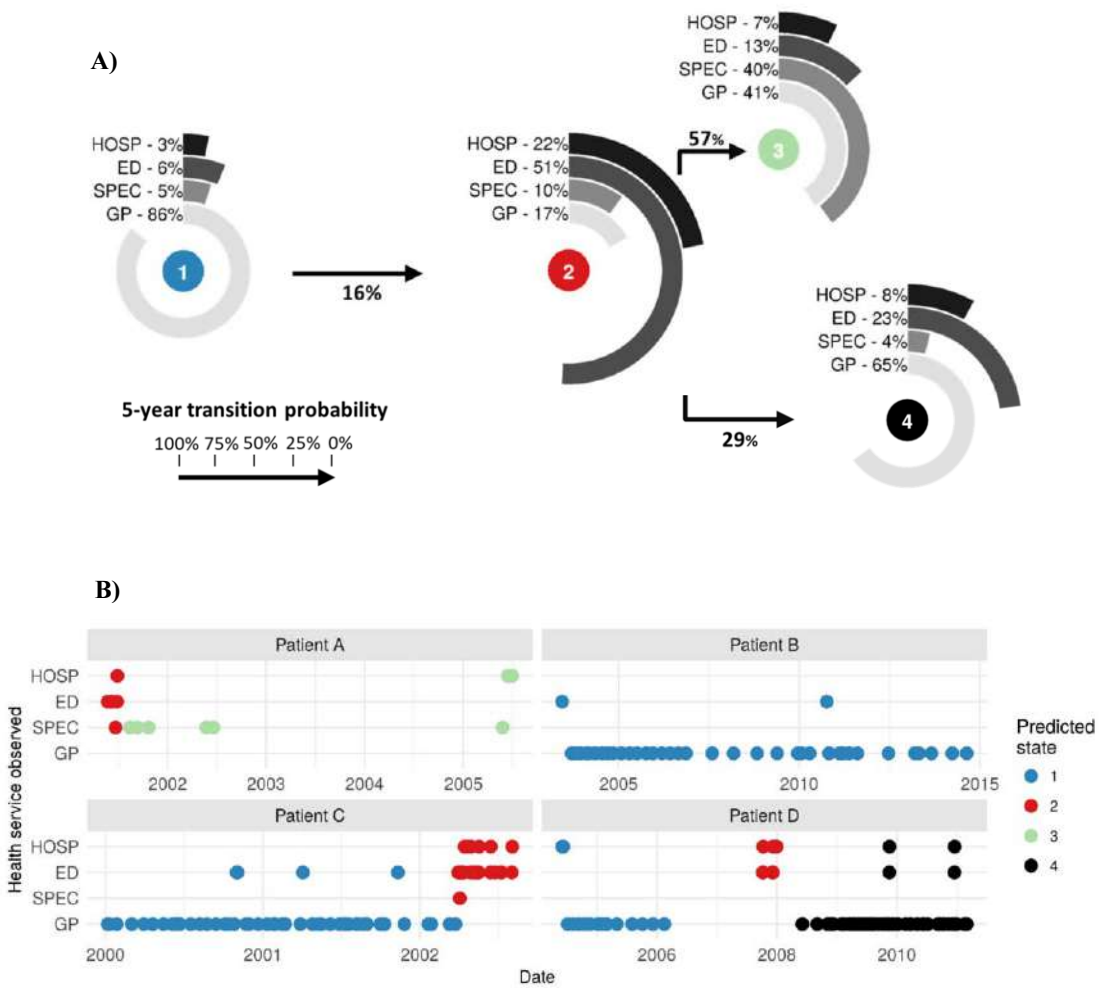

Figure 1 ***A)*** *Diagram of 4-state model of COPD progression based on healthcare utilization. Radial bars represent the probability of each health service (HOSP = hospitalization, ED = emergency department visit, SPEC = specialist visit, GP = general practicioner visit) within a state (labeled 1 to 4), while distance (horizontally) between each state represents the transition probability over 5 years (more distant states represent lower transition probability).* ***B)*** *Observed health service use trajectories of four illustrative patients. Health service types are plotted on separate lines, while patients' predicted state (from1 to 4) at observation time is represented by the dot color*

Table 1 describes the marginal associations between patients' baseline covariates and 5-year transition rates. Noteworthy associations include hypertension, IHD, and stroke increasing the probability of transitioning to and remaining in state 2 (RR ≥ 1.3 and ≥ 1.5, respectively), while cancer is the only covariate associated with higher transition probabilities from state 2 to 3 (1.3). No covariates have large effects on transition probabilities from state 2 to state 4.

Table 1– Risk ratio of transition between states after 5 years by patient characteristics.

Start state	1		2		
End state	1	2	2	3	4
Variable					
Age (10 years)	0.8	1.3	1.0	0.8	1.1
Sex (Male)	0.9	1.2	1.2	0.9	1.0
AMI	1.0	1.0	1.0	1.0	1.0

Cancer	1.0	1.0	0.9	1.3	0.9
CHF	1.0	1.1	1.2	0.9	1.0
Diabetes	0.9	1.1	0.9	1.0	1.0
Hypertension	0.8	1.8	2.1	0.7	0.9
IHD	0.9	1.4	1.5	0.9	0.9
Mental illness	0.9	1.1	1.1	1.0	1.0
Stroke	0.9	1.3	1.6	0.6	1.1

Discussion

We applied a continuous-time hidden Markov model to healthcare utilization data for a cohort of COPD patients to model their unobserved, latent, disease progression. The model allowed us to learn trajectories through underlying disease states from heterogeneous, sparse and incomplete observations. We found that the model provided interpretable results, allowing us to generate hypotheses about how healthcare utilization evolves at different stages of disease progression.

The discrete states suggest slow progression from a controlled state of the disease (state 1) to one that requires acute care (state 2) and is typically more transient. Patients will mostly transition rapidly from that acute state to one where their disease is managed with primary and specialized care (state 3). However our model specification allowed us to identify an alternative trajectory from state 2 to state 4 where patients are potentially managed inadequately (lower specialist care and higher ED visits than state 3). This pattern suggests possible disparities in patient management (state 3 vs state 4) following hospitalizations and emergency care (state 2) as a window for targeting further investigations into COPD trajectories.

Including patient covariates in the model allowed us to identify predictors of less favourable disease progression patterns. Having a history of different cardiovascular diseases (CHF, hypertension, IHD, and stroke) or of asthma; being older, and being male predicted more severe trajectories, either by precipitating transition towards a state requiring more hospitalizations and ED visits (state 2) or by increasing the probability of remaining in that state. A higher probability of remaining in state 2 typically occurred at the expense of transitions to more specialized care in state 3. We interpret this finding as suggesting that comorbid conditions may increase the risk of repeated acute care in COPD patients and reduce the rate of progression to a state with specialized management. Patients with a history of cancer, however, were more likely to transition to state 3, possibly due to their greater need for specialized treatment. Further analysis can validate these covariates as being modifiers of disease progression by investigating to what extent they predict similar healthcare use patterns outside of a COPD cohort.

These results demonstrate that with little specification beyond model topology (allowed transitions) and number of states, electronic health data can provide new insights and hypotheses on disease progression and management. At a clinical level, such models can improve prognoses by matching patients to typical trajectories of a sub-population. At a health systems level, decision makers can identify health service profiles (e.g. access to specialist care) that are predictive of slower disease progression.

An important aspect of this type of analysis is to weigh multiple criteria in model selection, such as interpretability and relative contribution of additional states [21], especially if the predictors of state transitions are also meaningful. Future research can explore the effect of specifying topologies allowing for transitions back to earlier states, more than one branching state, or higher order Markov chains (states depending on *n* previous states), as well as additional transition covariates such as prescribed drugs and treatments.

Certain limitations of our approach must be considered. Despite our longitudinal focus, covariates of transition probabilities could only be analyzed in terms of their respective baseline measures, a limitation of CTHMMs. Time-varying measures of comorbidities and other covariates would better reflect the evolving impact of patient characteristics on disease progression. In addition, classification of both comorbid status and inclusion in the COPD cohort was based on deterministic case definitions that ignore potential misclassification. An improved approach could learn a probablistic classification of both comorbidities and the modeled disease in a manner similar to how the model learned disease states.

Conclusions

By modeling complex longitudinal observations generated by latent disease states, we have created opportunities for future research in understanding the progression of COPD with potential applications to other chronic diseases.

Abstract

Timely mortality surveillance in France is based on the monitoring of electronic death certificates to provide information to health authorities. This study aims to analyze the performance of a rule-based and a supervised machine learning method to classify medical causes of death into 60 mortality syndromic groups (MSGs). Performance was first measured on a test set. Then we compared the trends of the monthly numbers of deaths classified into MSGs from 2012 to 2016 using both methods. Among the 60 MSGs, 31 achieved recall and precision over 0.95 for either one or the other method on the test set. On the whole dataset, the correlation coefficient of the monthly numbers of deaths obtained by the two methods were close to 1 for 21 of the 31 MSGs. This approach is useful for analyzing a large number of categories or when annotated resources are limited.

Keywords:

Machine learning, sentinel surveillance, cause of death

Introduction

Syndromic surveillance is "a real-time (or near real-time) collection, analysis, interpretation, and dissemination of health-related data to enable the early identification of the impact (or absence of impact) of potential human or veterinary public health threats that require effective public health action" [1]. Mortality is the indicator traditionally used to measure the severity of the impact of an event on a population and is of fundamental significance to health surveillance. As part of the French syndromic surveillance system SurSaUD, timely mortality surveillance is carried out by Santé publique France, the French public health agency [2].

Mortality surveillance is based on death certificates which consist of an administrative part and a medical part based on a model developed by the World Health Organization (WHO) [3]. The medical part is divided into two sections. First, the sequence of morbid events is reported in Part I in descending order from immediate to underlying causes of death (4 fields). Secondly, the unrelated but contributory causes of death are reported in Part II (2 fields).

The medical part consists of free-text fields where physicians write down one or more causes of death, with one or more words which are frequently misspelled. The French Epidemiology Center on Medical Causes of Death (Inserm-CépiDc), the institution responsible for the French national mortality database, then codes the medical causes of death. The coding follows WHO rules, using the 10th revision of the International Classification of Diseases (ICD-10). It can take between 6 and 24 months for the coded medical causes of the death to be made available to epidemiologists. Efforts at automating this coding task to reduce this delay have been made through several shared tasks during the CLEF eHealth campaigns [4,5].

Since 2007, an Electronic Death Registration System (EDRS) allows physicians to certify deaths electronically. The added value of EDRS for reactive mortality surveillance is to send free-text causes of death within a few minutes after the validation of the death certificate. A pilot study demonstrated that E-death certificates constitute valuable data for real-time mortality surveillance [6].

Timely mortality surveillance is based on the routine monitoring of syndromic groups [7]. A Mortality Syndromic Group (MSG) is defined as a cluster of medical causes of death (pathologies, syndromes, or symptoms) that meets the objectives of early detection and impact assessment of public health events. Definitions of MSGs are based on a list of ICD-10 codes, each code belonging to a unique MSG. We defined one hundred MSGs: sixty MSGs consist of acute or severe causes of death and are monitored for early alert purposes, and forty contain chronic diseases. All are used to evaluate the impact of public health events. They span twenty different topics including cardiac and circulatory conditions, respiratory conditions, cancer, infectious diseases, digestive conditions, genito-urinary conditions, symptoms, poisoning, and injuries.

Since e-death certificates are entered in free-text format, the automatic classification of medical causes of death into MSGs requires the use of Natural Language Processing (NLP). In a previous study, we implemented and evaluated two methods to classify causes of death into MSGs: a rule-based method and a Support Vector Machine (SVM) method. Two models were developed using the SVM method: one was based on surface features and the other was a hybrid model combining surface features and features obtained through the rule-based method. We evaluated the performance of the methods on seven out of one hundred MSGs (influenza, lower respiratory diseases, asphyxia and abnormal respiration, acute respiratory diseases, sepsis, chronic digestive diseases, and chronic endocrine diseases). These MSGs were chosen to illustrate the variation within three main dimensions: their epidemiological relevance to mortality surveillance, their frequency of occurrence in death certificates, and the relatedness of their definitions (e.g., acute vs chronic diseases). The results showed that the rule-based method and the hybrid model displayed high performance with F-measures over 0.94 for all seven MSGs. The SVM model achieved lower performance compared to the other two models with F-measures varying from 0.91 to 1 for all MSGs except for chronic digestive diseases (0.88).

The objectives of the present study were to 1) analyze the performance of the rule-based method and the hybrid model to classify causes of death into sixty additional MSGs, and to

2) compare the trends in the monthly numbers of certificates classified into MSGs from 2012 to 2016 using both methods. This second analysis was also performed on the seven MSGs from the previous study.

Materials and methods

1. Corpus characteristics

Data consisted of the medical section of e-death certificates received routinely between 2012 and 2016 (203,797 certificates). E-death certification has been gradually rolled out, recording 5% of the national mortality in 2012 and 12% in 2016. These data were anonymized and contained both administrative and demographic information as well as free-text medical causes of death. To evaluate the performance of the classification methods, we used 4,500 annotated death certificates. We define the term "entity" as an expression of a cause of death on a field of the medical part of the death certificate.

2. Training and test splits

Using random sampling without replacement, the dataset was split into two parts: a training set using death certificates from 2012 to 2015 and a test set using death certificates from 2016. Three thousand five hundred certificates were annotated for the training set and one thousand for the test set. For this annotation task, each annotator had a detailed definition of each MSG based on lists of ICD-10 codes. Two annotators assigned MSGs to each field of the medical part of death certificates in both subsets. The two annotated subsets were compared to each other. Errors were discussed between the two annotators and corrected if necessary. The agreement rate was 0.90 on the test set. Final annotated subsets represent the ground truth against which the methods tested were evaluated.

3. Data preprocessing

The data and dictionary were preprocessed by applying 6 steps: conversion of all characters to lowercase, removal of diacritics, standardization of compound words (i.e. the replacement of hyphens by spaces to obtain two distinct words), replacement of punctuation (except commas, simple quotes, and semicolons) by a space, stop words removal, and removal of multiple spaces in the text and at its beginning and end. The preprocessing steps aimed to obtain a narrower set of more relevant terms.

4. Rule-based method

The rule-based method consisted of assigning MSGs to all entities from death certificates based on an ad-hoc dictionary provided by the Inserm-CépiDc. This dictionary is composed of entities found in previous death certificates with their corresponding ICD-10 codes. The principle of the rule-based method is to assign an MSG based on ICD-10 codes to an entity found in a death certificate when it matches an entity found in the dictionary. Our method relied on four steps : 1) entity normalization through the removal of unnecessary words, replacement of synonyms, acronym expansion, etc., based on more than 900 rules; 2) text segmentation based on comma and semi-colon punctuation marks, prepositions, a few causal expressions, and factorization of coordinated elements (e.g., "hepatitis A and B" is replaced by entities "hepatitis A" and "hepatitis B"); 3) spelling correction using a Levenshtein distance computed with words from the dictionary; and 4) dictionary matching. This method aimed to find entities from the dictionary on death certificates, from the longest span to the shortest one, without overlap. Assignment of an MSG was attempted after each step.

5. Machine learning method

Among the supervised machine learning methods, we trained a linear SVM classifier [8, 9] using the default hyperparameter (C parameter equal to 1). Since it may be possible to associate 0, 1, or more MSGs to each field of a death certificate, we performed a multi-label classification using the one-versus-all strategy [8]. The SVM classifier was trained for all MSGs. We implemented a hybrid model using a combination of surface features and the MSGs previously predicted using the rule-based method as its features. We selected bag-of-words unigrams (set of unique words for each example in the training set), bag-of-words bigrams (set of unique sequences of two consecutive words for each example in the training set), and character trigrams (providing a degree of robustness to spelling errors) as surface features. Previous studies show that those surface features provide the best classification performance on French mortality data [9]. This classifier was implemented using the scikit-learn library in Python [10].

6. Evaluation metrics on the test set

Both methods were previously trained and developed on the training set. This study focused on the analysis of MSGs that were found in similar proportion and with at least three mentions in the training set, test set, and data from 2012 to 2016. We analyzed the performance of the two methods on sixty MSGs belonging to eighteen topics.

Three evaluation metrics were considered: precision, recall, and F-measure. In order to simplify the reporting of the results we defined three groups of MSGs depending on the performance of the methods on the test set:

- Group 1 contained MSGs with similar performance for both methods. We defined similar performance as having the three evaluation metrics belonging to the same performance level. The performance levels of each evaluation metric were defined using four categories: $\geq$0.95, [0.90-0.95), [0.85-0.90), and <0.85.
- Group 2 contained the remaining MSGs with similar performance for either the rule-based method or the hybrid model.
- Group 3 contained the remaining MSGs with heterogeneous performance for each method. We defined heterogeneous performance as the precision and recall belonging to different performance levels.

The cut offs for the performance levels were based on the objectives of the mortality surveillance system. A surveillance system implemented for the timely detection of outbreaks must be based on methods with high recall and precision [11].

7. Comparison of the evolution of the monthly numbers of death certificates from 2012 to 2016 using the two methods

We applied the rule-based method and the hybrid model on the entire 2012-2016 dataset in order to verify how the performance measured on the test set would translate to the whole set. All of the causes of death contained in the certificates were classified using both methods. We then counted the number of death certificates by MSGs and by month for both methods (nb_E-death$_{RBM,month}$ and nb_E-death$_{Hybrid,month}$ for each MSG). The comparison of the monthly numbers of MSGs was based on:

1. Visual analysis of the monthly trends of each MSG. We defined 3 patterns: a) the monthly trends of an MSG using the rule-based method and the hybrid model overlap; b) the existence of a small difference between the 2 curves; c) the existence of a large difference between the 2 curves.

2. The calculated difference (Δ_i) of the monthly numbers of death certificates between the two methods expressed as a proportion for the MSG i (formula below) where m corresponds to each month from 2012 to 2016 (m=60 months in total) and i refers to each analyzed MSG.

1. $$\Delta_i = \frac{\frac{\sum_{m1}^{m60}\left(\text{nb E-death}_{RBM,i,m} - \text{nb E-death}_{Hybrid,i,m}\right)}{60}}{\frac{nbEdeath_{RBM,i} + nbEdeath_{Hybrid,i}}{2}}$$

3. The calculated correlation coefficient of nb_E-deathRBM,i and nb_E-deathHybrid,i.

2. This comparison was performed first for the seven MSGs of the previous study and then for only the MSGs with performance (3 metrics) of either method over 0.95.

8. Comparison of the monthly trend of MSGs to an external data source

For MSGs (such as "influenza" or "low acute respiratory infections" [12]) which are expected to have a similar temporal pattern to those of winter infectious epidemics, we visually compared the patterns of the monthly numbers of death certificates and the monthly numbers of attendances of the pathology. For this, we collected from the SurSaUD system the monthly numbers of attendances in emergency departments (EDs) with clinical diagnoses of "influenza" and "low acute respiratory infections" from 2012 to 2016. This analysis focused on two of the seven MSGs of the previous study for which an external data source was available.

Results

1. Analysis of performance of the rule-based method and hybrid model on the test set

1.1 MSGs with similar performance for both methods (Group 1)

Among the twenty-two MSGs of Group 1, performance (3 metrics) of the methods was over 0.95 for 19 MSGs (Table 1). Those excellent performance values are due to distinct features (consistency of entities, useful cues, and context for entity identification) depending on the MSG.

Table 1: Number of MSGs for which performance metrics belong to a performance level; France 2016 data.

	Group 1	Group 2	
Performance level	Both methods	Rule-based method	Hybrid model
≥0.95	19	6	6
[0.90-0.95)	0	1	2
[0.85-0.90)	1	0	1
<0.85	2	3	1

They belonged to nine different topics (Figure 1): 1-Cardiac and circulatory conditions (4 MSGs/11 MSGs analyzed in this topic), 2-Cancer (1/1), 3-Respiratory conditions (3/4), 4-General symptoms (3/9), 5-Infectious diseases (1/6), 6-Nutritional and Endocrine conditions (1/2), 7-Nervous system conditions (4/4), 10-Mental and behavioral disorders (1/3), and 15-Digestive conditions (1/1). Two MSGs had performance below 0.85 ("5-Bacterial infections" and "16-Other undefined and unspecified causes of death").

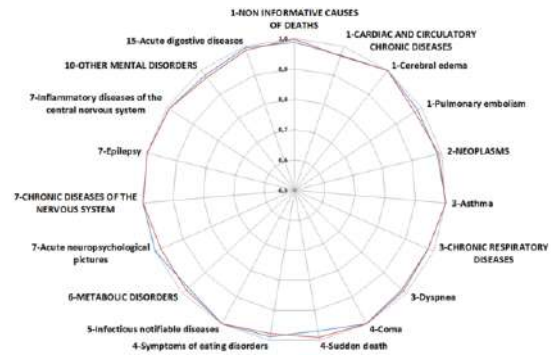

Figure 1: F-measures of the rule-based method (blue) and the hybrid model (red) for nineteen MSGs of Group 1 with performance over 0.95; France 2016 data.

1.2 MSGs with similar performance for either one or the other method (Group 2)

Eighteen MSGs belonged to Group 2. Similar performance (3 metrics) was observed solely with the rule-based method for 8 MSGs. Similar performance was also observed solely with the hybrid model for eight other MSGs. Similar performance belonging to different levels were provided by the two methods for 2 MSGs.

Performance of either the rule-based method or the hybrid model was over 0.95 for a majority of the MSGs in this group (12/18) (Figure 2). Performance of the rule-based method or the hybrid model was also comprised between [0.90-0.95) for three MSGs, while lower performance (below 0.85) was measured for four MSGs (Table 1).

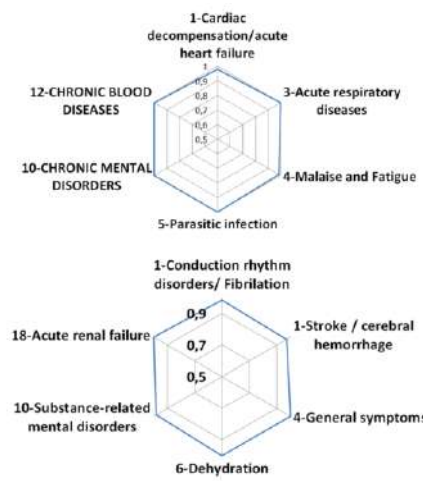

Figure 2: F-measure of the rule-based method (upper part) or hybrid model (lower part) for MSGs with performance (3 metrics) over 0.95 for one of both methods; France 2016 data.

1.3. MSGs with heterogeneous performance (Group 3)

Group 3 contained twenty MSGs with heterogeneous levels of precision and recall. While the rule-based method achieved a higher recall than the hybrid model for more than half of the MSGs (11/20), the rule-based method achieved either higher or lower precision than the hybrid model for six MSGs and seven MSGs, respectively (Table 2). The precision of both methods was similar for seven MSGs and recall was similar for three MSGs.

Table 2: Number of MSGs of Group 3 with performance level (PL) obtained using the rule-based method over, below or equal to the PL obtained using the hybrid model; France 2016 data.

	Precision	Recall
$PL^{a}_{RBM} > PL_{Hybrid}$	6	11
$PL_{Hybrid} > PL_{RBM}$	7	6
$PL_{RBM} = PL_{Hybrid}$	7	3

[a]PL: Performance level

2. Comparison of the monthly numbers of death certificates classified into MSGs by the two methods

2.1 Seven MSGs of the previous study

For five out of seven MSGs evaluated in the previous study, the trends in the monthly numbers of death certificates using the rule-based method overlapped the trends of the monthly numbers of death certificates using the hybrid model. The monthly trends were closely correlated for the two other MSGs. They all had small Δ_i. (Table 3).

Table 3: Number of MSGs according to the levels of $\Delta_i$and the visual pattern of the monthly numbers of death certificates. France-2012-2016

		Visual patterns		
	Δ_i	Overlap	Good correlation	Low correlation
7 MSGs	Small	5	2	0
19 MSGs* Group1	Small	7	6	1
	Intermediate	0	1	1
	High	0	0	3
12 MSGs* Group 2	Small	5	3	0
	Intermediate	0	2	0
	High	0	0	2

*MSGs with performance over 0.95

Small: Δ_i varying from -5% to 5%; Intermediate: Δ_i varying from [-10% to -5%] or to [5% to 10%]; High: Δ lower than -10% or over +10%

2.2 MSGs of Group 1 with performance over 0.95

Correlated trends were also observed for 7/19 MSGs in Group 1 with performance over 0.95 in the test set. The Δ_i of those MSGs ranged from -5.0% to 5.0% (Table 3) and their correlation coefficient was very close to 1. A good visual correlation was also observed between the monthly variations of deaths certificates for 7/19 other MSGs with performance over 0.95, even if a gap was noticed between the monthly numbers of deaths certificates provided by the two methods (Table 3). These seven MSGs also had Δ_i varying from -5.0% to 5.0%, except for "7-Acute neuropsychological pictures" for which $\Delta_i$was 5.9% (Table 3). Correlation coefficients of these MSGs were over 0.99.

A poor visual correlation between the trends of the monthly numbers of deaths using the two methods was observed for five other MSGs which achieved performance over 0.95 for both methods in the test set. For these MSGs, Δ_i were mostly lower than -10.0% or over 10.0% (Table 3).

2.3 MSGs of Group 2 with performance over 0.95

Overlapping trends of the monthly numbers of deaths provided by the two classification methods was observed for 5/12 MSGs of Group 2 with performance of one or the other method over 0.95 (Table 3). For these MSGs, Δ_i ranged from -3.9% to 1.7% and the correlation coefficient was 1.

Five MSGs also had a good visual correlation between the trends of the monthly numbers of deaths of the two methods (Table 3). For 3 MSGs, Δ_i was small with a correlation coefficient over 0.99.

Poor visual correlation of the trends was observed for two MSGs ("10-Chronic mental disorders" and "5-Parasitic infections"). The Δ were 12.5% and 24.3% and coefficient correlation were 0.98 and 0.96 respectively.

3. Comparison of the monthly trends of MSGs to an external data source

The monthly trends of the number of death certificates including a mention of "influenza" was very close for the two methods. Compared to the trends of the monthly numbers of ED attendance for influenza, seasonality and peaks were concomitant even if magnitudes were different. We noted that the number of deaths increased only during winters, the epidemic period of influenza in France (Figure 3). Likewise, the same observations were valid for the MSG "Low acute respiratory infections".

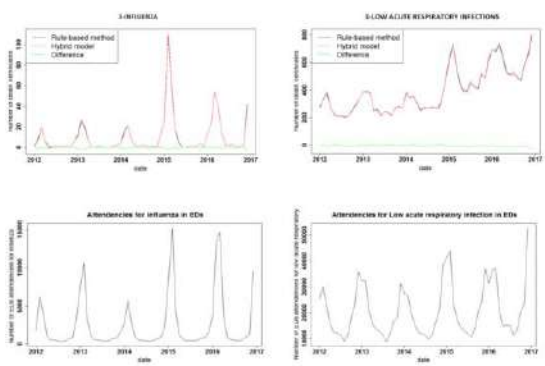

Figure 3: Trends of the monthly numbers of death certificates classified by the rule-based methods and the hybrid model for "influenza" and "low acute respiratory infections"(upper part) and evolution of the monthly numbers of EDs attendances for the same pathologies (lower part); France 2012-2016 data.

Discussion

The current study has shown that more than half of the sixty MSGs achieved both precision and recall over 0.95 for at least one of the two classification methods on the test set (19 MSGs from Group 1, and 6 MSGs from Group 2). When the classification methods were applied to the whole dataset we observed that 13/19 MSGs of Group 1 and 8/12 MSGs of Group 2 as well as the seven MSGs previously evaluated in the prior study had small differences between the monthly numbers of deaths certificates obtained using the two methods, with correlation coefficients close to 1. These results suggest that both the rule-based method and the hybrid model initially implemented, tuned and evaluated to classify medical entities into seven MSGs, are suitable for classification into a larger number of MSGs. This is of particular interest since 10/13 MSGs of Group 1 and 7/8 MSGs of Group 2 have been defined as

needing routine monitoring for the timely detection of outbreaks. Among the other 6/19 MSGs of Group 1 and 4/12 MSGs of Group 2 with performance over 0.95 measured on the test set, 6 had a low visual correlation associated with intermediate or high differences between the monthly numbers of deaths obtained using the two methods. The definitions of those MSGs contained rare and/or a large variety of diseases, like "5-Infectious notifiable diseases", "5-Parasitic infections" or "10-Chronic mental disorders". The training and test sets included an insufficient amount of death certificates containing these medical entities to capture the variety of those rare pathologies.

For two MSGs of the previous study, "Influenza" and "Low acute respiratory infections" with high performance and overlapping trends using both methods, the trends of MSGs were concomitant with those provided by an external data source. These MSGs built using NLP methods correctly reflect the pathologies we want to routinely monitor. This last step should be applied on the remaining MSGs in order to complete this study. The challenge is to find the most appropriate external data sources among specific surveillance systems, notifiable diseases systems, or the Health National Data system.

Group 3, which contained MSGs with heterogeneous precision and recall for the same method, is more complex to analyze. To meet the objective of a reactive detection of events, a high precision is needed to limit false positive cases. To measure the impact of an event, the surveillance system also needs a high recall to avoid underestimation of the impact. Results on the test set showed that recall was mostly higher with the rule-based method than with the hybrid model. However, neither of the two methods provided a consistently higher precision. As both high recall and precision are required to set up an accurate surveillance system, we cannot recommend the use of the studied classification methods to analyze the MSGs of Group 3. A complementary study including an error analysis and a larger training set is required to improve the two methods to classify entities into MSGs from Group 3 and also into MSGs from Groups 1 and 2 that have lower performance.

The current study proposes an approach that goes beyond the traditional evaluation based on a test set. This is interesting, especially when there are many categories to evaluate or when the annotated resources are quite limited and do not capture the large variety of entities to classify. The analysis of the temporal pattern of the number of death certificates for each MSG (including the comparison with an external data source) enabled us to confirm that these indicators (MSGs) accurately capture the targeted health situation we would like to monitor. This approach is also a way to verify whether the misclassifications of one of the two methods are homogeneously distributed over time or are observed in specific periods. Indeed, such a timely mortality surveillance system based on MSGs will be used to provide specific information to health authorities during emergent public health events or during an excess period of deaths (e.g. winter epidemics) to help decision-makers adapt counter measures and prevention messages.

Abstract

Foodborne disease is a growing public health problem worldwide and imposes a considerable economic burden on hospitals and other healthcare costs. Thus, accurately predicting the propagation of foodborne disease is crucial in preventing foodborne disease outbreaks. Few studies have investigated the dependencies between environmental variables and foodborne disease activity. This study develops a regularization-based eXtreme gradient boosting approach for foodborne disease trend forecasting considering environmental effects to capture dependencies hidden in foodborne disease time series. A real case in Shanghai, China was studied to validate our proposed model along with comparisons to traditional and benchmark algorithms for foodborne disease prediction. Results show that the foodborne disease prediction approach we propose achieves slightly superior performance in terms of one-day-ahead prediction of foodborne disease, and presents more robust prediction for 2-7 days ahead prediction.

Keywords:

Algorithms, foodborne diseases, machine learning

Introduction

Foodborne disease encompasses a wide spectrum of illnesses and is a growing public health concern worldwide, which is the result of eating food contaminated with bacteria, viruses, and toxic or hazardous substances [1]. It is the leading cause of symptoms of nausea, vomiting, abdominal pain, diarrhea, fever, paralysis, rash, and other symptoms across all age groups, especially vulnerable groups such as children, older people and those with impaired immunity [2]. Foodborne diseases are estimated to cause 600 million - almost 1 in 10 people in the world - fall ill and 420,000 die every year [3]. Although recent molecular methods have improved the detection, identification and characterization of foodborne disease in the environment and clinical samples, widespread emergence of the viruses still presents a challenge to the prediction technique. For healthcare authorities, developing emergency preparedness plans to manage the surge in the number of patients increase during a pandemic is important if foodborne disease could be predicted in a timely and accurate manner [4]. The reliable forecast of foodborne disease allows better coordination of mitigation and intervention resources in public health system and reduces the strain on healthcare systems [5].

A vast number of quantitative approaches have been devoted to forecasting foodborne disease [6,7,8,9]. Cawley et al. proposed a sparse Bayesian kernel survival analysis model to predict the growth of a foodborne microbial pathogen, which achieved better accuracy than models based on traditional survival analysis techniques [6]. Rasam et al. applied geographical information system (GIS) and satellite remote sensing technologies in interactive mapping of foodborne disease and analyzing dynamic changes for foodborne transmission risk factor [7]. Mohammed et al. proposed an adaptive neuro-fuzzy inference system (ANFIS) to forecast the total cases of norovirus, and the algorithm showed high accuracy and remarkable prediction of norovirus cases in drinking water [8]. Hill constructed an agent-based model to provide a reasonable representation of how the norovirus spread between students among classrooms in a school [9]. Several studies have contributed to the growing body of evidence that points to the role of environmental variables in the transmission of the foodborne disease [10,11], where linkages between certain environmental factors and specific foodborne disease type have been investigated. However, within current research there has been limited assessment of the global impact of the environment on foodborne diseases, and specifically the temporal transmission of foodborne disease. Incorporating considerations for environmental factors in foodborne disease spread may address uncertainties and non-stationarity existing in foodborne disease observations.

To address this gap, we apply a regularization-based eXtreme gradient boosting approach in the creation of a prediction model that can reveal hidden patterns in foodborne disease data related to environmental factors, particularly meteorology and air quality. The contributions of the study can be divided into three folds. *First*, environmental information is fused into the model to assess their impact on foodborne disease spread. Prediction results are compared to explain the significance in including environmental variables. *Second*, L_1-regularization (least absolute shrinkage and selection operator, LASSO) [13] is employed to identify the most explainable variables and reduce the sparse effect for multiple environmental factors in the prediction model. The LASSO has two advantages over other feature selection techniques in terms of stability and computational efficiency, which are preferable in our case to select most revelent and non-redundant environmental variables for foodborne disease prediction. *Finally*, a systematic comparison between several machine learning models and our approach is conducted through a real dataset from the Shanghai Municipal Center for Disease Control and Prevention (SHCDC) to demonstrate the performance of our proposed model.

The rest of this paper is organized as follows. Methods presents the model details of the proposed regularization-based eXtreme gradient boosting approach for foodborne disease trend forecasting. Results presents a real case study, where foodborne disease time series obtained from Shanghai is applied to demonstrate the performance. Finally, the discussion provides the summary and concluding remarks.

Methods

Data Description

A national foodborne disease monitoring and surveillance system was established in 2010, covering all 31 provinces, major municipalities and autonomous regions in Mainland China. Among those covered regions, Shanghai municipality has been confronted with the challenge of reducing the burden of foodbore disease. To determine a diagnosis of foodborne illness, clinicians review history and and underlying condition for patients who report gastrointestinal symptoms, vomiting, fever, or drowsiness. In collaboration with SHCDC, the daily number of total foodborne disease cases, along with five other channels of foodborne disease such as the daily numbers of positive cases and foodborne cases conducting laboratory test, was collected from 1st-Jan-2014 to 25th-Oct-2017. During this period of 1394 days a total of 52163 cases were reported by selected survillance hospitals. The meteorology data including daily reports of sunshine, humidity, ground temperature, pressure, rainfall, air temperature, wind speed, max wind speed and wind direction from 2014 to 2017 were collected from Shanghai Meteorological Bureau. The daily concentrations of ambient air pollutants from 2014 to 2017 were also obtained from Shanghai Environmental Protection Bureau website, where average values of sulfur dioxide (SO_2), nitrogen dioxide (NO_2), ozone (O_3), particular matter less than 2.5 μm in diameter ($PM_{2.5}$), particulate matter less than 10 μm in diameter (PM_{10}), carbon monoxide (CO) and air quality index (AQI) from different monitoring stations were calculated. The missing values of each variable were imputed with the mean computed from the remaining records of that variable. After preprocessing, these three sources of databases were aggregated according to the recorded dates. With consideration of periodicity such as date, week, month, year, day of week, day of month and day of year, the dataset was composed of a total of 29 variables. For our study, the daily number of total foodborne disease cases was the predictive variable of all models, and meteorology data and ambient air pollutants data were the input variable.

KPSS and Kruskal-Wallis test

The stationarity and linearity analysis of the foodborne disease series were performed. *First*, the non-stationary characteristic of the time series was detected by means of KPSS (Kwiatkowski, Phillips, Schmidt, and Shin) test [14]. Then, Kruskal-Wallis test [15] was applied to confirm the existence of non-linearities, which was performed by splitting the time series into five packages of data and detecting the equality of these five distribution functions to learn whether those samples were from the same distribution.

L_1-regularization for Important Environmental Factor Selection

The prediction task can be challenging given limited data and multiple environmental factors due to overfitting and strong correlations among different environmental factors. Variable selection methods are commonly used to in such scenarios. LASSO was applied in our study to identify an appropriate variable set of environmental factors for improving the prediction accuracy of foodborne disease.

Proposed by Tibshirani, LASSO is widely employed to estimate parameters and select variables in regression analysis [12]. The LASSO estimator is a particular case of the penalized least squares regression using L_1-penalty to shrink regression coefficients toward zero. Thus the most explainable variables whose coefficients are not equal to zero are selected. Typically, we assume that $X \in N \times p$ is the input data matrix, for which the first column is time index, and the remaining $(p-1)$ columns are predictors including environmental components and other channels of foodborne diseases for continuous N days. $Y \in N \times 1$ represents daily number of total foodborne disease cases during the same continuous N days. Given the standardized predictors x_{ij} for $i = 1,2,\dots,N$ and $j = 1,2,\dots,p$, and the response values y_i, the LASSO estimator is described as

$$x_{ij}\hat{\beta}_{LASSO} = arg\,min\{\sum_{i=1}^{N}(y_i - \beta_0 - \sum_{j=1}^{p} x_{ij}\beta_j)^2 + \lambda \sum_{j=1}^{p}|\beta_j|\} \quad (1)$$

LASSO is implemented with training data to select the most robust predictors using least angle regression algorithm by employing the LARS package in the R (Version 3.3.2). The following methods are also applied with R based on the corresponding R packages, such as xgboost, stats, adabag, gbm, etc.

eXtreme Gradient Boosting Approach

With the predictor subset selected by LASSO, machine learning models are applied to forecast foodborne disease cases. The gradient boosting model proposed by Friedman has been empirically proven to have high efficiency [13]. As one of popular gradient boosting models, tree boosting is a highly effective and widely used machine learning method. In this paper, a scalable end-to-end tree boosting approach, namely eXtreme gradient boosting (XGBoost) has been applied to perform foodborne disease forecasting. XGBoost is widely used by data scientists to achieve state-of-art results on difficult machine learning challenges [14].

For a given data set with N samples and p features $\mathcal{D} = \{(\mathrm{x}_i, y_i)\}$ $(|\mathcal{D}| = N, x_i \in \mathbb{R}^p, y_i \in \mathbb{R})$, a tree ensemble model uses K additive functions (K trees) to predict the output.

$$\hat{y}_i = \sum_{k=1}^{K} f_k(x_i), \quad f_k \in \mathcal{F}, \quad (2)$$

where $\mathcal{F} = \{f(x) = \omega_{q(x)}\ (q: \mathbb{R}^p \to T, \omega \in \mathbb{R}^T)$ stands for the space of regression trees (also known as CART). Here q represents the structure of each tree that maps an instance to the corresponding leaf index. T is the number of leaves in the tree. Each f_k corresponds to an independent tree structure q and leaf weights ω. For each instance, the decision rules in the trees (given by q) are applied to classify it into the leaves and calculate the final prediction by summing up the weight in the corresponding leaves (given by ω). To learn the set of functions used in the model, we minimize the following objective in equation (3) .

$$L(\emptyset) = \sum_{i=1}^{N} loss(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(f_k), \quad (3)$$

where the first part in equation (3) is the differentiable convex training loss that measures the difference between the prediction $\hat{y}_i$ and the target y_i. The second term Ω is the complexity of the trees. The model complexity $\Omega(f_k)$ is defined by the following equation,

$$\Omega(f_k) = \gamma T + \frac{1}{2}\lambda \sum_{j=1}^{T} \left|\left|\omega_j\right|\right|^2, \quad (4)$$

where T is the number of leaves in the tree, λ represents for the regularization weight, γ is the minimum loss reduction and $||\omega_j||$ stands for the score for corresponding leaves. The tree $f_k(x)$ is defined in the following equation (5),

$$f_k(x) = \omega_q(x), \omega \in \mathbb{R}^T, q: \mathbb{R}^d \to 1,2,\dots,T. \quad (5)$$

The tree ensemble model in equation (3) includes function as parameters and cannot be optimized using traditional optimization methods in Euclidean space. Instead, the model is trained in an additive manner. Formally, let $\hat{y}_i^{(t)}$ represents

the prediction of i-th training sample at the t-th iteration, we will need to add f_t to minimize the following objective.:

$$L^{(t)} = \sum_{i=1}^{N} loss\left(y_i, \hat{y}_i^{(t-1)} + f_t(x_i)\right) + \Omega(f_t) \quad (6)$$

The f_t that most improves the models is greedily added to the model structure. By embedding the regularization term with equation (4) and (6) it can be further approximated based on the Taylor's expansion as follows:

$$\tilde{L}^{(t)} \approx \sum_{i=1}^{N} \left[loss\left(y_i, \hat{y}_i^{(t-1)}\right) + g_i f_t(x_i) + \frac{1}{2} h_i f_t^2(x_i)\right] + \gamma T + \frac{1}{2}\lambda \sum_{j=1}^{T} ||w_j||^2, \quad (7)$$

where $g_i = \partial loss(y_i, \hat{y}_i^{(t-1)}) / \partial \hat{y}^{(t-1)}$, $h_i = \partial^2 loss(y_i, \hat{y}_i^{(t-1)}) / \partial \hat{y}^{(t-1)}$ are the first and second order gradient statistics on the loss function .

Define $I_j = \{i | q(x_i = j)\}$ as the instance set in leaf j. We can rewrite equation (7) as follows.

$$\tilde{L}^{(t)} \approx \sum_{j=1}^{T} [\left(\sum_{i \in I_j} g_i\right) \omega_j + \frac{1}{2}\left(\sum_{i \in I_j} h_i + \lambda\right) \omega_j^2] + \gamma T. \quad (8)$$

Given a fixed decision rule $q(x)$, the optimal weight w_j^* of leaf j can be computedby setting the first-order derivatives of $\tilde{L}^{(t)}$ equal to zero, obtaining the following expression:

$$w_j^* = -\frac{G_j}{H_j + \lambda}, \quad (9)$$

where $G_j = \sum_{i \in I_j} g_i$ and $H_j = \sum_{i \in I_j} h_i$. The corresponding optimal value is calculated as

$$\tilde{L}^{(t)}(q) = -\frac{1}{2} \sum_{j=1}^{T} \frac{G_j^2}{H_j + \lambda} + \gamma T \quad (10)$$

The optimal XGBoost classifier is obtained with the sequential optimization at each scenario.

Benchmark Algorithms for Comparative Analysis

We implemented benchmark algorithms with their standard implementations and compared them to the XGBoost.

- Linear Regression (LR): The dependent variable is considered as categorical in nature while classification is done by calculating the error [16].
- Support Vector Regression with Linear Kernel (SVR): Attempts to minimize the generalization error bound so as to achieve generalized performance. SVR is based on the computation of a linear regression function in a high dimensional feature space where the input data are mapped via a nonlinear kernel [17].
- Bagging (Treebag): A method for generating multiple versions of a predictor to get an aggregated predictor. The aggregation averages over the versions when predicting a numerical outcome [18].
- Gradient Boosting Model (GBM): Combines the results of different prediction models by iteratively learning from the losses which occurr at the previous step through calculation of negative gradient [13].

Evaluation

The two indices, root mean square error (RMSE) and mean absolute percentage error (MAPE), are selected for evaluation of the errors. The RMSE is a frequently used measure of the differences between values predicted by a model and the values observed, which is the square root of the average of squared errors and scale-dependent. The MAPE is also a popular measure of prediction accuracy of a prediction method in statistics. The absolute value in the calculation is summed for every forecasted point in time and divided by the number of fitted points. Compared to the RMSE, the MAPE is scale-independent. The formulas for calculation are defined as follows:

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}, \quad (11)$$

$$MAPE = \frac{1}{N}\sum_{i=1}^{N}\frac{|y_i - \hat{y}_i|}{y_i}, \quad (12)$$

where N is the number of data samples, $y_i (i = 1,2, \dots, N)$ is the observed number of foodborne cases and $\hat{y}_i (i = 1,2, \dots, N)$ is the predicted daily number of total foodborne disease cases.

Results

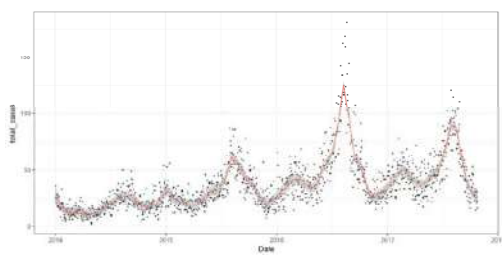
The descriptive statistics summary of the daily number of foodborne disease cases and environment factors are given in Table 1.

Table 1– Decriptive Statistics of the Data (Daily Based)

Variable	Mean	SD	Min	Max
Total foodborne cases	37.30	24.07	2.00	181.00
Sunshine(h)	4.49	4.00	0.00	12.70
Relative humidity(%)	73.17	12.56	35.00	98.00
Ground temperature(℃)	18.66	9.25	-2.70	40.20
Pressure (Pa)	1015.90	8.88	992.80	1039.70
Rainfall (mm)	3.98	12.71	0.00	155.40
Air temperature(℃)	17.71	8.55	-6.10	34.80
Wind speed(m/s)	2.55	0.92	0.50	7.40
Max wind speed(m/s)	4.97	1.22	2.50	10.40
$PM_{2.5}(\mu g/m^3)$	47.31	30.68	5.00	216.00
$PM_{10}(\mu g/m^3)$	66.39	37.06	8.00	256.00
$SO_2(\mu g/m^3)$	15.35	8.55	6.00	75.00
$CO(\mu g/m^3)$	0.80	0.27	0.40	2.20
$NO_2(\mu g/m^3)$	43.38	19.38	5.00	143.00
$O_3(\mu g/m^3)$	106.50	44.54	11.00	286.00
AQI	83.14	37.89	23.00	266.00

In time series plot of the daily number of total foodborne disease cases (Figure 1), a moderate peak is observed in 2015, with two sharp peaks followed in 2016 and 2017 respectively. Before 2015, steady growth in the daily number of total foodborne cases was recognized, which demonstrated the nonlinearity existing in foodborne disease occurrence.

Figure 1– Time Series Plot of Daily Foodborne Disease Cases

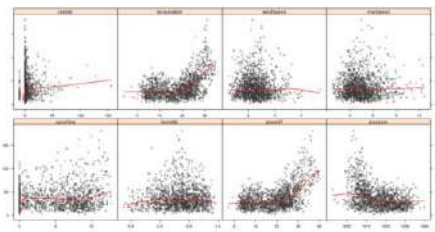


Correlation, Stationarity and Linearity Analysis Between Disease and Environment

The Pearson correlation analysis was implemented to explore the relationship between external factors and foodborne disease cases. Daily numbers of the positive cases, the laboratory testing cases and the norovirus testing cases, as well as the daily percentage of total positive cases were found to be strongly correlated with the daily number of total foodborne disease cases, with positive correlation values of 0.71, 0.65, 0.65 and 0.44 respectively. The qualitative relationships between daily foodborne disease cases and weather conditions were exploited with paired scatter plots as shown in Figure 2. For each subfigure in Figure 2, the x axis denotes the corresponding environmental factor, while the y axis represents the daily number of total foodborne disease

cases. As seen from the figure, weather conditions such as ground temperature, air temperature and pressure were highly

Figure 2- Scatter Plot Matrix Between Foodborne Disease and Environmental Factors



correlated with the daily number of total foodborne disease cases. These findings are further verified through quantitative analysis of Pearson correlation calculation, where the correlations between ground temperature, air temperature, pressure and daily number of total foodborne disease cases reached 0.48, 0.47 and -0.38 respectively. Weak correlations were also observed between air quality conditions and daily number of total foodborne disease cases. Except for O_3, SO_2, NO_2, $PM_{2.5}$, PM_{10}, CO and AQI were negatively correlated with the daily number of total foodborne disease cases, with a maximum absolute value of 0.29 found at NO_2.

The null hypothesis that the foodborne disease series was level (or trend) stationary was rejected by KPSS test results, with p value smaller than 0.01 (p_{trend}<0.01, p_{level}<0.01). The Kruskal-Wallis test also depicited that nonlinearity existed in foodborne disease occurrence with an extreme small p value (p=9.43 x 10^{-144}).

Trend Prediction with Regularization Based XGBoost

The collected foodborne disease cases and environmental datasets were employed to validate the effectiveness of regularization based XGBoost methods. The entire dataset was divided into two partitions, with observations from 1st , Jan, 2014 to 19, Jan, 2017 (1116 samples) for training and observations from 20, Jan, 2017 to 25, Oct, 2017 (279 samples) for testing. The seasonal ARIMA (SARIMA) models were first implemented to encompass the potential critical predictors for instance and the historical daily number of total foodborne disease cases, and then applied as a benchmark model without considering any environmental factors. The parameters in $SARIMA(p,d,q)(P,D,Q)_s$, which represented seasonal factors (s), autoregressive (AR) order (p), degree of differentiating (d), moving average (MA) order (q), seasonal AR order (P), seasonal differential order (D) and seasonal MA order (Q), were selected using both partial autocorrelation and iterative searching approach. Through the comparisons of RMSE and MAPE on the validation dataset (the last 20% of training samples in training dataset), the prediction results showed that $SARIMA(6,0,0)(3,0,0)_7$ achieved best generalization ability with a minimum MAPE of 18.04% on validation dataset compared with other parameter combinations. The selected model ($SARIMA(6,0,0)(3,0,0)_7$) was employed to predict the daily number of total foodborne disease occurrence in 1-7 days' advance with test dataset. The predictive performance steadily decreased when the forecasting horizon increased due to uncertainty and complexity in future foodborne disease occurrence. The best prediction was achieved at 1-day ahead prediction, with a minimum RMSE and MAPE of 11.72 and 21.34% respectively. To illustrate the effects of environmental factors and other monitoring channels of foodborne disease in foodborne disease forecasting, XGBoost method was applied to predict the cases. Before model building, the LASSO was firstly adopted to derivative of 27 external variables for selecting the most explainable features. For 1-day ahead prediction, 12 of 27 variables including daily numbers of other foodborne diseases (positive cases, laboratory testing cases, norovirus positive cases), daily percentage of total positive cases, air temperature, sunshine, humidity, wind speed, maximum wind speed, CO, year, and day of week were found to be critical in improving the performance of XGBoost. With proposed regularization based XGBoost method, we were able to obtain a RMSE of 11.71 and a MAPE of 21.15% on the same test dataset with SARIMA model, slightly improving the predictive performance.

Discussion

We further compared the daily foodborne disease forecasting performances obtained from other machine learning models including linear regression (LR), support vector regression with linear kernel (SVR), bagging (treebag), gradient boosting model (gbm), and XGBoost model. Table 2 shows the forecasting performances obtained on test dataset.

Table 2– Performance of Mutiple Models on Test Dataset

Model	Horizon	RMSE	MAPE (%)	Model	Horizon	RMSE	MAPE (%)
SARIMA	1	11.72	21.34	treebag	1	13.07	23.32
	2	12.49	22.44		2	14.72	25.02
	3	13.37	24.06		3	14.18	24.44
	4	13.98	24.42		4	14.79	25.40
	5	14.89	24.92		5	15.30	27.03

	5	14.87	30.53		5	15.45	27.44
	6	15.35	31.60		6	15.89	28.67
	7	15.78	33.80		7	16.17	27.63
SVR	1	11.65	22.78	XGBoost	1	11.71	21.15
	2	13.21	26.58		2	13.21	24.14
	3	12.88	25.89		3	12.85	25.30
	4	13.98	27.99		4	13.98	27.14
	5	14.16	28.41		5	14.21	26.60
	6	14.31	29.17		6	14.14	26.25
	7	14.51	30.77		7	13.59	25.51

Varying with the forecasting horizon, both SARIMA and XGBoost achieved a stable and robust predictive precision in terms of RMSE and MAPE. However, when the forecasting horizon increased, the predictive errors of XGBoost remained steady, but had a rising trend with SARIMA model. The performances of 1-day ahead prediction on test dataset are further provided in Figure 3 as an example, of which x axis denotes date and y axis is the daily number of foodborne disease cases. From these performances we suggest when the forecasting horizon is within 4 days, SARIMA model can be deployed for real application. When the forecasting horizon is greater than 4, regularization based XGBoost model is recommended.

Conclusion

This paper presents a regularization based model based on eXtreme gradient boosting approach for foodborne disease trend forecasting. Environmental factors including weather conditions and air quality conditions were incorporated into the prediction model and the LASSO technique was applied to shrink the predictors and identify the critical factors that would affect foodborne disease progagation. The real case demonstrated a satisfactory and robust performance in terms of 5-7 day ahead prediction, with a lowest MAPE of 25.52% for 7-day ahead forecasting. However, the model does not significantly improve the predictive performance within 4 days of environmental factors and foodborne disease.

(d) Treebag (e) GBM (f) XGBoost method

Figure 3– Foodborne Disease Prediction with Different Machine Learning Techniques

Future works still need to be done to investigate relationship between specific type of foodborne disease (e.g norovirus foodborne disease) and environmental factors. Moreover, spatial factor should also be modeled for accelerating the investigation of foodborne disease outbreak.

Abstract

Chronic diseases are the leading cause of morbidity, disability and mortality worldwide. It is well established that the majority of chronic diseases can be prevented by targeting modifiable lifestyle-related risk factors. Thus, early risk assessment and mitigation at the individual level can significantly reduce the health and economic burden of chronic diseases. Lifetime health has emerged as a potential paradigm to assist individuals to avoid harmful lifestyle-related habits to reduce the risk of chronic morbidity. In this paper, we leverage eHealth and Quantified Self technologies, novel health data visualizations, and artificial intelligence methods to develop a digital-based lifetime health platform (PRISM) to empower individuals to self-assess, self-monitor, and self-manage their risks for multiple chronic diseases and associated morbidities.

Keywords:
Chronic Disease, Precision Medicine, Risk Assessment

Introduction

Chronic Non-Communicable Diseases (NCD) are long term medical conditions that affect the health and quality of life of millions of citizens worldwide. According to the World Health Organization, chronic diseases were responsible for 71% of all deaths worldwide in 2016 [6] . Four major chronic conditions–cardiovascular disease, diabetes, cancers, and chronic respiratory disease–are noted as the leading causes of chronic disease morbidity and mortality in almost all countries [6]. While the onset of chronic diseases manifests in adulthood [5], recent global trends reveal that younger and younger individuals are at higher risk of developing chronic diseases than all other medical conditions combined (i.e. communicable, nutritional, perinatal, and maternal conditions) [6]. The probability of premature death—i.e. between 30 and 70 years of age—from major chronic diseases ranges from 9-12% and 6-12% for men and women respectively in high income countries [6].

In addition to the enormous impact on one's health and quality of life, chronic diseases create adverse economic effects on health systems, communities, and families. It is estimated that chronic diseases will cost the global economy more than $30 trillion over the next few years [7]. As such, strategies to mitigate and prevent the onset of chronic conditions are of national and international concern, with the NCD Countdown alliance aiming for a one-third reduction in the risk of premature death by 2030 [6].

Chronic disease prevention, however, is multi-faceted due to a complex network of underlying factors that influence the risk of a disease [5]. Generally, chronic diseases stem from a wide range of modifiable lifestyle-related risk factors (diet, physical activity, smoking), and non-modifiable risk factors (age, sex, and family history) [5]. Highly prevalent chronic conditions share a range of underlying modifiable and non-modifiable risk factors; therefore, it is not uncommon to find individuals at-risk of multimorbidity. At the individual level, effective chronic disease prevention entails the early identification of risk, and then proactively mitigating these risks throughout the individual's lifetime by addressing modifiable risk factors and increasing adherence to protective lifestyle-factors (i.e. factors that protect against the risk of diseases) [5]. Another vital aspect of chronic disease prevention is continuous tracking of key health metrics, such as blood pressure, and weight.

Current preventive interventions are mostly ineffective in tackling the chronic disease pandemic; traditional health systems are reactive as opposed to being proactive, and episodic as opposed to being lifetime-based [1]. Thus, attention has turned to alternative strategies to deliver personalized and cost-effective chronic disease preventive interventions. *Lifetime Health* has emerged as a potential paradigm to empower and assist citizens to achieve long-term health goals, avoid harmful lifestyle-related habits, and thus prevent the onset of chronic diseases [8]. A central aspect of the lifetime health paradigm is the early identification and assessment of risks at the individual-level, and then proactively targeting those risks.

The objective of this research is to provide citizens with the necessary tools and resources to empower them to (a) self-assess their cumulative chronic disease risk, and (b) provide them evidence-based and personalized self-management recommendations to modify lifestyle related risk factors. We believe that by presenting personalized risk information in an intuitive and informative manner, it is possible to incentivize individuals to pursue behavior modification strategies to mitigate the onset of chronic diseases.

In this paper, we present the digital health-based *Personalized Risk Investigation, Stratification and Mitigation* (PRISM) platform that leverages Quantified Self wearable technologies, artificial intelligence methods, and health data visualizations to empower citizens to self-assess, self-monitor and self-manage their risks for chronic diseases. PRISM currently provides risk assessments for five chronic conditions (Cardiovascular disease, Diabetes, Hypertension, Stroke, COPD), and eight cancers. PRISM aims to help citizens to maintain a healthy status, and in turn help the healthcare system by reducing the cost of managing chronic diseases.

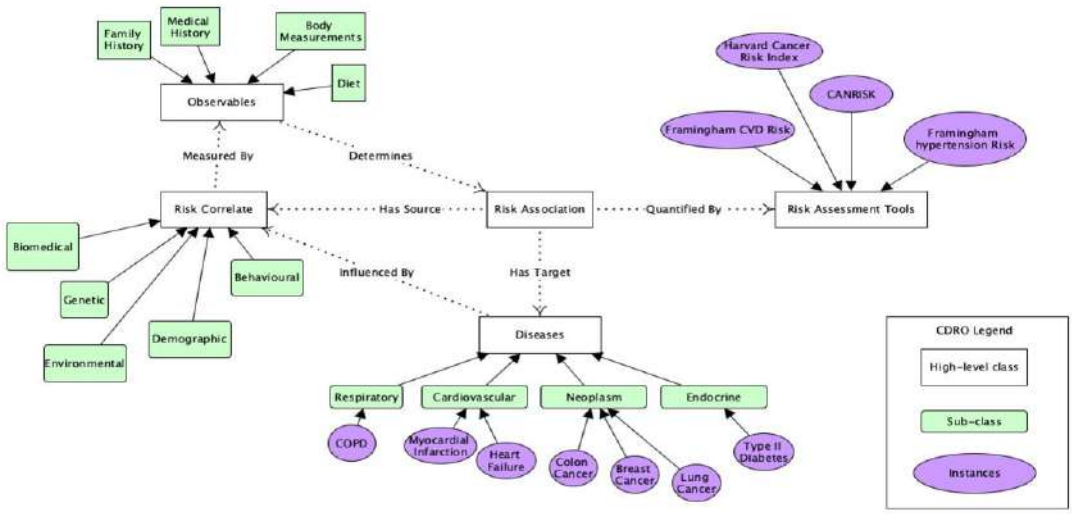

Figure 1 – Chronic Disease Risk Ontology (CDRO)

Related Work

Most existing eHealth-based tools focus on self-assessment, self-monitoring, or self-management of health or chronic disease-related risks separately with varying approaches. Web-based chronic disease risk assessment tools such as Your Disease Risk [3], and My CancerIQ [2] utilize computerized risk assessment algorithms to calculate personalized risks for multiple chronic diseases based on information gathered via short health surveys. These tools employ basic visualization techniques to communicate personalized disease risk scores and provide a set of canned self-management recommendation messages following the completion of segregated disease risk assessments. However, the abovementioned web-based tools do not store any health data and, thus, do not provide any form of self-monitoring features or lifetime health services. Deng et al. [9] on the other hand, presents a web-based health interface to facilitate collection and monitoring of health data, and assessment of a limited number of major chronic diseases. The web-based health platform, called MyHealthAvatar, takes a lifestyle and fitness focused approach and, thus, does not explicitly focus on preventing chronic disease-related risks. The CARRE project [10] is another eHealth-based tool that aims to provide personalized empowerment health services targeting cardiorenal diseases and associated comorbidities. The tool employs a knowledge repository that stores information related risk factors and risk associations specific to cardiorenal diseases. Thus, the tool is disease-specific and does not address a wide range of chronic diseases.

PRISM Design Approach

We have taken a *personalized lifetime health* approach that targets chronic disease prevention at the individual-level. The design and functional scope of PRISM is guided by the lifetime health approach [8]. In functional terms, PRISM is designed to empower citizens to (i) assess their risks for multiple chronic diseases based on personal health data integrated with socio-economic and environmental data to further personalize risk assessments, (ii) receive a cumulative health and multimorbid risk scores based on the aggregation of multiple chronic disease risk factors, (iii) monitor and visualize their personalized health risks and disease-specific risks, (iv) learn about the influence of individual risk factors towards the potential incidence of different chronic diseases, (v) modulate the influence of existing risk factors, to observe the net changes in the risk assessment scores, and (vi) plan personalized risk mitigation and behavior change strategies.

Methods

To achieve the functional scope of PRISM, we take a health knowledge management approach [4] to (i) logically model and map the mutual interactions between risk factors, chronic diseases, and associated multimorbidities; (ii) model and computerize validated chronic disease risk assessment tools; and (iii) utilize interactive health data visualizations to quantify and present personalized risk and health status information.

Chronic Disease Risk Assessment Knowledge Model

The central elements of PRISM are an evidence-based knowledge resource that represents the complex relationships between health determinants—i.e., genetics (family history and health history) and phenotypic information (physiological, behavior and psychosocial parameters), biomedical (conditions and pathology), risk factors and chronic diseases. These relationships are the basis for assessing an individual's comorbid chronic disease risk and for determining the impact of risk modification on the onset of chronic conditions.

We have developed an agile ontology-based knowledge model—referred Chronic Disease Risk Ontology (CDRO)—that represents knowledge about chronic diseases and their risks factors from several validated knowledge sources. The CDRO logically outlines the synergistic associations between risk factors (modifiable and non-modifiable), chronic diseases and multimorbidity (a subsection of CDRO is shown in Fig 1.) The initial design of CDRO is inspired by the work of Third et al. [14]. In our work, we have extended this ontology by introducing formal representation of multimorbid diseases, while focusing on a holistic and health-centered approach to the assessment and prevention of chronic disease risk. CDRO represents the following concepts as high-level classes:

- *Risk Correlates*: The underlying factors that positively or negatively influences the risk of major

chronic and multimorbid diseases. Risk correlates are organized by type (i.e. modifiable vs. non-modifiable) and category (i.e. demographic, environmental, genetic, biomedical, and behavioral). Typically, these risk correlates are surrogates for deeper biomedical mechanisms and pathologies that have a direct association with chronic diseases.

- *Diseases*: All chronic and multimorbid diseases.
- *Observables*: An individual's measurable health-related attributes, which are used to quantify exposure to risk correlates/determinants.
- *Risk Association*: Mutual association between the source of risk (i.e. risk correlate) and target of risk (i.e. chronic disease). A risk association between source risk and target risk is determined by specified observables that provide measures of the risk exposure. A risk association is quantified by the traditional probability measures used in medical literature, including Relative Risk (RR) and Odds Ratio (OR). Risk association is a triple, which consists of a risk source (i.e. risk correlate), risk target (i.e. chronic disease), and observable which is used to determine the threshold by which the risk association holds true.
- *Risk Assessment Tools*: Validated chronic disease risk assessment tools that are represented a set of executable rules encoded in a formal logic expression language. These rules quantify the risk association between a risk or protective factor and chronic disease, and between a chronic disease and associated comorbidities.

In addition to the abovementioned concepts, CDRO contains sub-concepts, ontological relations (object property assertions, data property assertions), and axioms. CDRO is flexible and can be extended to accommodate additional diseases and risk or protective factors.

CDRO serves as the evidence-based knowledge resource for PRISM to (a) assess multiple chronic disease risks; (b) integrate these risks with the individual's health determinants to calculate a co-morbid risk; (c) visualize the influence of multiple risk factors on chronic disease risks; and (d) design behavior modification plans based on personal health profile.

Computerization of Validated Risk Assessment Tools

We computerized validated risk assessment and prevention protocols for: (a) Five chronic conditions: Cardiovascular disease, Diabetes, Hypertension, Stroke, and COPD; and (b) eight cancers: Breast cancer, Colon cancer, Kidney cancer, Ovarian cancer, Melanoma, Pancreatic cancer, Uterine cancer, Lung cancer. These chronic diseases were selected as they are the most prevalent and highly interrelated. This provides us the opportunity to investigate the influence of one disease towards the onset or complication of another disease—i.e. the underlying influence of risk factors leading to co-morbidities in individuals. We used validated risk assessment algorithms such as the Framingham Cardiovascular Risk Score [13] and CANRISK for diabetes [12].

Computerization of the assessment tools involved identifying its constituent risk assessment variables—i.e. individual demographic information, lifestyle information, biomedical (and their ranges to determine acuity levels) and environmental variables. An RDF based risk assessment data model was developed to capture the patient-specific risk assessment variables and calculated risk assessment scores. It may be noted that across multiple risk assessment tools, there is a significant overlap between the risk assessment variables. We capture a variable once and use it across multiple risk assessment tools. We represented the paper-based risk assessment tools as an executable decision tree that takes as input values of its risk assessment variables and outputs a risk assessment score. Each chronic disease risk assessment tool was implemented as a unique decision tree, where these multiple decision trees were integrated along common risk assessment variables to form a risk assessment graph. We have employed a reactive approach for the execution of the computerized risk assessment tools, whereby as new health data is received it is exposed to all the computerized risk assessment tools to generate a risk assessment. A risk assessment decision tree is activated if the received data corresponds to its risk assessment data list. In this way, we ensure that risk assessment is not done selectively rather a holistic risk assessment is performed in response to the availability of current and relevant risk assessment data.

PRISM's web-interface allows users to input their own health data. Additionally, we have developed data input interfaces to capture health data from personal health devices, such as wearable devices and smart watches.

Development of PRISM Lifetime Health Platform

The PRISM platform is developed as web- and mobile- app. The PRISM architecture consists of 5 functional layers:

1. *Data layer*: responsible for capturing and integrating citizens' health data from heterogenous data sources to generate holistic and multi-dimensional personalized health profiles.
2. *Knowledge layer:* encapsulates the CDRO, together with a range of validated and computerized chronic diseases risk assessment tools. This layer uses captured personal health data to generate personalized multimorbid risk trajectories.
3. *Analytics layer:* performs a range of data analytics to analyze end-users' health profiles and generate stratified individual and multimorbid disease risk scores.
4. *Information layer:* uses advance visual analytics to present an interactive dashboard for users to visualize their personalized health status and risk for multiple chronic diseases. We use the D3.JS visual library to generate intuitive and interactive visualizations that display personalized risk information to lay individuals.
5. *Application layer* serves as the digital health interface for end-users to interact with PRISM. This layer was developed by utilizing a user-centered design approach, and consists of (i) the PRISM dashboard as a front page, which utilizes interactive visualizations to provide a summarized overview of an individual's health status and risk for multiple chronic diseases; (ii) a self-monitoring tool, to facilitate exploration of historical trends and patterns of personalized disease risks and health metrics, and to uncover correlations between various metrics by comparing data curves; (iii) a health profile logbook where end-users can input and update their personal health and lifestyle-related information.

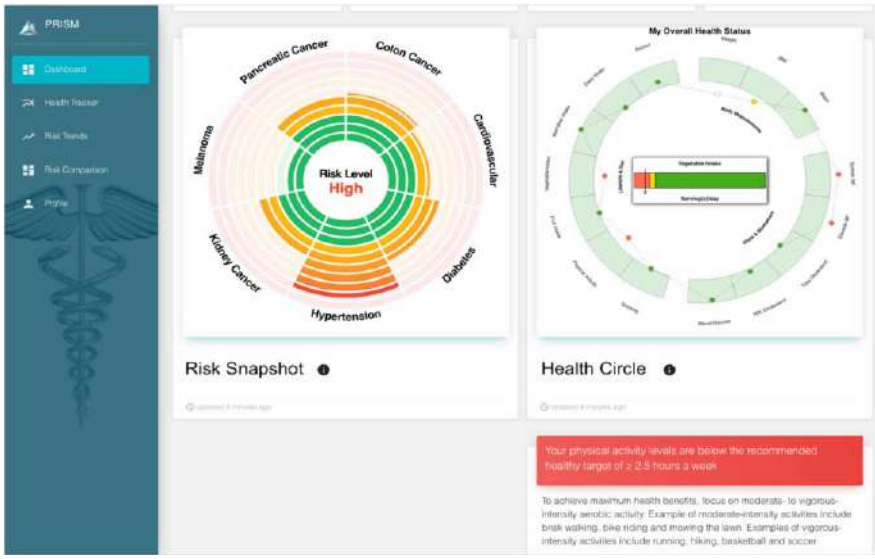

Figure 2 – PRISM Dashboard

Results

The outcome of this research is a web-based citizen empowerment eco-system that aims to provide personalized lifetime health services. Figure 2 shows a screenshot of the PRISM dashboard, with two central visualizations.

Risk Snapshot presents a stratified level of risk (i.e. low vs. moderate vs. high risk) for multiple chronic disease. The visualization is tailored to individuals' personalized health profiles, such that only diseases that exceed a pre-specified risk threshold will be revealed. The disease risk scores are standardized by PRISM's back-end system, such that all scores have the same risk measure unit and range. At the center of the visualization is a stratified level of multimorbid risk, calculated by integrating the singular disease risk levels.

Health Circle presents an overview of an individual's modifiable health metrics. The set of health metrics are organized into different categories, such as body measurements, vitals and biomarkers, and lifestyle factors. The surrounding circular green band represents the recommended healthy range. Therefore, health metrics that are outside the borders of the green band are above or below the healthy range. Furthermore, individual health metrics are color-coded to reflect their impact on an individual's health status. At the center of the circle is a horizontal bullet chart, which conveys the healthy, moderate risk, and high-risk ranges for each metric.

The designed visualizations are dynamic and interactive to encourage active exploration of personalized health data. For example, clicking on a specific disease on the Risk Snapshot will display the disease's associated modifiable risk factors on the Health Circle, while concealing other non-associated factors. Furthermore, clicking on a specific disease on the Risk Snapshot will reveal the disease's risk in numeric format (i.e. 10-year risk probabilities). This helps in providing context to the stratified risk levels.

Another example of PRISM's dashboard interactivity is when the user hovers over a specific risk factor on the Health Circle, the horizontal bullet chart appears at the center of the visualization. Such interactivity enables users to reflect on their health status. Additionally, each health metric is associated with a set of health recommendation messages tailored to individual health profiles. These messages appear below the Health Circle when the users click on a specific metric, and they are color-coded according to the risk level.

Evaluation Framework

A crucial aspect in the development of eHealth-based interventions is to determine the extent to which the target population will use it (i.e. individuals at-risk of chronic diseases). Therefore, the PRISM lifetime health platform will undergo a mixed-methods evaluation study to determine usability of the platform. Participants will be recruited to interact with PRISM using pre-defined goal-based scenarios. While participating in this exercise, participants will be encouraged to think-aloud (i.e. verbally express their thoughts about the platform). Furthermore, interactions with the platform will be recorded to understand what features participants are interested in. Quantitative and qualitative data collected will be used to determine usability of the platform and identify the factors that impact usability from end-user's perspective. Evaluation of usability and functionality of PRISM will provide valuable outcomes to guide the development of subsequent stages of the platform.

Discussion and Concluding Remarks

Personalized and proactive chronic disease preventive strategies represent the most effective approach towards reducing the health and economic burden of chronic diseases at the individual- and population-levels. In this research we have taken a novel approach to demonstrate the feasibility of delivering personalized and preventive lifetime health services to empower citizens to self-asses, self-monitor, and self-manage their health risks via an eHealth-based intervention. PRISM utilizes a health-centered, as opposed to disease-centered, approach to prevent the onset of chronic diseases and associated morbidities. The majority of existing eHealth-based chronic disease interventions are either directed towards chronic disease patients exclusively or individuals at-risk of developing a chronic condition. However, we take a population-wide approach, such that PRISM is intended to target individuals at *any* level of risk. Such interventions are underused in practice

yet represent an effective approach towards chronic disease prevention. Focusing preventive interventions on a subset of the population (i.e. high-risk individuals) is often suggested as a reason for the inefficient current preventive care practices. Therefore, in addition to presenting a novel solution to chronic disease prevention, our research aims to overcome the shortcomings that exist in current preventive health practices due to lack of population-wide intervention strategies.

A contribution of this research is the development of a scalable knowledge model that illustrates the impact of specified risk factors on multiple chronic diseases. Our knowledge model extends the work done by Third et al. by further analyzing the mutual relations between risk/protective factors, chronic diseases, and associated comorbidities. The knowledge model encapsulates a set of validated and evidence-based rules to quantify these complex and interrelated associations in terms of conventional risk measures, such as RRs and ORs.

From a public health perspective, PRISM can be described as an integrated health platform that has the capability of disseminating evidence-based knowledge to the public. Knowledge dissemination in public health is a formal and structured process that aims to spread health-related knowledge to improve population health outcomes. The literature indicates an urgent need for innovative programs that aim to disseminate knowledge regarding chronic disease prevention and management [11]. We believe that PRISM can help in closing this gap by: (i) increasing access of knowledge to various of target groups, including individuals at low, intermediate and high risk of developing chronic diseases; (ii) utilizing the interactive visualizations incorporated to translate preventive care knowledge to lay citizens; and (iii) displaying tailored recommendations by linking preventive care knowledge to citizens' personalized risk profiles.

Future work will include a re-evaluation of features, functionalities and contents of PRISM based on the results of the evaluation study and participants' feedback.

In conclusion, PRISM is an innovative digital health platform that is designed to empower citizens to avoid chronic morbidity and maintain a healthy, disease-free life. Additionally, PRISM offers the potential to help shift outdated reactive health services to personalized and predictive.

Abstract

Current approaches to gathering sexually transmitted infection (STI) case information for surveillance efforts are inefficient and lead to underreporting of disease burden. Electronic health information systems offer an opportunity to improve how STI case information can be gathered and reported to public health authorities. To test the feasibility of a standards-based application designed to automate STI case information collection and reporting, we conducted a pilot study where electronic laboratory messages triggered a FHIR-based application to query a patient's electronic health record for details needed for an electronic case report (eCR). Out of 214 cases observed during a one week period, 181 (84.6%) could be successfully confirmed automatically using the FHIR-based application. Data quality and information representation challenges were identified that will require collaborative efforts to improve the structure of electronic clinical messages as well as the robustness of the FHIR application.

Keywords:

Health Information Exchange, Disease Notification, Sexually Transmitted Diseases

Introduction

Sexually Transmitted Infections (STIs)

Undiagnosed and untreated sexually transmitted infection (STI) is associated with adverse outcomes such as infertility, increased HIV transmission and acquisition, and adverse pregnancy outcomes. Several STI health services are recommended by the U.S. Centers for Disease Control and Prevention (CDC) to protect the reproductive and sexual health of young men and women, including annual chlamydia and gonorrhea screening of sexually active women ≤ 24 years of age, pregnant women, and older at-risk women; chlamydia and gonorrhea screening of anatomic sites of exposure (urethral, rectal, or pharyngeal) of men who have sex with men (MSM); retesting of all infected persons after treatment for chlamydia or gonorrhea; and syphilis testing of pregnant women as well as sexually active MSM [6].

Surveillance of STIs and STI Services

Surveillance, a cornerstone of public health [23; 29], is the routine assessment of disease prevalence and burden as well as the utilization of health care services. Ministries of health seek to perform surveillance on a range of diseases including STIs. For example, most ministries seek to monitor the quality of STI health services received by at-risk groups such as adherence to recommendations for chlamydia and gonorrhea testing and retesting, syphilis testing, test results, patient and partner treatment, and the incidence of adverse STI outcomes.

Surveillance of STIs relies upon physicians and laboratories to manually, spontaneously report STI cases to public health authorities [2]. However, passive approaches are known to be burdensome for reporters, producing incomplete and delayed reports which can hinder the assessment of disease in the community and potentially delay the recognition of patterns and outbreaks [17; 20; 28]. For example, in a recent analysis of STI cases laboratories reported between 63.1% and 71.7%, and physicians reported between 6.3% and 44.4%, of syphilis, gonorrohea, and chlamydia cases [15].

Electronic Reporting of STIs

While most U.S. health agencies continue to publish offiical paper-based forms for STI case reporting [10; 16], surveillance practice is evolving towards electronic methods for data capture. The adoption of electronic health record (EHR) systems and health information exchange (HIE) among clinical organizations and systems [3; 4], driven by policies like the 'meaningful use' program in the United States [7], is creating an information infrastructure that public health organizations can leverage for improving surveillance practice [9].

To date, the focus of modernizing STI reporting has been on the implementation of electronic laboratory reporting (ELR). ELR messages utilize HL7 (Health Level 7) Version 2 standards to encode information about tests ordered and test results pertaining individual patients. The rapid adoption of ELR over the past decade now enables over two-thirds of health departments in the U.S. to improve the surveillance of STIs and other conditions [22]. Yet there are key data missing from ELR messages that public health agencies need to investigate STI cases. For example, at the time the lab result is electronically delivered to the physician, the ELR message does not contain the treatment to be prescribed by the physician. Therefore public health authorities need case information from providers beyond what is available in the initial ELR message.

To access complete information on STI cases, public health authorities seek to implement electronic case reporting (eCR) where case reports from providers are generated or submitted electronically. The goal is to leverage EHR systems and HIE networks to facilitate eCR. Although desired, there exist few standardized methods to support eCR within commercial EHR systems and few existing implementations of eCR.

Research Objective

Given the need for better community-level surveillance of STIs and limited experiences with eCR, we sought to develop and test a standards-based eCR service within the context of

an existing HIE network. The goal was to establish the feasibility of such an approach to support public health work.

Methods

To examine whether eCR processes could be automated, we implemented and tested a standards-based application within an existing HIE network. The application received ELR messages indicating a positive lab result for chlamydia or gonorrhea and returned a completed eCR report with case information extracted from the patient's EHR. The completed eCR reports were stored in a local database to enable analysis for the study, but this repository could be used to transmit completed reports to a public health authority. Our work received approval from the Institutional Review Board (IRB) at Indiana University.

Geography and Population Information

The State of Indiana ranks 15th among U.S. states by population with just under 6.5 million residents, according to the 2010 census. Consistent with national data, minority race and ethnicity are over-represented in STIs. For example, the 2015 rate of gonorrhea among black (African-American) individuals was 836/100,000 people compared to the rate among whites (Caucasian) of 87.7 and for Hispanic individuals of 85.0. The rates for Chlamydia were 2234 for black, 319 for white, and 545 for Hispanic, and the rates for primary and secondary syphilis were 26.8, 6.6, and 16.6, respectively.

The Indiana State Department of Health (ISDH) STD Control Program divides the state's 92 counties into ten districts for morbidity reporting and disease intervention purposes. These district offices are the recipients of contracts with the STD Program for the state's approximately 30 disease intervention specialists. The Marion County Public Health Department (MCPHD) STD Control Program has responsibility for STD reporting in District 5, which includes Marion County (Indianapolis) and the seven surrounding counties: Boone, Hamilton, Hancock, Hendricks, Johnson, Morgan, and Shelby. This district makes up the majority of the Indianapolis MSA. District 5 (population of 1.7 million), and Marion County (population of 903,393) always account for the largest share of Indiana's STI morbidity. In 2015, District 5 accounted for 39% of the state's chlamydia and 47% of the state's gonorrhea morbidity. This reflects, in part, racial health disparities in the district which is substantially more diverse than the state.

According to the CDC's 2015 STD Surveillance Report, Indiana reported a total of 28,886 cases of Chlamydia and ranked 27th among states in rate (437.9/100,000) while Marion County ranked 25th among U.S. counties and independent cities at 949.3 cases/100,000 people. Indiana is ranked 23rd among states for gonorrhea with a case rate of 118.9/100,000 people, while Marion County is ranked 16th among U.S. counties and independent cities in the rate of gonorrhea cases with 344.1 cases/100,000 people.

Indiana Network for Patient Care

The Indiana Network for Patient Care (INPC) is one of the largest community-based HIE networks in the United States [24]. The INPC connects 117 hospitals representing 38 health systems with physician practices, long-term post-acute care facilities, laboratories, and radiology centers. The INPC maintains nearly six billion structured observations for over 12 million individuals. Nearly two million electronic health care transactions are processed every day.

Since 2000, the INPC has leveraged electronic laboratory messages sent from hospitals to automate the reporting of notifiable disease information to public health authorities. Using a technology dubbed the 'Notifiable Condition Detector' or 'NCD,' developed by the Regenstrief Institute, the INPC examines each incoming electronic lab message to determine if the results should be reported to public health authorities. In other words, the NCD is how the INPC facilitates ELR. In prior studies, the NCD was shown to have good sensitivity and specificity as well as improve the completeness and timeliness of public health reporting processes [11; 18]. This study leveraged the NCD to identify positive lab tests for chlamydia and gonorrhea sent during the study period. Specifically, the NCD identified tests from a value set defined in CDC case definitions and published by the Public Health Informatics Institute [26].

A FHIR-based Service for eCR

In partnership with the Georgia Tech Research Institute, the Regenstrief Institute implemented a FHIR-based application within the INPC. FHIR (Fast Healthcare Internet Resources) is an emerging HL7 standard that seeks to expose discrete health data through web services [19]. Using a FHIR-compliant server, organizations can expose health data as FHIR resources to external applications that can use requested resources to perform various functions. FHIR services have been integrated into existing EHR platforms like OpenMRS [21], i2b2 [25], and OMOP [1; 8].

For this study, the Regenstrief Institute installed a FHIR-based eCR application developed by Georgia Tech, entitled the Public Health Case Reporting (PHCR) platform. The application receives as input HL7-compliant ELR messages (Verion 2.5.1 Observation Result messages) from the NCD. These messages represent positive lab results for individuals tested for chlamydia and/or gonorrhea. The positive lab test messages trigger the PHCR application to query a previously-implemented FHIR-compliant server that exposes INPC data as resources for additional details about the disease case. The FHIR service running on top of the INPC provides the requested resources which are used by the PHCR application to populate an eCR along with the data from the original ELR message. These data are stored in a local database that permit the eCR to be submitted to a public health authority. Georgia Tech further developed a Web-based dashboard that enables the eCR data to be visualized from the database, which is useful for testing purposes as well as quality control. Source code for the project is available via GitHub in two distinct repositories: https://github.com/gt-health/ecr_manager and https://github.com/gt-health/PACER

The architecture implemented for the pilot study is depicted in **Figure 1**. The application developed by Georgia Tech is labeled as the PHCR Controller. The FHIR-based service that interacts with the INPC is labelled as the FHIR Controller. Messages from the NCD are fed into the PHCR Controller using a HL7 Version 2.5.1 Receiver. The Dashboard is a web application that displays eCR records stored in the local database connected to the PHCR Controller.

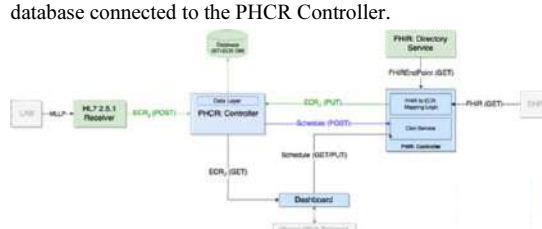

Figure 1– Architecture.

Once the FHIR-based service in the INPC returns a completed eCR, the report data are stored in a local database. Using a web application developed by Georgia Tech, the completed eCR reports can be viewed in a web browser. Figure 2 depicts part of a completed eCR report in a web browser for a test patient. The eCR contains details on the patient, guardian (if under 18 years of age), diagnosis, medications, and lab results. Also available are data on symptoms, health care facility, provider, clinic visits, travel history, and immunization history. These are the data elements important to disease investigators at public health authorities.

Figure 2 – Screenshot of electronic case report viewer application showing test patient information, including demographics, diagnosis, and laboratory results.

Data Collection and Analysis

Once implemented within the INPC, the FHIR-based eCR service was tested for one week (November 30, 2017 to December 6, 2018). Data were collected from the incoming ELR messages received by the INPC as well as the eCR reports generated by the FHIR-based service. Patient details, confirmatory lab test details, and corresponding ICD diagnoses from the eCR were collected to ensure that the correct linkages were made between initial ELR and final eCR for a given patient. Error logs were captured to identify issues with the service as well as potential mismatches between patients identified in the ELR messages and known patients in the INPC.

A descriptive analysis was performed to summarize the results of the pilot test. The throughput of the service was calculated along with general descriptions of the population with a positive STI observed during the pilot period. R (version 3.4.3) was used to calculate descriptive statistics and ggplot was used to create histograms and bar charts.

Results

A total of 214 ELR messages were received by the INPC from 16 health systems during the pilot test period. All (100%) ELRs were correctly matched to a patient's longitudinal medical record in the INPC via the FHIR service.

A date of disease onset was confirmed in the patient's medical record using ICD diagnosis codes for only 181 (84.6%) patients, enabling the FHIR service to return a completed eCR to the public health agency. Additional errors included:

- 5 (2.3%) ELR messages were missing test dates; and
- 4 (1.9%) ELR messages had phone numbers in an invalid format.

The distribution of patient age, stratified by gender, is depicted in Figure 3. Overall there were more females (N=157) diagnosed with an STI than males (N=57). However, the median age for both groups was similar (22 years for females and 23 years for males).

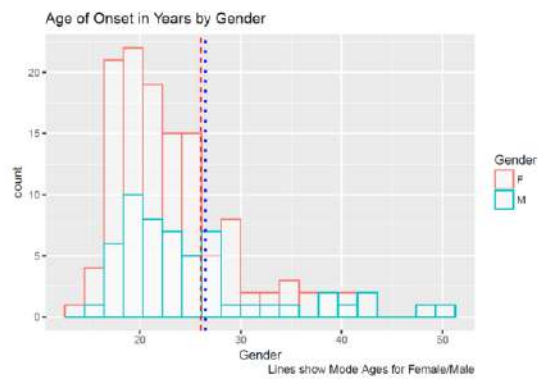

Figure 3 – Distribution of age by gender for those with a positive chlamydia or gonorrhea test.

The most prevalent laboratory test codes are summarized in **Table 1**. There were a total of 680 test results observed as several ELR messages contained multiple test results. Of the top seven lab tests observed, five were identified in the ELR message using the LOINC coding standard and two were identified using local lab codes (MIDAM is a regional lab located in Indianapolis, Indiana).

Table 1 – Prevalent laboratory test codes observed in electronic lab messages exchanged using the FHIR service.

Laboratory Test Code	Laboratory Test Code System	Laboratory Test Description	Count
21613-5	LOINC	*Chlamydia trachomatis* DNA	117
31208-2	LOINC	Specimen source identified	94
970000571	MIDAM	*Chlamydia trachomatis+ Neisseria gonorrhoeae* rRNA	93
4993-2	LOINC	*Chlamydia trachomatis* rRNA	89
5028-6	LOINC	*Neisseria gonorrhoeae* rRNA	89
10001637	MIDAM	*Chlamydia trachomatis* rRNA	52
24111-7	LOINC	*Neisseria gonorrhoeae* DNA	49

Discussion

In a pilot study to establish the feasibility of a standards-based approach to automate the collection of information in support of electronic case reporting for public health surveillance, we implemented a FHIR-based application that could query an HIE network for data necessary for eCR work processes. Real-world ELR messages for positive cases of chlamydia and gonorrhea were transmitted to the application over the course of one week. The application successfully queried the FHIR-based service at the HIE for 100% of lab positive results. For a high proportion (85%) of cases, the application could automate completion of the eCR for transmission to a public health authority. Therefore the pilot project established strong feasibility for automating eCR information flows, which has the potential to save time and cost for the health system as most eCR processes currently rely on clinical and public health personnel to call, fax, or manually enter information to and from organizations. Although feasible, we recognize that additional testing, refinement and study of FHIR-based approaches will be necessary to implement and scale eCR applications to automate information capture.

Although the pilot was considered successful, some errors challenged the application. ELR messages, the input that triggered the eCR process, were missing test dates in a small proportion (2.3%) of cases. In other cases (1.9%), the patient's phone number was improperly formatted. Data quality issues such as completeness and improper data representation are common in health care as documented in prior studies [12; 31]. Similarly, one quarter (25%) of the most common lab results were encoded using a local laboratory information system terminology as opposed to the internationally recognized standard LOINC. This challenge has also been observed in prior examinations of routine ELR messages sent to public health organizations [13]. These data quality and standardization challenges require work to make solutions like the PHCR application more reliable across the wide variation of ELR data feeds found in the health care system.

While a high proportion (85%) of cases were confirmed using EHR data returned from the INPC, several patient records were missing an ICD-based diagnosis that the eCR application requires to confirm a positive case of disease. Since each patient had a positive, confirmatory laboratory result for one of the two target diseases, these patients should have the respective disease documented in their EHR. The most likely reason why this diagnosis was missing from the EHR is clinic workflow as the lab result was reported to clinicians after the patient was no longer in the clinic or the emergency department and therefore clinic staff did not go into the EHR to update the record.

Tackling the data quality and standardization challenges will enable applications like the PHCR to better automate public health reporting processes. Health care organizations, information system vendors, and HIE networks can and should work to ensure that data are complete and properly represented in electronic messages using available health information standards. Solutions like terminology mapping exist to support efforts at improving data standardization [5]. Efforts also exist to support data quality improvements [14; 30].

Furthermore, applications like the PHCR need to be flexible and adapt to information feeds that may not perfectly provide all of the data necessary to trigger a case report for public health. This may require public health organizations to relax the rules for confirming a case, or application developers may need to configure software to enable eCR information moving forward even if the report is not complete. Thus we all have work to do in order to make applications like PHCR robust.

Currently the CDC, with support from the Robert Wood Johnson Foundation, is conducting a pilot program to test a 'digital bridge' between clinical and public health organizations for notifiable disease reporting in conjunction with the meaningful use program [27]. This project could provide a method for scaling automated eCR approaches beyond what we tested in this study. However, this project has not yet published early findings or preliminary results. More implementation and evaluation of these efforts will be required to achieve adoption rates as high as ELR. Furthermore, public health organizations should investigate policy drivers that may encourage eCR application adoption by health systems.

Conclusions

A pilot study to examine the implementation of a standards-based approach to support electronic case reporting for public health demonstrated feasibility. While successful, the pilot study identified errors and challenges that need to be addressed before a FHIR-based approach to electronic case reporting can be implemented and scaled across the health system. Technical and workflow improvements will be required to facilitate broad adoption of standards-based eCR in support of public health.

Abstract

Smartphones offer new opportunities to monitor health-related behaviours in the real world. This allows researchers to go beyond traditional data collection methods, such as interviews and questionnaires that suffer from recall bias and low spatio-temporal resolution. In this study, we present an experiment that uses advanced analytical methods to identify daily activities relevant to assess social functioning, from geolocation data. Twenty-one healthy volunteers used a smartphone to continuously record their GPS location for up to 10 days. Participants also completed a diary to record their daily activities that was used as ground truth. Using clustering algorithms and semantic enrichment methods we were able to predict these activities from the GPS data with a precision of 0.75 (standard deviation [SD] 0.13) and a recall of 0.60 (SD 0.11). Although performed on a limited sample, our study shows potential for continuous, and passive geolocation-based monitoring of patient behaviour in mental health.

Keywords:

Schizophrenia [MeshTerm]; Smartphone [MeshTerm]; Geographical Positioning System.

Introduction

The use of personal digital devices with geolocation capabilities continues to grow, with an estimated three billion people using smartphones around the world [1]. This offers new opportunities for gaining insight into human behaviours based on geolocation data, at cheaper costs and higher spatio-temporal resolution than traditional methods (e.g. questionnaires, activity diaries or interviews) [2].

These new opportunities are particularly relevant to domains such as mental illness, where resources are incresingly lacking and changes in behaviours are a key factor to monitor [3,4]. For example, Social functioning is one of the mainconcepts used to monitor the mental health status of people living with psychotic disorders [5]. Social functioning considers aspects such as withdrawal, employment, independence, interpersonal functioning, social activities and recreational activities [5]. These are currently assessed via self-reported questionnaires, or by observations of relatives or clinical staff. Though the validity and reliability of these instruments have been confirmed in previous studies, they have a high risk of recall and selection bias in reported information because they rely on patients' and relatives' memory, as well as a willingness and ability to record past behaviours [6–8]. Furthermore, such questionnaires are recorded infrequently, and may fail to capture the dynamic phenotypic expression of psychotic disorders characterised by interacting and fluctuating symptoms [9].

Mobility metrics derived from geolocation data have been shown to be correlated with disease status in different mental health conditions such as depression and anxiety [10,11], dementia [12,13], and bipolar disorders [14]. However, often such geolocation-derived metrics (e.g. distance travelled, number of places visited, time spent out from home) are rather crude; much more details about patients behaviours could be retrieved from geolocation data with less information loss.

In this paper, we present a method that uses clustering and semantic enrichment via the OpenStreetMaps (OSM) API [15] to identify daily activities relevant to assessing social functioning from passively and routinely collected geolocation data. We tested our method in a population of 21 healthy volunteers, from whom we collected both geolocation and daily activity data for a period of ten days.

Methods

Study population

We conducted the study among students and staff at the faculty of Biology, Medicine and Health at University of Manchester in spring 2017. Participants were recruited via University and student mailing lists. Each participant received a £20 at the end of the study, as a compensation for their time and effort. The study was approved by the University Research Ethics Committee 2 at the University of Manchester (ID number: 2017-0886-2473).

Data collection

Each participant was asked to collect data for ten randomly chosen days during a period of four weeks after entering the study. Participants received a schedule indicating randomly selected recording days and email reminders sent by a member of the research team (SLB). Participants could ask for data recording re-scheduling, if needed.

On data recording days, participants were instructed to collect geolocation data using an application on their smartphone, called GPSLogger for Android [16]. Participants who did not own an Android phone were provided with one (i.e. Samsung

Galaxy S6) for the duration of the study. GPSLogger for Android collects raw geolocation data (i.e., geolocation timestamp, latitude, longitude, altitude, speed and direction) without profiling or analysing it. For this study, the sample frequency was set to one sample every 10 seconds, and to limit noise we set GPSLogger for Android to record only data points with an accuracy of at least 40 meters. As prescribed by Android in their developer manual [17], this means that each data point had a 68% probability to be within a circle having 40 meters radius and centre on the recorded location. To avoid missing data due to an empty battery, we instructed participants to fully charge their phone at least once a day. Participants were asked to start recording data in the morning, perform everyday activities as normal, and stop recording when going to bed. A data recording day was considered as valid if the participants recorded for more than one hour during the day. After each data recording day, the data were transferred automatically to a secure server at a University of Manchester via a secure connection. As a gold standard for evaluating the accuracy of the algorithms to identify daily activities from geolocation data, participants were also asked to complete an activity diary for each data recording day. This was structured as a diagram containing the places they visited and activities they undertook, including time stamps. Days recorded in the diary were considered as valid if they reported a clear sequence of all the activities performed during the day.

Geolocation data processing

In this study, we built on our previous work [18], where we developed a three-step analytical pipeline to predict activities from raw geolocation data (see Figure 1).

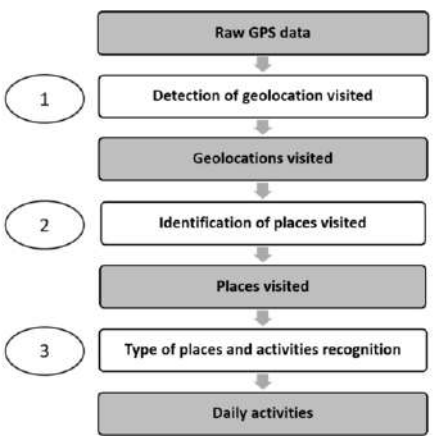

Figure 1– Pipeline to move from raw geolocation data to daily activities [18].

Geolocation visited detection

Time- and density-based methods can be used to identify the geolocations visited from raw geolocation data points. The time-based method was developed by Ashbrook & Starner [19]. It assumes that, when the geolocation signal of a person is lost for a certain time period (defined by a time threshold), it is reasonable to think that the individual has entered a building and performed an activity during this time. However, this method can lead to false recognition since the signal can also be lost in other scenarios (e.g. when a person is passing through a tunnel). Therefore, we modified the algorithm by introducing a distance threshold of 50 meters that has also to be met. Thus, only when the time interval between two consecutive geolocation data points was greater than the time threshold and they were not more than 50 meters apart, it was assumed that the person had stopped to perform an activity in a building.

The density-based method was developed by Fehér et al. [20]. It assumes that when a person has stopped at a geolocation to perform an activity, their geolocation data points will move slightly within a certain range (i.e. a circle with a radius of 50 metres) for a certain period (i.e. 10 minutes). The centroid of this circle is classified as a visited geolocation.

Because the two methods use complementary strategies to identify geolocations visited, we combined the results from the two methods. For each group of data points identified as a visited geolocation by either method, we retained the centroid and the number of points composing the group. For both methods, we applied various time thresholds (5, 6, 7, 8, 9 and 10 minutes).

Places visited

A place visited was defined as a unique location with which a group of geolocations visited close to each other could be identified (see Figure 2). We found places visited by using a modified k-means clustering algorithm [19], which was applied to the geolocations visited found in the previous step. The algorithm starts from the first identified geolocation visited and clusters it with all the geolocations visited within 50 meters. The coordinates of the place visited are subsequently calculated as a weighted mean, where the weights are the number of points of which each geolocation visited is composed. This accounts for the fact that geolocation visited from the density-based method are actually representative of several data points, which have been grouped together in the previous step. In the next iteration, the geolocations visited within 50 meters of the centroid are assigned to the cluster, with the centroid of the cluster that is updated with the newly-added geolocations visited. This process continues until the centroid coordinates no longer move. At this stage all the geolocations visited within the cluster are assigned to the same place visited, which is represented by the centroid coordinates. The algorithm restarts with the first geolocation visited that was not assigned to the current cluster. Ultimately, this step produces a list of cluster centroids that represent the places visited by the person.

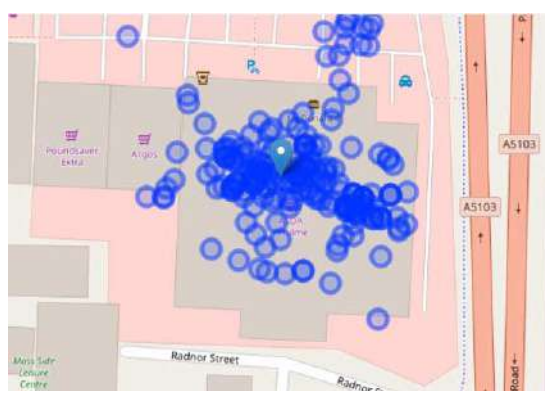

Figure 2–Place visited (map marker) identified from a group of geolocations visited (blue circles).

Semantic enrichment

We used the OpenStreetMap (OSM) platform for semantic enrichment of the places visited. OSM is a collaborative, free-editable and reusable map database, which offers information about places all over the world [21]. OSM was accessed via the

package osmdata [22] in the R statistical computing software, which allows queries to the OSM API to retrieve information about the surrounding Places of Interest (POIs) of specific geolocation coordinates. Such POIs have a geographical and a semantic component. The former represents the geolocation coordinates of the POI shape on the map (e.g. buildings, roads or wider areas such as a university campus). The latter describes the type of POI (e.g. university, restaurant, and bar) and other additional features (e.g. address, opening times, and others), and thus provides semantic enrichment.

To identify the most likely POI for a visited place we implemented the following strategy. First, we checked whether a place visited was within a building. If that was the case, we controlled whether there was a POI within that building with a relevant key-value pair. If that was true, the place visited was associated to that POI (in case of multiple POIs it was associated with the closest). If there was no POI inside the building, we checked whether the building had a relevant key-value pair and associated the place with that. If that was not the case, we looked at whether the building was part of a wider area or group of buildings (e.g. university campus, hospital, residential area). In that case, the place was associated to the smallest area including the building. Finally, if the place was not within a building, the place was associated with the closest POI on the map within a maximum of 50 meters. If none of the above conditions were met, the place visited remained unclassified.

After identifying the most likely POI for a visited place, we assigned an activity to that place using a bespoke ontology that we manually developed for this purpose. In the ontology we used all possible semantic tags that OSM uses, which is formed by a combination of a key and a value (e.g. building = university). OSM already divides such key-value pairs in relevant categories on the basis of the type of place. We used these categories to associate activities relevant to social functioning to the identified POIs (Table 1). For example, the category "sustenance", which contains POIs where people can eat (i.e. pubs, restaurants and bars), was associated to social activities such as "eating out" or "going to the pub"; or the OSM "education" category, which includes places such as schools and college, was associated to "attending classes/lectures". Some OSM categories did not have direct link to activity categories in our study. Such places were then assigned as "other" by two authors in the most relevant activity category from table 1.

Table 1– Activity categories and related activity examples

Area of social functioning	Activity examples
Employment	Working, attending lectures/classes
Shopping	Groceries, clothes, other
Sports	Swimming, gym, team sports, other
Social activities	Visiting friends/relatives, going to a pub/night club/, eating out, other
Recreational activities	Going to the cinema, going to a concert, going to the theatre, other
Other	Religion related, financial related

We also identified each participant's home and work place. The home was identified as the place that most often was either the first or last place visited across all recorded data among the places with a "residential" tag in OSM. As all our participants were working or studying in Manchester, the algorithm would look for eligible places in Manchester first, then in the county (Greater Manchester) and finally in the region (North West England). Once the algorithm found the participant's home, all other POIs with a "residential" tag were classified as "visiting family and friends" under the "Social activity" category. As our participants were studying and working in different locations (e.g. attending lectures or meetings in different university buildings, or training in different hospitals), we decided to use the information about their profession (e.g. university staff and medical students) to identify their work place. Particularly, we labelled as work all places with a tag related to university or hospital.

Figure 3 – Results from the OSM API that highlight all the buildings with a key-value pair that matched our ontology around the POI under study (red star).

Outcome measures

The main outcome measure of this study was the accuracy of our algorithm in predicting the daily activities that were reported in the participant's activity diary. Our secondary outcome was to estimate the accuracy with which our algorithm would estimate the number of unique activities performed during the day (e.g. often called "Number of places visited" or "Number of significant locations" in the literature), as this has been shown to be an important indicator of disease status in mental health conditions [6,11,23,24].

We compared the activities predicted by our algorithm to what was recorded by participants in their activity diaries. We considered activities as predicted correctly if there was a match between the activity category identified by the algorithm, such as the areas of social functioning identified in Table 1, and what was reported in the activity diary. To calculate performance, we also accounted for the number of times an activity was performed. For example, if someone had reported to have gone shopping two times during the day, and our algorithm detected three shopping sessions, two of the detected sessions would be considered as correctly classified (e.g. true positive) while the third would be considered as incorrectly classified (e.g. false positive). We assessed performance with recall, precision and F1 scores. Recall is defined as the number of correctly classified activities out of those recorded in the social functioning diary. Precision is defined as the number of correctly classified activities out of the total number of activities identified by the algorithm. The F1 score is defined as the harmonic mean of precision and recall. To have an idea of the extent to which a completely passive algorithm could associate places visited to activities on OSM, we also calculated the proportion of places visited classified, out of all the ones identified for each participant. Finally, we calculated the root mean squared error (RMSE) for the number of activities

inferred per day by our algorithm, compared to what reported by participants in their activity diaries.

Results

Participants' characteristics

We recruited 21 participants among students and staff at the University of Manchester. Overall, fourteen participants (56%) were female, and the mean age was 25.4 years (Standard Deviation [SD], 6.7 years). The majority were students (seventeen), with only four being staff at the university. Five participants used their own smartphone for the study, all others used a smartphone that we handed out to them.

Collected data

Out of the 210 days (i.e. 10 days times 21 participants) that potentially could have been collected, 157 were analysable (i.e. having both valid geolocation and activity diary data). Of these, we had to exclude four days, as the objective was to analyse participants' daily routines but two participants went back home to their families outside the UK during the Easter Holidays. Overall, nineteen participants provided at least one analysable day and were included in the analysis. For these, the mean number of analysable days provided was 8.3 (SD 1.7). In the activity diary, each participant reported a mean of 7 unique activity categories (SD 1), for a mean total of 46.4 (SD 10.8) activities recorded throughout the study.

Evaluation

Table 2 shows the performance of our method in inferring daily activities based on geolocation data. Performance was similar across the different time thresholds. Recall was 0.58 (SD 0.11) for the 10 minutes threshold and 0.60 (SD 0.11 and 0.12) for the 6 minutes and 8 minutes thresholds. Precision was 0.72 (SD 0.13) for the 5 minutes threshold and 0.76 (SD 0.13) for the 10 minutes threshold. The F1 score was around 0.65 (SD 0.11) for all the time thresholds we tried. The mean proportion of uniquely identified places classified was always above 0.90, with the exception of the five minutes threshold. Finally, the RMSE of unique places identified was 1.1 (SD 0.3) across all thresholds (results not shown in the table).

Table 2 – Overall mean performance across all participants.

Time threshold (min)	Mean Recall (SD)	Mean Precision (SD)	Mean F1 score (SD)	Mean proportion of labelled places (SD)
5	0.59 (0.14)	0.72 (0.13)	0.64 (0.11)	0.89 (0.11)
6	0.60 (0.12)	0.75 (0.13)	0.65 (0.1)	0.92 (0.06)
7	0.59 (0.11)	0.74 (0.13)	0.65 (0.1)	0.92 (0.07)
8	0.60 (0.11)	0.75 (0.13)	0.65 (0.1)	0.93 (0.06)
9	0.58 (0.11)	0.76 (0.14)	0.65 (0.1)	0.92 (0.06)
10	0.58 (0.11)	0.76 (0.13)	0.64 (0.1)	0.91 (0.06)

Discussion

We conducted an experiment that uses clustering and semantic enrichment to derive people's daily activities from geolocation data in a study with 21 healthy volunteers. Performance was similar across the time thresholds we tested, with an F1 score of 0.65. The RMSE of unique places identified was 1.1 (SD 0.3) across all thresholds.

Our study is the first to combine different methods (time-based and density-based) to identify geolocations visited in one analytical pipeline, as well as performing semantic enrichment using geographical information from OSM. To the best of our knowledge, Saeb et al. [10] is the only previous study that used geolocation data to infer actual daily activities relevant to mental health. They used the Foursquare API [25] that can be used to identify places for travel & transport, nightlife, spiritual activities, outdoors & recreation, arts & entertainment, medical offices, food, home, and shopping. In their study, they tested two different strategies. The first one was totally passive with POIs indentified only by using the Foursquare API based on geolocation data. However, this strategy disregards activities such as visiting friends and relatives or work, which are important indicators of social functioning. For the second strategy, they combined the information provided by Foursquare API with other phone and sensor data (e.g. screen utilisation, sound, and accelerometers among the others) to train a predictive model on the daily activities recorded by participants. Although this method achieved a mean AUC of 0.88, it requires a high involvement by participants, who have to label the data to train the model.

Our results show potential for geolocation data to be used for monitoring social functioning in mental health. However, before this type of methods can regularly be used in practice, ethical and privacy concerns of using geolocation data to monitor people whereabouts need to be overcome [26]. This could be done with two main strategies. First, developers should always give people the option to stop recording their location at any point. Furthermore, as much computation as possible should be done on the person's device in order to transmit limited amount of sensitive information. Second, the purpose and advantages of using this type of remote monitoring strategy should be clearly explained to patients and families. In fact, people are willing to share their geolocation data in other fields, if they clearly understand the purpose and perceive a benefit out of it (e.g. Google Maps [27]). However, as behavioural phenotyping based on geolocation data is still in its infancy, providing evidence of the advantages of this approach is not straightforward.

For the future, we envisage different ways in which our method could be improved. First, locations where people actually stopped could be better identified by integrating the speed measurements within the first step of our analytical pipeline. Second, additional information about POIs (e.g., opening and closing times) could be used to derive more sophisticated rules for identifying relevant POIs during the semantic enrichment. Finally, active learning could be explored to train our algorithm by asking participants to label, in real time, locations for which there is a high level of uncertainty.

Our analysis has several limitations. First, our study was performed on a small study sample who have been followed for a limited amount of time. Second, our ground truth was based on participants willingness and ability to recollect their activities and whereabouts. Therefore, we acknowledge that there might have been instances in which participants erroneously reported, or forgot to report, some activities. However, without actively following participants during the study this is the only practical and acceptable strategy to collect the ground truth in these type of studies. Finally, since OSM is an open source project where users can add and edit information, some records in this database might be inaccurate or out-dated.

Conclusions

We predicted daily activities of 21 healthy volunteers from geolocation data that was passively recorded on their smartphones. Using clustering algorithms and semantic enrichment methods we obtained a precision of 0.75 (SD 0.13) and a recall of 0.60 (SD 0.11). The study demonstrates the feasibility of monitoring daily activities relevant to social functioning, and has potentially valuable applications in mental health.

Abstract

With the novel approach of molecularly stratified therapies based on genetic characteristics of individual tumors, the need for databases providing information on molecular alterations and targeted treatment options is increasing rapidly. In Molecular Tumor Boards (MTB) professionals discuss molecular alterations and provide biological context for therapeutic options using external knowledge databases. The identification of informative databases and the information on their specific contents can greatly facilitate and standardize the functioning of a MTB. In this work we present a list of databases which have been deemed useful and relevant for MTB in a clinical setting. We describe workflows to recommend the use of specific databases at different steps in the clinical curation process. Information obtained from these databases is a necessary prerequisite to evaluate molecular alterations and devise rational targeted therapies in MTB.

Introduction

According to the American Cancer Society, cancer was the cause of approximately 600.000 deaths in the US alone in 2017, which makes it the second leading cause of death. Furthermore, 1,5 million new cancer cases were diagnosed in the same year [1].

The treatment of this widespread disease poses many challenges. There is a widespread molecular variation of cancer types among each other. In addition, cancers that are considered the same type show also large intra- and intertumoral heterogeneity. This results in therapies which are used to treat a specific cancer type that can have extremely different outcomes in different patients. Kwak et al. could show that patients with ALK fusion genes showed limited response to first line chemotherapy in comparison with other patients with the same cancer type (lung adenocarcinoma). A treatment with Crizotinib, however, improved the outcome in these patients significantly [2]. The variance of responses to therapy in oncology creates the need for a more personalised way of treating patients based on their specific genetic, biomarker, phenotypic or psychosocial characteristics. This new paradigm is summarized in the concept of precision medicine [3].

Naturally this new approach also provokes new challenges. Oncologists have to get a deep insight into various variables which until recently represented only a side note or were not considered at all. Establishment of Molecular Tumor Boards (MTB) provides the opportunity to discuss molecularly characterized cases among specialists like molecular pathologists, clinical oncologists, biologists and bioinformaticians. Cases discussed in MTB are normally limited to those patients who did not benefit from or respond to standard therapies. At the National Center for Tumor Diseases in Heidelberg (NCT) an MTB was established in 2013 and meetings are currently held twice a week. In preparation for an MTB the patients' tissue samples are sequenced at the German Cancer Research Center (DKFZ). Bioinformaticians prefilter the data for mutations which are relevant for clinical evaluation. The molecular oncologist receives this prefiltered list and clinical data for each patient. With these parameters the oncologists first investigate individual molecular drivers and recommend treatment options which are subsequently discussed in the MTB [4,5].

Preparing a MTB is a time-consuming task. The need for information about genes, variants, pathways or studies is served by many different publicly available databases. As these databases are highly specialized, a deep and detailed understanding is required to connect and combine information from multiple sources. The goal of our study is to identify required steps to reveal known or inferred associations between mutations and possible therapies. For each step, we propose a category of knowledge databases, that can facilitate the process. Thereby we aim to support oncologists in finding therapy options for specific patients based on their individual genetic characteristics.

Methods

In order to identify databases which are required to gather essential information needed to give substantiated therapy suggestions we interviewed experienced oncologists at the NCT in Heidelberg. These oncologists routinely prepare an MTB twice a week and impose strict requirements for the databases they use to gather and prepare evidence for suggested treatments. A strong emphasis is set on publicly available web applications, which are easily accessible, do not require an installation and thus are immediately utilized. The list of databases which was provided by the oncologists was complemented in close consultation by additional databases we found by using scientific and non-scientific search engines.

After a general assessment of the content, the databases were grouped by their specialization into five subgroups (Table 1).

Table 1 – List of Selected Scientific Databases Used to Prepare a MTB. Based on Glocker et al. 2018 [6].

Specialization	Database	Content
Genetics (Variants/ Proteins) (G)	COSMIC	Genes, diagnoses
	CIViC	Genes, variants
	OMIM	Genes, proteins, pathways, diseases, expression, drugs, function, localisation, publications
	OncoKB	Genes, genetic variation, cellular coactors / processes
	ClinGen	Genes, variants, tumor types, drugs with evidence levels
	cBioPortal	Genes, variants, interventions, diseases
	Clinvar	Analytics tool, genetic variations, clinical evidence levels
	UniProt	Proteins, regulations, domains, functions, diagnoses, Protein variants
	Expression Atlas	Organism, localisation of proteins in body and brain, cell lines, diseases
	Varsome	Genes, variants, region browser, transcripts
	CRAVAT	High-throughput assessment and priritization of alterations, predictive scores
Pathways (P)	Reactome	Genes, pathways, cellular processes, reactions, protein complexes
	Kegg	Pathways, hierarchies, genes and proteins, similarity between gene sequences, small molecules, networks, gene variations, diseases, drugs, substances
Medication (M)	PharmGKB	Genes, chemicals, diagnoses, pathways, dosing guidelines, drug labels
	Guide to Pharmacology	Diseases, targets, inhibitors
	DGIdb	Genes, inhibitors, gene-drug interactions
Literature (L)	Pubmed	Literature
Studies (S)	ClinicalTrials	Studies
	EudraCT	European studies

In collaboration with oncologists, we identified examples for commonly used workflows in clinical routine using molecular findings. Drawing from these examples, we engineered exemplary (prototypical) workflows of steps required to gain hints for therapy suggestions for different patients or cases.

Results

Associating genetic and clinical information to give therapy suggestions is a task that often requires external knowledge. This knowledge is dispersed in various publicly available databases and has to be interlinked by a professional. In order to support physicians in the search for relevant information, typical clinical workflows were formalized. In these workflows, clinical problems were constituted and databases for the solution of the problem were proposed.

In clinical routine oncologists are confronted with difficult cases. A common task is to search for new treatments for patients who progressed on guideline-recommended therapies. Steps involved in a search based on clinical parameters are shown in the first workflow (Figure 1). The clinician starts with a search for studies a patient may benefit from in databases with the specialization on studies. Searching available medical literature in Pubmed also can give an indication to case reports, clinical trial reports or preclinical evidence for treating the specific diagnosis (Figure 1).

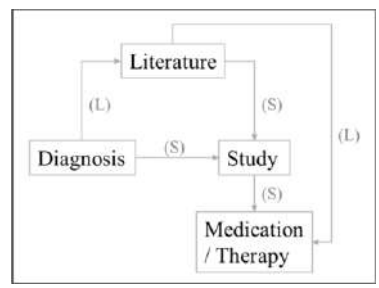

Figure 1 – Typical Clinical Workflow to Find Therapies for Patients Who Do Not Respond to Guideline Conform Therapies. To gain deeper insights with the help of information from external knowledge, databases are recommended for the steps of the workflow. (L): Literature, (S): Studies.

For a workflow of precision medicine, molecular diagnostics is performed upfront and has to be considered. This leads to lists of molecular alterations, which are reviewed and curated by the physician. In this case the diagnosis is often of secondary importance and genetic alterations are the mainpoint of focus. One way to find a treatment for a patient with a specific mutation is to research the respective gene or protein. This information is located in the databases listed with the specialization on genetics in Table 1. With this information, it is possible in some cases to find a drug or a study targeting this protein in medication databases or in studies databases. If no evidence of a direct link between a specific alteration and a drug is available the possibility to interrupt the pathway can be investigated in Kegg or Reactome. With the knowledge about the pathway which is impeded by the mutated protein the possibility to treat a patient with targeted drugs increases as proteins up- or downstream within the pathway may function as targets for available therapies. This newly identified targets can be researched with information from medication databases or studies databases.. For patients with cancers of unkown primary (CUP), the mutation of genes and respective proteins can shed light on the origin of the disease. This may open up

new options for medication or other therapies within established clinical pathways (Figure 2).

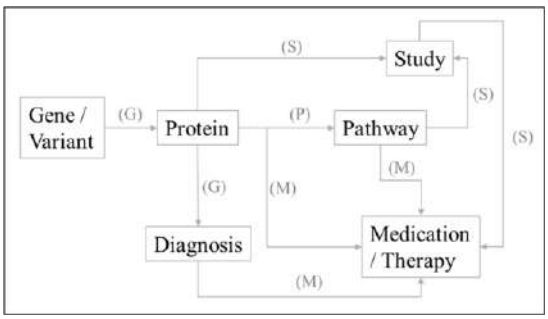

Figure 2 – Typical Clinical Workflow in Precision Medicine. To gather important information databases are recommended for the steps of the workflow. (G): Genetics (Variants/Proteins), (M): Medication, (P): Pathways, (S): Studies.

For example, with the information of a patient with the diagnosis CUP and a specific mutation in the IDH2 gene (IDH2 p.R172W) the physician can query COSMIC for the mutated gene. The input of IDH2 in the search field reveals general information about the gene and its associated protein, as well as a list of known variants. The search for p.R172W results in two hits on the same position. More detailed information can be obtained by following on one of the hits. The tissue distribution of the specific variant of the protein together with the literature used for references suggest a disease in the biliary tract (cholangiocarcinoma), chondrosarcoma or acute lymphatic leukemia. In a second step an inhibitor targeting IDH2 can be searched in the Guide to Pharmacology where Enasidenib is proposed as an FDA approved IDH2 inhibitor for AML (acute myeloid leukemia). Even if there are no direct inhibitors for a specific mutated protein, the oncologist has the chance to find a fitting clinical study for the mutated protein or even a study for cholangiocarcinoma patients.

Discussion

With the identification of workflows, medical and oncological questions can be solved more efficiently with the help of relevant databases. The information gathered from external databases can offer a new view on the situation of the patient. Starting with little information, like the mutated gene, the oncologist can get a notion of the specific diagnosis with which new diagnostics can be performed to verify this tentative diagnosis and new therapy options may arise. Furthermore the oncologist can achieve a better overview on approved inhibitors and available clinical studies. This information can help finding therapy options for patients with therapy-refractory advanced cancers.

As the essential information is spread in various databases a workflow can be useful to grasp the important facts. With the classification of the databases a first step for choosing the right databases for a clinical evaluation is made. Figure 1 and Figure 2 offer algorithms for choosing specific knowledge databases which can be used in various clinical problems arising in precision oncology. Naturally, this list shows only a mere fraction of knowledge bases found in the web but presents a cross section of databases used routinely by trained molecular oncologists in the MTB at NCT Heidelberg.

Furthermore, the recommendation of databases is only the first step in a long way to find therapy options for a patient. Professionals have to query the databases one after the other in order to ensure the completeness of the information gathered. This is still a time consuming task even with a set of recommended databases. In order to facilitate and accelerate the search for relevant information the next step will be an automation of the process. This would involve the interpretation of all databases in a structured manner via API integration. With the automated query of various databases we want to present relevant facts in one view to enable oncologists to grasp all information at one glance.

Conclusions

In order to facilitate the overwhleming task of research therapy options for patients with complex molecular alterations, public databases were categorized. Categorized databases were then recommended for different steps in typical clinical workflows. With this effort we want to support clinicians who face challenges of bringing molecular alterations into a therapeutically relevant context. This work is a starting point for the preparation of an MTB in hospitals which want to provide patients with novel therapeutic options and perspectives by considering specific molecular characteristics of their tumors.

Acknowledgements

This work was conducted within the frame of the DataThereHouse (DTH) project in cooperation with the National Center for Tumor Diseases (NCT) Heidelberg, supported by the Federal Ministry of Education and Research (BMBF). The project is concerned with the integration of data from different sources including the Heidelberg University Hospital as well as the German Cancer Research Center (DKFZ) Heidelberg for all oncological entities.

Towards a Framework for National eHealth Evaluation and Monitoring: A Combined Top-Down and Bottom-Up Approach Using Sweden as Example

Chen Hsi Tsai, Sabine Koch

Department of Learning, Informatics, Management and Ethics, Health Informatics Centre, Karolinska Institutet, Stockholm, Sweden

Abstract

Conducting evaluation and monitoring of national eHealth implementation aligned with national eHealth strategies should be prioritized concerning the insufficient scientific evidence and the current challenges in measuring eHealth effects and impacts where most approaches aim to measure at the micro level. This study aimed to build an evaluation and monitoring framework for national eHealth, using the Swedish national eHealth strategy as example, and to develop the process in doing so. Combining both top-down and bottom-up approaches, the WHO-ITU national eHealth strategy toolkit, as a systematic guidance, and two Swedish reports were used for development of the framework. Experts' opinions on the framework were collected and converged by the Delphi technique. The final draft suggested a framework containing 19 eHealth outcomes, 13 eHealth outputs, and 107 eHealth outcome and output indicators for 4 prioritized stakeholders, which can support comprehensive measurements to follow up the current advancement of eHealth in Sweden.

Keywords:

eHealth, Health impact assessment, Health policy

Introduction

Following the global adoption of eHealth, many have come to acknowledge the value of a national or regional eHealth strategy. A national eHealth strategy is a comprehensive nationwide approach of pinpointing and implementing eHealth solutions with appropriateness [1]. To ensure that national entities invest wisely in eHealth with scarce resources and to facilitate a more rapid dissemination of sustainable national eHealth solutions are a few benefits that can be realized once a national eHealth strategy is in place [1].

The Swedish national eHealth strategy was issued and updated in 2006, 2011, and 2016 by the Swedish Ministry of Health and Social Affairs and the Swedish Association of Local Authorities and Regions (SALAR) [2-4]. In the latest document, namely, Vision for eHealth 2025, Sweden wished to "be the best in the world at using the opportunities offered by digitization and eHealth to make it easier for people to achieve good and equal health and welfare…[4]" The three action areas: the work on regulatory frameworks in eHealth, the consistent use of information structure/terms, and the establishment of technical standards, were the main focus for future work towards the national vision of 2025.

Efforts in Swedish national eHealth evaluation and monitoring was first seen in the report, "eHealth and IT in Swedish County Councils" [5] (referred to as the SLIT report), published by the SLIT group of Sweden (IT Strategists/IT Managers/CIO's in the county councils of Sweden) since 2003. The SLIT report aimed to provide a picture of the extent of eHealth solutions and IT introduced and used in health care annually. Even though many existing indicators and measurements were presented, the ambition of the report was not to collect and present data on the impacts or effects of national eHealth but on existence, use, expenditure, and future local strategies.

A nationally coordinated effort was not carried out until 2018 when the Follow-up Model for eHealth and the First Pilot Measurement [6] (referred to as the eHealth 2025 model), the first Swedish follow-up model for eHealth according to the Swedish Vision for eHealth 2025, was published by the steering group of eHealth 2025, a collaboration of the Swedish Government and SALAR. The model, which was based on existing data/indicators from Swedish authorities and national or international organizations, consisted of a list of values that the national eHealth should contribute to realize and three follow-up areas. The purpose of the model was to measure the progress of Swedish national eHealth against the national strategy and to stimulate discussion of how eHealth should be developed and prioritized in order to achieve the Vision for eHealth 2025.

Aiming to deploy guidance for the development of national eHealth vision, action plan, and evaluation and monitoring framework for all governments, the WHO-ITU National eHealth Strategy Toolkit [7] (referred to as the WHO-ITU toolkit) was published by the World Health Organization (WHO) in collaboration with the International Telecommunication Union (ITU) in 2012. Although monitoring and evaluation have often been overlooked and under-valued in the process of adopting national eHealth [8], the third part of the WHO-ITU toolkit was dedicated to a systematic top-down approach for developing an evaluation/monitoring framework as part of the national eHealth strategy, which should be crucial in order to indicate the progress of national eHealth and assess the impacts followed by the efforts [7].

The challenging nature of planning and conducting evaluation and monitoring in eHealth results in the lack of scientific evidence in procedures used to assess eHealth solutions [9]. Moreover, a challenge exists where most monitoring and evaluations only measure the adoption and usage of eHealth at a micro level. In respect of the challenges, it is urgent to generate scientific guidance, which enables a contextualized evaluation and monitoring on effect and impact of eHealth at a national level aligned with national eHealth strategy.

Using the Swedish context as example, the aims of the study were:

1. to build a draft of a framework for national eHealth monitoring in relation to the Swedish national eHealth strategy.
2. to develop and demonstrate the method of drafting the framework.

Methods

Study Design

The study was designed into four phases, generating a preliminary framework, revising based on Delphi, proposing indicators, and establishing the final framework.

Phase 1: Generating a Preliminary Framework

In the first phase of the study, the three documents of the Swedish national eHealth strategy [2-4] and the WHO-ITU toolkit [7] were chosen to be reviewed carefully.

To align the Swedish national eHealth strategy with the systematic guidance of the WHO-ITU toolkit, a top-down approach was taken at this phase. According to the WHO-ITU toolkit, major stages for developing a national evaluation and monitoring framework included defining output and outcomes indicators for identified stakeholders, defining baseline and target measures for indicators, and defining supporting governance and processes as shown in Figure 1. This study was delimited to the first stage, define output and outcomes indicators for identified stakeholders, given the sequential process and the requirement of a more realistic implementation setting for the latter two stages.

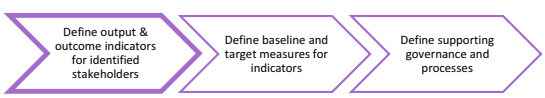

Figure 1– Stages for Developing a National eHealth Evaluation and Monitoring Framework [7]

The backbone for the first stage of developing a framework was extracted from the WHO-ITU toolkit (as shown in Figure 2) for further alignment with the Swedish national eHealth strategy. eHealth outputs were defined as deliverables related to the adoption/take-up of eHealth and shall be delivered through the national action plan; whereas eHealth outcomes were related to the results of the adoption/take-up of eHealth solutions and shall be based on the national eHealth vision [7].

By rigorously analyzing the three documents of the Swedish national eHealth strategy, the national visions and the corresponding prioritized stakeholders were identified. Thereafter, the Swedish national eHealth visions were rephrased in categorizations of the identified stakeholders to fill in the eHealth outcomes of the backbone. The national eHealth action areas mentioned in the Swedish national eHealth strategy were recreated in more general forms and linked to the eHealth outcomes. As a result, the preliminary framework of the study was generated by the two authors of the study.

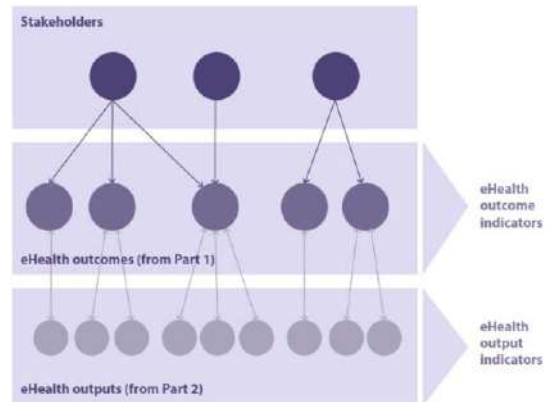

Figure 2– Relationship Between Stakeholders, eHealth Outcomes and Outputs, and Indicators [7]

Phase 2: Revising Based on Delphi

In consideration of the fractional knowledge of eHealth evaluation and monitoring for the Swedish national context, the Delphi technique was chosen in order to seek consensus of opinions on the developed framework with structured group communication [10].

The second phase focused on obtaining feedback from the Delphi panel of experts through two rounds of questionnaires. The foreword, study description, and background knowledge were presented to the respondents in the initial round of the Delphi questionnaire. Provided with a simplified version of the preliminary framework, the respondents were asked if the items in the framework were clear, unambiguous and complete and if anything should be removed, modified, or added. Validation of the questionnaire was done by conducting a pilot round with 2 experts who were not invited to join the Delphi panel. Answers and feedback were analyzed and utilized for revising the preliminary framework.

A recapitulation of feedbacks and the revised framework were provided in the second round of the questionnaire, where the respondents were asked to rate the importance of the listed eHealth outcomes with a five-point Likert scale of which the level of one indicated not important at all; and the level of five indicated absolutely essential. Ratings were analyzed with descriptive statistics to present the aggregated judgments and convergence of opinions from the Delphi panel.

Phase 3: Proposing Indicators

After the revision and the importance rating, the outcome and output indicators were further defined during the third phase. The eHealth 2025 model [6] and the SLIT report from 2017 [5] were chosen as references to be reviewed. A bottom-up approach was taken to fill in the revised framework with existing suitable indicators that were used for measurements in Sweden shown in the reports as well as to propose new indicators created by the authors.

Phase 4: Establishing the Final Framework

Eventually in the last phase, with the proposed eHealth outcome and output indicators, the revised framework was updated as the final draft of the eHealth evaluation and monitoring framework for Sweden (referred to as the final framework).

Table 1– Examples of the Revision of Modified and Additional eHealth Outcomes and Outputs (revision marked as blue)

eHealth outcome	eHealth output
C4. Improve the ability of citizens and patients • to gain trouble-free access to information on patients' rights or duties in relation to health and social care	
C5. Improve the ability of citizens and patients • to gain trouble-free access to information on available health and social care options, their quality, accessibility, staff friendliness and results; information on choice in care, the care guarantee and its significance in a user-friendly way.	Quality assessment guidelines for health and social care service established National registers of available health and social care options and providers established

Study Sample

Despite the controversial issues on what makes an expert in the Delphi panel [11], an expert for this study was defined as an individual involved in the Swedish national eHealth strategy work for the last ten years. Experts from national reference groups who have been involved in national eHealth strategy work from the beginning were considered as ideal study participants. Purposive sampling was used when selecting study participants. Verbal invitations and emails were sent to 17 experts to ask for willingness to join the Delphi panel. A positive response via email or verbally was seen as successful recruitment. 6 experts expressed willingness to participate. However, only 4 experts answered the initial round of the Delphi questionnaire and 5 experts in the second round.

As the study was primarily based on document review except the collection of expert opinions through the Delphi technique, obtaining consent was considered unnecessary. Nevertheless, there was no sensitive personal data acquired from the respondents and their identities were not disclosed.

Data Collection and Analysis

Qualitative data collected through the initial round of the questionnaires was compared with the preliminary framework to observe the respondents' feedback on outcomes/outputs that were added, removed, and modified. The comparison was used as the basis for revision of the preliminary framework.

Statistical analysis was carried out to present the central tendencies, mean and median, and levels of dispersion, standard deviation and quartile deviation, of the rated importance of the eHealth outcomes in the second round. Due to the single round of importance rating, it was difficult to draw conclusion and claim that the items have reached consensus. Therefore, quartile deviation was calculated as an indication of the consensus level for each item rated [12]. An item with a quartile deviation that was less than 0.60 was considered to have achieved a level of high consensus, whereas, a quartile deviation that was greater than 0.60 and less than 1.00 was seen as achieving a level of moderate consensus [12]. In other words, merely the consensus levels were reported without omitting any item from the framework after the second round of the questionnaire.

Results

In the preliminary framework, a total of 4 prioritized stakeholders, namely citizens and patients, health and social care professionals, researchers, and decision-makers, were identified. 15 unique national eHealth visions were extracted and transformed into 16 unique eHealth outcomes. 12 repetitive national eHealth action areas were linked with the 17 eHealth outcomes and rephrased as 7 repetitive eHealth outputs.

4 respondents in the panel answered the initial round of the questionnaire. They possessed different backgrounds and have worked in public health care organizations, research institutes, industries and national entities over the years. The comparison between the preliminary framework and the respondents' feedback suggested revision on the preliminary framework. The revision contained six modified eHealth outcomes, two additional eHealth outcomes, two modified eHealth outputs, and six unique additional eHealth outputs. A modified outcome and two additional outputs with the linking outcome were extracted from the stakeholder, citizens and patients, to show as examples in Table 1.

5 respondents answered the second round of the questionnaire. Four of the eHealth outcomes containing two sub outcomes and one containing three sub outcomes were divided into separate items resulting in 25 eHealth outcomes to be rated. The 25 eHealth outcomes were labeled according to stakeholders, for instances, the first outcome of citizens and patients was C1. 18 eHealth outcomes achieved the level of high consensus (quartile deviation ranging from 0.25 to 0.50), whereas, 7 eHealth outcomes achieved the level of moderate consensus (quartile deviation ranging from 0.75 to 1.00). The descriptive statistics of the 7 eHealth outcome with level of moderate consensus were presented in Table 2 on the next page.

The indicators used in the two reports [5, 6] were selected and proposed as the eHealth outcome and output indicators, which resulted in the establishment of the final framework containing 107 indicators. An eHealth outcome and its related indicators was taken from the final framework as example shown in Table 3. The first indicator in black color was extracted from the eHealth 2025 model [6]; the second in dark blue was from the SLIT report 2017 [5]; and the third in light blue was developed by the authors of the study.

Table 3– An Example of an eHealth Outcome and its Related Indicators Extracted from the Final Framework

eHealth outcome	eHealth outcome indicator
H6-8. Improve the ability of health and social care professionals	Proportion of prescribers who received at least one report from My Prescription Service during the year
• to make use of ICT-based decision support systems and	Number of usage sessions of the Swedish Information Services of Medication (Svenska informationstjänster för Läkemedel)
• to gain access to research and guidelines whenever in care setting	Number of usage sessions of each type of decision support (e.g. digital warnings on specific patient risks, reminders of actions that need to be taken, etc.)
• to have access to support of standardized care processes	

Table 2– Rating of Importance and Consensus on the 7 eHealth Outcomes with Level of Moderate Consensus

eHealth outcome	Mean	Median	Standard deviation	Quartile deviation
C2. Enable citizens and patients to track health and social care personnel who have had access to their records	4.20	4.00	0.84	0.75
C6.Enable citizens and patients to write comments addressed to authorized care professionals	4.20	5.00	1.10	1.00
C8. Enable citizens and patients to obtain advice about care and health based on the information they documented	4.40	5.00	0.89	0.75
C9. Improve the ability of citizens and patients to find and contact health and social care units of different types (for problem discussion)	4.00	4.00	1.00	1.00
H3. Ensure information registered in one place in the health and social care system is accessible at other points such as state entities, county councils, municipalities and private/third sector professionals	4.00	4.00	1.22	1.00
H7. Improve the ability of health and social care professionals to gain access to research and guidelines whenever in a care setting	4.40	5.00	0.89	0.75
D3. Improve the ability of decision-makers to gain access to high-quality data with respect for citizen/patient integrity through automatic and secure transfer of registered information in the health and social care systems to health databases and national quality registers for management and follow-up purposes	4.00	4.00	1.00	1.00

Discussion

Analysis of Results

According to the results, respondents' opinions varied on the importance of 7 eHealth outcomes as they achieved a level of moderate consensus. It was difficult to draw any conclusions on whether some eHealth outcomes were more important than others. However, since all eHealth outcomes received high rating of importance with mean values greater or equal to 4.00, the outcomes of the developed framework seemed to be relevant.

With the two reports [5, 6] as references, some of the eHealth outcomes and outputs, not all of them, could be filled in with indicators. Yet we could not conclude in how far the outcomes and outputs were met during or after implementation of the Swedish national eHealth strategy since a benchmark should be conducted beforehand to realize the progress and long-term impacts [13, 14].

Regarding the method used for building the framework, several points can be observed and suggested from the experience of this study. When comparing the eHealth 2025 model and the developed framework of this study, we saw the difference between development approaches. A bottom-up approach was mainly used for the eHealth 2025 model, where the structure of the model was put together by collecting pieces of results from other similar work. This might lead to a model/framework considered fragmented. This study, on the other hand, utilized the WHO-ITU toolkit as an important reference which provided a systematic way of developing the backbone of the framework with a top-down approach. In this case, the framework could be better aligned with the visions and actions of the national eHealth strategy. Thereafter, a bottom-up approach was taken to fill in indicators for measurements against the national eHealth strategy. Also, it would be essential to take in all major documents and updates of the national eHealth strategy while working on the establishment of such a model/framework considering the comprehensiveness and evolvement of the strategy. The Delphi technique was used as part of the process for seeking feedback from experts on the backbone of the developed framework. However, other methods such as nominated group, which would require a physical assembly, could be used depending on the practicalities.

Limitations

Having only 6 experts accept the invitation suggested a much smaller Delphi panel with fewer experts as compared to the recommended number, 15 to 20 experts [15]. Therefore, the result of the panel formation was compromised even though a bigger and more diverse panel with experts possessing different backgrounds was originally planned. The response rates were, in turn, low for both rounds of the Delphi questionnaire, with 4 and 5 respondents respectively. Although some suggested that two iterations of Delphi questionnaires were sufficient [11], the convergence and level of consensus on the eHealth outcomes generated by this study might be critically scrutinized as most studies suggested three to four rounds were required [10, 15]. Nevertheless, concerning the constraints of time, finance, and practical matters, the Delphi technique was considered suitable for this study.

Comparison with Other Similar Work and Suggestion for Future Research

There have been international programs seeking to evaluate and monitor the impacts of national eHealth. Unfortunately, most of them focused on the impacts of a single national eHealth service/solution [16, 17], such as the electronic health record systems. Interestingly, the Australian National E-Health Transition Authority has published a report [18], which aimed to summarize the achievements of national eHealth implementation according to Australian national eHealth policies and programs. The indicators for measurements presented in the Australian report and the eHealth outcome and output indicators of the framework developed by this study shared similar aims as to assess the adoption and impacts of national eHealth and the implementation of a national eHealth strategy. However, most indicators from both sources captured data regarding the adoption rather than the impacts.

A benchmark of comprehensive measurements on the current status of national eHealth in Sweden and the implementation of the national eHealth strategy using the framework developed by the study can be a question for further research so that the progress of achievement on the national eHealth outcomes and outputs according to the national eHealth strategy can be compared with baseline data and presented in the future.

Regarding the obstacles of measuring the impacts of national eHealth, the Nordic eHealth Research Network as part of the Nordic Council of Ministers have revisited the issue in their reports [13, 14, 19]. As suggested, parallel development of policy/strategy and the identification of appropriate corresponding indicators [13] can be a better solution in the future in order to smooth out the difficulties in following up on the progress of an eHealth policy/strategy and its impact. Close collaborations between researchers and policy makers can be beneficial [13] as many of the eHealth outcomes that we aimed to achieve are currently stated on a high level since the policy makers have set the national eHealth visions in such manner with their expertise. Researchers, with their skill set, can collaborate with policy makers and help break up the high-level eHealth visions into detailed measurable items and identify adequate indicators in order to successfully monitor the national eHealth advancement. After all, eHealth impacts and outcomes monitoring requires not only the identification of the types of eHealth solutions and their impact mechanisms aligned with the eHealth strategy but also the identification of related care quality indicators and data [14].

Despite the obstacles and current challenges, we hope the experience of this study can contribute to the knowledge of developing a more comprehensive evaluation and monitoring framework of national eHealth with a systematic approach provided by the WHO-ITU toolkit for countries who wish to do so.

Conclusions

In conclusion, the study initiated a discussion in national eHealth evaluation and monitoring by presenting a method of drafting a framework for national eHealth evaluation and monitoring using a draft of the Swedish framework as an example [20]. Developed with a systematic approach and aligned with the Swedish national eHealth strategy, the draft of the framework, which contains 19 eHealth outcomes, 13 eHealth outputs, and 107 indicators for 4 prioritized stakeholders, this can be used for comprehensive national-scale measurements to follow up on the current advancement of Swedish national eHealth.

Abstract

Pre-Exposure Prophylaxis (PrEP) is an approach for preventing the human immunodeficiency virus (HIV), which entails the administration of antiretroviral medication to high-risk seronegative persons. If taken correctly, PrEP can reduce HIV infection risk by more than 90%. The aim of this study was to identify and examine PrEP-related perceptions and trends discussed on Twitter. Using open-source technologies, text-mining and interactive visualisation techniques, a comprehensive data gathering and analytics Web-based platform was developed to facilitate the study objectives. Our results demonstrate that monitoring of PrEP-related discussions on Twitter can be detected over time and valuable insights can be obtained concerning issues of PrEP awareness, expressed opinions, perceived barriers and key discussion points on its adoption. The proposed platform could support public-health professionals and policy makers in PrEP monitoring, facilitating informed decision making and strategy planning for efficient HIV combination prevention.

Keywords:
HIV; Data Mining; Social Media.

Introduction

Pre-exposure prophylaxis (PrEP) is the administration of antiretroviral therapy to prevent seronegative persons from getting infected with human immunodeficiency virus (HIV). It is most commonly taken orally as a pill either daily or on demand, but other forms are also being tested in clinical trials (e.g. vaginal gels, injectables, and implants). The World Health Organization (WHO) recommendations state that individuals at high-risk should be offered PrEP as an additional prevention choice, as part of a broad HIV prevention strategy [1], outlining five key populations at-risk for contracting HIV [2], i.e. (a) men who have sex with men (MSM), (b) people in prisons and other closed settings, (c) people who inject drugs, (d) sex workers, and (e) transgender persons.

The rapid spread of social media has changed the way that people share their personal health experiences with others as well as the manner of seeking disease information and treatment alternatives [3]. Through social media, huge volumes of data are constantly being generated, providing a significant data source for research. In particular, patient-generated data referring to personal experiences in a way that is unsolicited, spontaneous and up-to-date, in large volumes and with a high degree of variance, is of great interest for research on public health surveillance [3]. Social networks focusing on health-related topics (e.g. medication and treatment options, side-effects, etc.) are particularly useful, since they are providing a wealth of information that includes strong semantic associations. The exploitation of social media facilitates the need to "hear the patient's voice", providing a unique opportunity to obtain input that cannot be acquired through official healthcare channels [4], either because certain groups don't have access to them, or because people are reluctant to provide sensitive information.

However, mining social media presents considerable challenges, which are linked with the inherent characteristics of user-generated data, e.g. vastness and no structure, recency, uniqueness, frequency, and salience [5]. The analysis techniques, relying typically on text mining/Natural Language Processing (NLP), need to be adjusted to the intricacies of the short, informal and colloquial text that people use to express themselves when posting online [6]. Specifically, in health-related use cases, the use of layman, descriptive, subjective and often misspelled terms complicate NLP tasks such as syntactical analysis, tokenizing and direct matching with medical lexicons. Supervised learning algorithms are rendered more difficult by the high amount of noise in the frequently vast collection of data, which demands more computational power and poses significant problems concerning performance.

Twitter is a very popular microblogging and social networking platform, through which users can post "tweets" i.e. short messages consisting of 280 characters maximum. Twitter is a common data source for opinion and knowledge mining on public health topics [5], such as pharmacovigilance [7], [4], prescription drug abuse [8], epidemiology surveillance [9], chronic diseases [10], mental health [11], and quality of care in hospitals [12] to name a few. One of the key barriers in sexual health communication is the patients' reluctance to seek information through their close personal networks [13]. Thus, the perceived anonymity offered by social media allows users to discuss sexual health issues and share their experiences within their online social circles.

This work aimed to examine whether PrEP-related trends and useful information can be identified in Twitter discussions by using text-mining techniques. While Twitter data have been exploited for PrEP-related analysis [13]-[15], the current study elaborated on systematizing and reinforcing such analyses through a comprehensive Web-based platform integrating various text-mining and visual analytics methods. In particular, an Exploratory Data Analysis (EDA) was employed, in order to detect the main discussion topics, the most frequent terms and popular hashtags along with possible side-effects regarding PrEP. In addition, sentiment analysis was used to investigate the public awareness on PrEP, the views and emotions towards it, as well as potential barriers for its adoption. The geographic distribution of the collected tweets along with the sentiment analysis scores were assessed, in order to discover potential insights on regions with low PrEP awareness or where PrEP meets obstacles for its acceptance.

In the following, we present the employed methods for the development of the platform, the obtained results, and discuss our findings along with future work directions.

Methods

Data Acquisition

Data acquisition relied on the SEST platform, an in-house developed software application [7]. SEST focuses on the systematic data aggregation and exploitation from various sources of unstructured text through NLP techniques, aiming to support public health surveillance applications. Built upon the microservices architecture, it enables the repurposing of its modules to accommodate alternative workflows/scenarios, interoperability with other systems through standards-based data exchange and semantic annotation of NLP results for further analysis.

Using SEST, which exploits the Twitter Streaming API [16], tweets were collected from September 2017 to December 2017 through two different collection streams:

1. "PrEP Datastream": tweets gathered with keywords: (truvada) OR (hiv AND PrEP) OR (preexposure AND prophylaxis AND hiv)
2. "Pill Datastream": tweets gathered with keywords: (pill AND prevent AND hiv) OR (pill AND protect AND hiv) OR (pill AND protect AND AIDS)

The "Pill Datastream" was set up to obtain tweets related to PrEP from users that might be unaware of the terminology of PrEP and/or its commercial name, i.e. truvada. The collected data were stored in MongoDB [17], an open-source, flexible and scalable NoSQL database that stores data in JSON format, while the RESTHeart API [18] was used for the create, read, update and delete (CRUD) operations in the SEST platform. For each gathered tweet, its content was stored in JSON format along with its unique id, the creator name, and the creation timestamp. For geolocation, only the location stated in the creator's bio was stored and not the geographical coordinates for each tweet (if available), aiming to preserve the creator's privacy. In addition, only tweets written in English were collected.

Data Analytics

Various types of analytics were applied in the collected tweets based on text-mining and NLP techniques implemented in R (Figure 1). In the preprocessing stage, punctuation and stopwords were removed from the text and special points of interest, namely, hashtags (i.e. #PrEPworks), mentions (i.e. @UNAIDS) and URLs, were detected using regular expressions. Through the Term Frequency - Indirect Document Frequency (TF-IDF) normalisation algorithm, term frequencies of the corpus were calculated and word associations with a correlation threshold of 0.2 were presented. The main discussion topics and the 7 most prevalent terms per topic were detected using the Latent Dirichlet Allocation (LDA).

Sentiment analysis was performed to discover the polarity of expressed opinions in the corpus overall, but also per tweet and per creator. For the polarity calculation, the AFINN lexicon was used that has been especially developed for sentiment mining of microblogging text, featuring also slang words [19]. The emotions expressed within the corpus were mapped to the 8 basic human emotions (namely, anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) via the NRC Word-Emotion Association Lexicon [20]. Both lexicons had to be adjusted to exclude terms that skewed the polarity, such as "negative" and "positive", which in this specific context refer to the HIV status of an individual, and to include colloquial terms and abbreviations often mentioned in the collected tweets (i.e. "ftw", which means "for the win", and "dope" meaning "great").

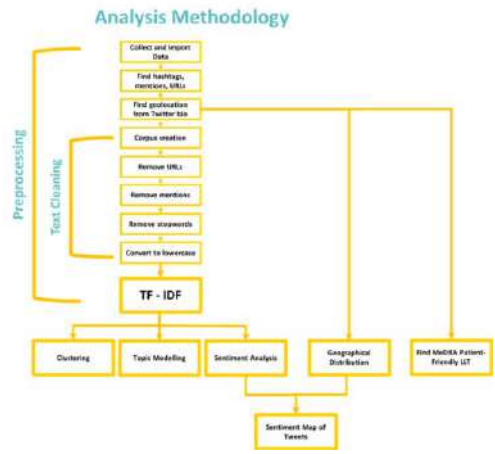

Figure 1 - Analysis Methodology

Since more than 23,000 tweets contained location information in the users' bios, they were extracted and converted to coordinates via the Google Geolocation API [21]. Locations that returned more than one set of coordinates or that did not correspond to real locations were rejected.

Possible mentions of side effects were identified by matching terms in the corpus of the recently released MedDRA® patient-friendly Low-Level Term (LLT) lexicon [22], which contains 1,440 terms that patients use to describe Adverse Drug Reactions (ADRs) and maps them to MedDRA® terms.

EDA was then applied to enhance the understanding of the collected data, uncover underlying trends, outline important variables, and detect outliers/unexpected behaviours that might signify important insights regarding the research questions. Visualisation plays a pivotal role in EDA, as it enables intuitive pattern recognition, when studying public health trends over time.

The Shiny package in R was used for the visualisation of the analysis; an interactive Web application (Figure 2) was deployed online, providing an overview of the acquired data along with suitable visualisation techniques for each aspect of the analysis and the ability to select text-mining parameters such as frequency and correlation thresholds where applicable.

Figure 2 - Homepage of the PrEP trends monitoring platform

Results

Over the course of 4 months, we identified more than 32,000 PrEP-related tweets (31,854 from the "PrEP Datastream" and 804 from the "Pill Datastream"), which constitute only a small fraction of the total Twitter datastream at a given time. 60.5% and 69.3% of the tweets were retweets in the "PrEP Datastream" and the "Pill Datastream", respectively. We expected that the "Pill Datastream" would contain original content from people seeking information about PrEP, but the bulk of

tweets came from institutional or NGO campaigns that propagated messages like "PrEP is a pill that you can take once a day to prevent HIV".

In the following, we present the results of each analysis step.

Frequent and Associated Terms

Using TF-IDF normalisation the most frequent terms address prevention, the key at-risk populations (i.e. "msm", "gay", "trans"), and countries or cities where PrEP becomes available such as Canada, Ireland, and the United Kingdom. Generic PrEP as well as free access to it or insurance coverage was similarly repeatedly discussed. Also notable was the high number of tweets discussing clinical trials and, more specifically, the inclusion of a more diverse sample, such as transgender people and women from different countries. The PrEP discourse within Black African communities seems to diverge, ranging from strong acceptance as a tool of empowerment among black women to a high level of doubt and stigmatisation within the black MSM community.

Word associations display the most similar terms to a selected word of interest above a user-defined threshold. The terms more closely associated with "buy" reveal that people seek to buy truvada "otc" meaning "over the counter" and find the "cheapest" options such as "viread", another antiretroviral drug.

Topic Modelling

Using the LDA algorithm, we identified the 50 and 30 top discussion topics for the "PrEP Datastream" and the "Pill Datastream", respectively, with 7 terms per topic shown. For the visualisation, the LDAvis [23] method was used, which presents the topics globally and reveals how much they differ from each other. All topics discussed were found relevant to PrEP and tend to cluster together in large numbers, which is expected considering the very similar context in all PrEP-related tweets. Smaller clusters and topics that are more separate from the large cluster represent specific events/tweets that were largely propagated in the Twitter stream, such as topic #21 (Figure 3) that contains the terms "thanks", "uk", "cases", "percent", "men", "plunge", "gay", and clearly refers to the impressive decline in HIV infections amongst MSM in London after PrEP was made available in clinics.

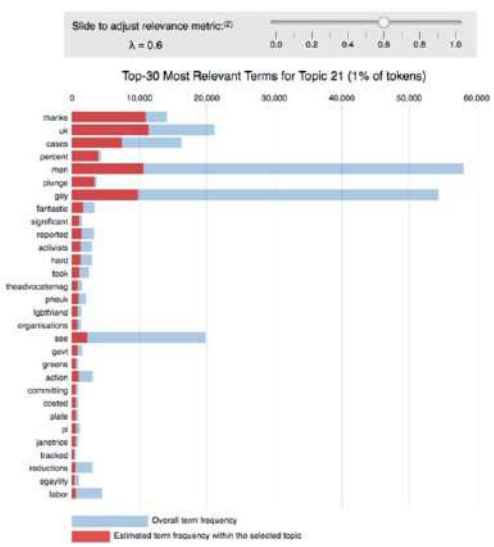

Figure 3 - Most relevant terms for topic #21 using the LDA algorithm

Sentiment Analysis

The overall sentiment was found positive, scoring 0.208 and 0.328 in a scale of -1 (absolutely negative) to +1 (absolutely positive) for the "PrEP" and "Pill" datastreams, respectively. The sentiment score densities calculated for each datastream show a more uniform distribution of sentiment for the "PrEP Datastream", while the "Pill Datastream" features a significant cluster of negative sentiment that, when traced back, reveals tweets expressing doubt and cautiousness regarding the existence of a pill that can prevent HIV infections. The most commonly expressed emotions in the corpus are trust and anticipation, with fear being very prominent in the "Pill Datastream".

Hashtags

Hashtags are a pivotal element of Twitter data analysis; not only do they signal emphasis in the context of a tweet text, they also act as nodes within the network, connecting various users and posts through a shared discussion topic. The use of a specific hashtag for a cause, event or awareness campaign is a common communication strategy adopted by organisations worldwide. The hashtags in the corpus were separately analysed and presented in a streamgraph visualisation. As expected, around the 1st of December (Word AIDS Day) a substantial peak was found for #WorldAIDSDay, #WAD2017, but also for HIV-related terms such as #TasP (Treatment as Prevention), #condoms, #EndTheEpidemic, etc. While this observation is evident, it serves as a validation control for accurately identifying trends over time using data-mining techniques. Observations of smaller peaks offer insights on events that influence the audience's perception and awareness of PrEP, such as the #Ireland hashtag that peaked after November 9th, 2017 when Ireland's first clinic monitoring PrEP was opened (Figure 4).

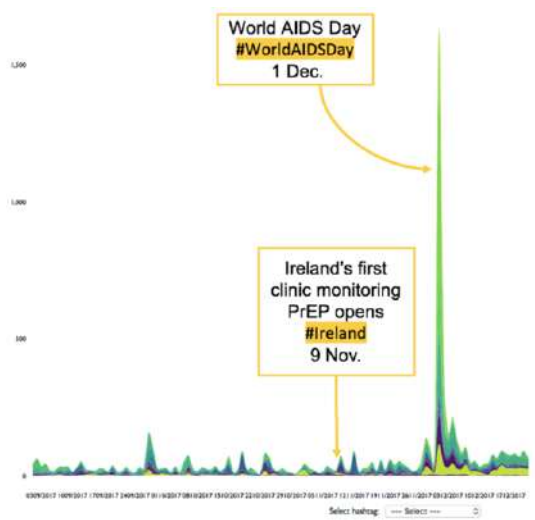

Figure 4 - Hashtags timeline

References to Side-Effects

The identified mentions to side effects that matched terms in the MedDRA® LLT lexicon concerned notably references to headaches, miscellaneous pain, and flu symptoms. A lot of noise was found in this mapping, because some lexicon terms are used in a different context than side-effect reporting, namely, "fatigue" for the phenomenon of "pill fatigue", "infection" as in "HIV infection", "worry" for being anxious about contracting HIV, and not as a result of taking PrEP medication.

It was evident that this type of analysis requires more sophisticated analysis and further research.

Geographic Distribution

The geographic distribution of tweets, in the form of an interactive map, holds special interest, with the largest clusters of PrEP discourse being in the USA, Western Europe, and South Africa. Notably, the distribution shows a similarity with the UNAIDS 2016 map of countries [24] that have either approved PrEP for commercial use, or are in the pilot phase (Figure 5). There is an apparent lack of PrEP-related tweets in Russia, China and Japan that although probably attributed to the language barrier and the existence of alternative social networks to replace the - often blocked entirely - western social media, may also hint at clusters of populations with intense HIV stigmatisation, especially considering the high HIV prevalence and increased rate of infection in those countries.

Figure 5 - Geographic distribution of tweets, and UNAIDS map of PrEP availability

The sentiment score for each tweet was calculated and is displayed on an interactive "sentiment map" (Figure 6). Although significantly different clusters of positive or negative tweets are not evident, there is a slightly more positive concentration of tweets in the UK, Ireland, and the USA.

Figure 6 - Geographic distribution with color-coded sentiment score per tweet

Influencers

Twenty-three (23) Twitter accounts per datastream, the vast majority corresponding to PrEP advocacy groups, LGBT networks and sexual health organisations, were found to post heavily about PrEP, representing more than 9% of the total posts collected. Those accounts constitute "PrEP Influencers", since they contribute to the dissemination of PrEP awareness across their networks and have a large number of followers (>10k mean follower count). The number of tweets per creator and per datastream as well as the sentiment score for the respective tweets is presented with a Treemap visualisation (Figure 7). Some accounts show negative sentiment associated with their posts as they mention issues like stigmatisation or feelings of guilt and isolation that may accompany a PrEP regimen.

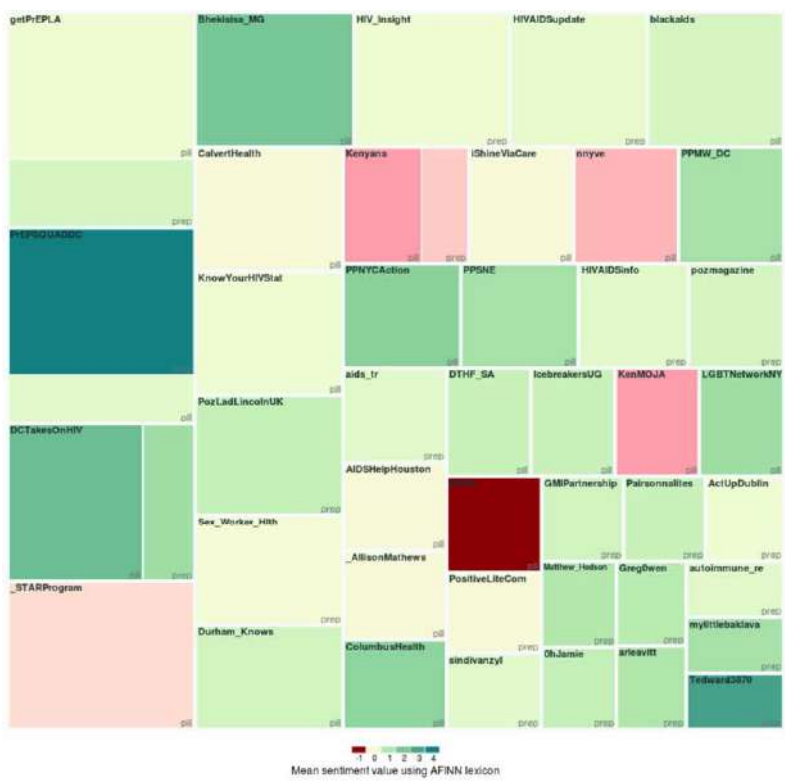

Figure 7 - Treemap of top 23 influencers and their expressed sentiment score for each datastream

Discussion and Conclusion

The collection of tweets during the 4-month period proved to be quite prolific and with very low amounts of noise, indicating that PrEP discussions can be identified successfully on Twitter. PrEP discourse seems to be continuously increasing on Twitter and in a rather fast rate, considering the collected data over time. Users disseminate information about PrEP, engage in sharing ideas, experiences and considerations about it, while activists, HIV support and PrEP advocacy groups appear to drive the demand for free and accessible-to-all PrEP worldwide.

Overall sentiment regarding PrEP is positive and the main concerns refer to stigma, medication cost, insurance coverage as well as vulnerable population groups with limited access to PrEP. The various interactive visualisation techniques that we employed allowed for a more flexible inspection and exploration of the collected data. Detection of critical events that impact the target audience's reaction to PrEP is possible by combining the monitoring of trending hashtags, frequent terms and most discussed topics on the interactive platform provided.

The preliminary, shallow text-mining analysis provided satisfactory results in some context, such as the identification of the most frequent terms and word associations, as well as hashtags monitoring. However, other aspects of the analysis, e.g. side-effect mentions and the sentiment analysis would greatly benefit from more sophisticated NLP tasks, especially considering the unofficial/layman, brief, full of typos and abbreviations language contained in tweets. Besides addressing the above limitations, Machine Learning methods is another necessary future step to enable the accurate detection of personal vs informative tweets, a task which constitutes one of our future work directions. To effectively address this requirement, we are currently exploiting a significantly larger data corpus, which was acquired through our platform.

Overall, our results indicate that the current work provides the foundations for a comprehensive analytics platform that can offer insights to public health professionals and policy makers, so as to assist them in taking informed decisions and developing efficient strategies for improving HIV prevention.

Abstract

Social media are proposed as a complementary data source for detection and characterisation of adverse drug reactions. While signal detection algorithms were implemented for generating signals in pharmacovigilance databases, the implementation of a graphical user interface supporting the selection and display of algorithms' results is not documented in the medical literature. Although collecting information on the chronology and the impact of adverse drug reactions is desirable to enable causality and quality assessment of potential signals detected in patients' posts, no tool has been proposed yet to consider such data. We describe here two approaches, and the corresponding tools we implemented for: (1) quantitative approach based on signal detection algorithms, and (2) qualitative approach based on expert review of patient's posts. Future work will focus on implementing other statistical methods, exploring the complementarity of both approaches on a larger scale, and prioritizing the posts to manually evaluate after applying appropriate signal detection methods.

Keywords:
Drug-Related Side Effects and Adverse Reactions, Social Media, Pharmacovigilance

Introduction

Pharmacovigilance, defined as "the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problem" [1] is mainly based on spontaneous reporting. A valid pharmacovigilance case should include four elements: a patient, at least one suspect medicinal product, one suspect adverse reaction and an identifiable reporter [2]. The presence of additional information, such as treatment dates, time-to-onset (TTO), drug indication, patient characteristics and outcome, ensures high quality information for Adverse Drug Reactions (ADR) [3] and allows causality assessment similarly to case reports usually evaluated in usual pharmacovigilance workflows.

However, one of the major limitations of the current pharmacovigilance systems is underreporting. Indeed, the underreporting rate is estimated to be between 78% and over 99% in France [4]. To overcome underreporting, social media was proposed as a potential source of information to complement case reports. Several previous studies have explored the added value of social media for pharmacovigilance [5-12].

Although social media cannot be considered as a "first line signal detection system" [11], research on social media for pharmacovigilance is required, as data extracted from this resource is different from data stored in pharmacovigilance databases [12]. Our work on the Vigi4Med project [12] investigated whether users' posts in social media were informative enough to be considered as pharmacovigilance reports (qualitative evaluation), and whether traditional signal detection methods were adapted to social media (quantitative evaluation).

Several tools facilitating the evaluation of posts have been described in the literature, such as Insight Explorer, MedWatcher social and PREDOSE [13-15]. PREDOSE focuses on drug abuse rather than ADRs surveillance. MedWatcher social does not allow the collection of supplementary data to perform causality assessment, and to measure if online posts can be considered as potential case reports. To our knowledge, Insight Explorer is the only tool that allows collecting of large amounts of data for causality and quality assessment. Indeed, users can enter data such as poster's information (patient age rank and gender, etc.), and product's description (route, length of use, dosage, etc.), but cannot enter information about case seriousness, adverse event's (AE) expectedness, and chronology. We propose that such tools should support additional information such as TTO, dechallenge (outcome when withdrawing a drug), and rechallenge (outcome when reintroducing a drug).

For the quantitative approach, signal detection methods have already been implemented to extract ADRs from social media [16]. To our knowledge, no graphical user interface has previously been described in the medical literature to facilitate the choice and application of signal detection methods when applied to social media data.

In this paper, we present the methods and tools that we developed and used to analyze the utility of social media for pharmacovigilance from qualitative and quantitative points of view. To demonstrate the performance and the usage of our approaches, we chose as a case study "strontium ranelate", a drug used for the treatment of osteoporosis since 2004 with safety concerns: after its marketing authorization in 2014, this drug was restricted in Europe due to its cardiovascular risk. Since March 2017, the marketing authorization holder has withdrawn the drug from the market.

Methods

Our qualitative approach is based on visualization and evaluation of a selection of users' posts from web forums by a pharmacovigilance expert, and on comparing posts' informativeness to French Pharmacovigilance Database

(FPVD)'s cases. This selection of posts is obtained automatically by extracting from web forums, annotating and filtering posts that contain at least one mention of "strontium ranelate" (or one of its commercial names), and one mention of an AE. The quantitative approach focuses on the analysis of the signals generated by statistical methods on social media.

In this section, we describe the steps we achieved to create our datasets, present our qualitative and quantitative analysis approaches and the tools that were developed for each of these approaches.

Dataset creation

FPVD's Dataset

Created in 1985, the French Pharmacovigilance Database (FPVD) centralizes anonymized reported cases of ADRs in France. By June 17, 2015, when we completed the extraction, the FPVD contained 582,193 reports. AEs recorded in the FPVD are coded using the Medical Dictionary for Regulatory Activities (MedDRA) which is an international medical dictionary approved by the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use. This dictionary is organized in 27 System Organ Classes (SOC) – the highest hierarchical level – and in 4 other levels including the Preferred Terms (PT) level, traditionally used in pharmacovigilance.

FPVD extraction requests were performed by the ANSM, the French Agency for Drug Safety (*Agence Nationale de Sécurité du Médicament et des Produits de Santé*). The request criteria were:

- Investigated period: same study period as for the forums (from 01/01/2004 to 06/17/2015).
- Drugs: strontium ranelate coded as suspect.
- All cases whatever the seriousness and AE description.

Web forums' dataset

We developed the open source tool Vigi4Med Scraper [17] to extract over 60 million posts from 22 French medical forums. Natural Language Processing (NLP) and machine learning techniques were then applied to identify drugs and AEs in the extracted posts [18].

For the qualitative approach, we created a filtered dataset composed of posts containing at least one mention of "strontium ranelate" (or any of its variants) and at least one AE. This filtered dataset was automatically selected from a total of 6,569,555 posts in which 55,350,564 drug/AE pairs were identified. The period included in our study starts on 01/01/2004, which is the commercialization date of "strontium ranelate" in France, and concludes on 06/17/2015, the date of the last extracted post.

For the quantitative approach, we normalized all the mentions of drugs and AEs detected automatically in the posts by the NLP and machine learning methods to improve precision [19].

Ethical aspects

This French study has to comply with the European General Data Protection Regulation (GDPR). First, according to Article 6, processing is lawful when "(a) the data subject has given consent to the processing", but also applies when "(e) processing is necessary for the performance of a task carried out in the public interest". Second, according to Article 9, "Processing of personal data […] concerning health" shall apply when "(e) processing relates to personal data which are manifestly made public by the data subject". Third, our data protection officer was notified of the data collection, and posts were stored on a secure server. Finally, the GDPR does not apply to "personal data rendered anonymous in such a manner that the data subject is not or no longer identifiable" which explains why we processed only pseudonymized information (see also Article 89 for the question of archiving data).

Qualitative analysis evaluation

Forums

For the qualitative approach, the pharmacovigilance experts were asked to evaluate forum posts from the filtered dataset. For each post, its characteristics and informativeness was evaluated regarding the following criteria:

- *The date of the post is included in the period of the study.*
- *The post contains a reporter, a patient, a drug and at least one AE that is possibly related to the drug and that can be coded by MedDRA.*
- *The post is from a user in France when the information was available.*
- *The post is about a personal experience.*
- *The post is not identified by the expert as a duplicate (the post is not exactly similar to or too close to another one according to the expert).*

The reviews of the posts were performed by a trained pharmacist. For doubtful or complicated posts, a trained pharmacovigilance expert made the final evaluation.

Graphical user interface for visualizing and validating user's posts

To enable pharmacovigilance experts to visualize and validate users' posts, a validation tool was developed using PHP and baseX, an open source XML database engine allowing indexation and interrogation of XML files (http://basex.org/). The input of this tool, in our case, is the XML file that contains users' posts that were automatically annotated by the NLP and machine learning tools.

As depicted in Figure 1, the different variables to assess by the pharmacovigilance specialist via the user interface were:

- Patient information: age, sex, medical history, and pregnancy status;
- Treatment information: drug, indication, dose, time period, and outcome;
- AE information: MedDRA term (as used in the FPVD) coded using PTs and SOCs, start date, and duration.

To evaluate a case, the expert had the possibility to evaluate and provide:

- Compatibility of the TTO, dechallenge and rechallenge;
- Drug causality;
- Case seriousness, based on Pharmacovigilance criteria (death, life threatening, etc);
- Expectedness: ADR labeled in the SPCs.

With this tool, validated users' posts can be exported to an XML file that contains new tags for the manual information registered by the pharmacovigilance specialist.

Comparison

We compared the informativeness (i.e. presence/absence of the information) of forums posts to the informativeness of case reports in the FPVD using the following variables:

- Patient's profile: age/class of age and sex;
- Treatment information: indication, dose and duration;
- ADR's outcome.

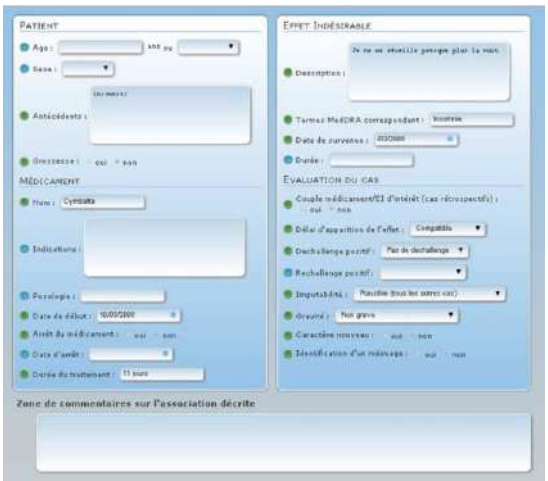

Figure 1– Screenshot of the validation tool

Furthermore, we compared the two data sources using the following variables:

- Patient's profile: age and sex;
- ADR's information: nature (SOC), seriousness and unexpectedness.

Student test was performed to compare the age (comparison of the mean). Chi2 and exact Fisher tests were used to compare qualitative variables. Tests were considered significant when p-value was lower than 5%.

In order to compare the SOC distribution, we conserved the four most represented SOCs in both data sources (with at least a size of five) and grouped the others in one category. Statistical calculations and comparisons were performed using R [21].

Quantitative evaluation

Graphical user interface to parameterize signal detection algorithms

The XML file exported from the validation tool was imported into R for statistical analysis. In order to easily and quickly apply signal detection algorithms to large amount of data extracted from web forums, we developed a web service that proposes traditional pharmacovigilance signal detection methods based on disproportionality. We used the implementation of the PhViD package to apply signal detection algorithms and decision rules as described below. For each of the algorithms, the graphical user interface enabled selection of the period to include, the minimum number of couples needed to generate a signal, and the drug to analyze, as shown in Figure 2. After choosing a method, the user has access to the drug/AE couples considered as a signal, the decision rule parameters value, and the ID of the posts describing the couple.

The decision rules we used to statistically consider a drug-AE couple as a signal [21] were based on the value of the lower bound of the 95% confidence interval ($CI_{95\%}$) of a statistic or of the p-value corrected with the False Discovery Rate (FDR) method:

1. Proportional Reporting Ratio (PRR):
   - $n \geq 3,\ PRR > 2\ and\ CI_{95\%}\left(ln(PRR)\right) > 0$
   - $CI_{95\%}\left(ln(PRR)\right) > 0, with\ FDR < 5\%$
2. Reporting Odds Ratio (ROR):
   - $CI_{95\%}\left(ln(ROR)\right) > 0$
   - $CI_{95\%}\left(ln(ROR)\right) > 0, with\ FDR < 5\%$
3. Reporting Fisher Exact Test (RFET, midRFET):
   - $RFET, with\ FDR < 5\%$
   - $midRFET, with\ FDR < 5\%$
4. Bayesian Confidence Neural Network (BCPNN):
   - $beta\ distribution\ a\ priori\ and$
     - $CI_{95\%}(Information\ Component) > 0$
     - $CI_{95\%}(Information\ Component) > 0\ with\ FDR < 5\%$
5. Gamma Poisson Shrinker (GPS):
   - $CI_{95\%}\left(ln(Empirical\ Bayes\ Geometric\ Mean)\right) > 2$
   - $CI_{95\%}\left(ln(Empirical\ Bayes\ Geometric\ Mean)\right) > 2, with\ FDR < 5\%$

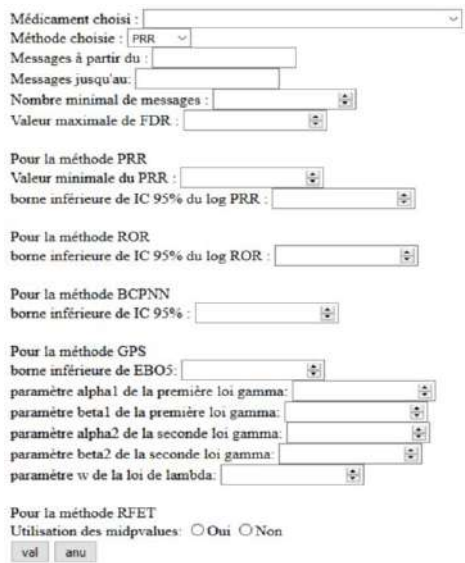

Figure 2– Screenshot of the signal detection tool (the input screen)

Results

Qualitative study

General findings

437 relevant cases were identified in the FPVD, with an average of 1.9 ADRs per case (840 ADRs in total). 387 relevant posts were detected in the web forum dataset. Among these posts, 47 were validated (12%) and 109 ADRs were detected (2.3 per post in average). These posts came from 7 of the 22 selected websites. Most of them came from esante.fr (60%) and 84% of the posts came from only 3 websites (esante.fr, doctissimo.fr and atoute.org).

Comparison of the informativeness

The informativeness of the cases in the FPVD was significantly higher than in the forums concerning patient information (95.7% vs 34% for age, 38.3% for class of age and 99.5% vs 40.4% for sex), the dose (49.9% vs 4.3%) and the outcome (89.5% vs 27.7%). Only the indication of the treatment was significantly more frequently known in forums than in the FPVD (55.3% vs 45.8%). There was no significant difference between the informativeness of the duration of treatment (66% in forums vs 74.1% in the FPVD).

Comparison of patients' profiles

Patients were significantly younger in forums than in the FPVD (mean age of 59.9 vs 72.0, p<0.0001) and they were mostly women in both data sources (94.7% in forums vs 97.2% in the FPVD) as presented in Table 1. No pregnancy was identified in forums, and this information was not available in the FPVD extraction.

Table 1– Comparison of the age and sex of patients in the FPVD and in the forums

Age Mean (sd) *Median (Q1-Q3)*		Sex Women *Men*	
Forums	*FPVD*	*Forums*	*FPVD*
59.9 (7.9) *58.0 (54.8-62.3)*	72.0 (11.1) *73.0 (64.0-80.0)*	18 (94.7%) *1 (53%)*	423 (97.2%) *12 (2.8%)*

Comparison of ADRs' profiles

Only two serious cases were found in forums against 203 in the FPVD (4.3% vs 46.5%, p<0.0001). No death was identified in forums whereas 7 were found in the FPVD.

There was no significant difference between the two sources for the number of cases containing at least one unexpected ADR (25.5% in forums vs 22.1% in the FPVD). Only three PT terms identified in forums were not reported in the FPVD: "Weight increased", "depression" and "hypertension".

There were more SOCs describing the ADRs in the FPVD than in forums (22 vs 11) which can explain the fact that the four first SOCs in the FPVD represented only 60% of the ADRs found (487 among 840) whereas they represented 72% of the ADRs found in the forums (79 among 109). The four SOCs most represented in the FPVD were "Skin and subcutaneous tissue disorders" (31%), "Gastrointestinal disorders" (13%), "Respiratory, thoracic and mediastinal disorders" (10%), and "General disorders and administration site conditions" (8%). In forums, the four most represented SOCs were "Nervous system disorders" (22%), "Gastrointestinal disorders" (21%), "Musculoskeletal and connective tissue disorders" (16%), and the SOCs "General disorders and administration site conditions" and "Skin and subcutaneous tissue disorders" (both representing 14% of the ADRs). Thus, SOC's distribution was significantly different between the FPVD and the forums (p < 0.0001), SOCs' distribution being more diverse in the FPVD.

Quantitative study

After normalization of drugs and AEs, we found 2,582,287 couples corresponding to 194,318 unique couples in 731,043 posts from 07/03/2000 to 07/02/2015.

143 unique drug /AE couples with strontium ranelate (1,021 couples in total) were detected in 297 posts published between 06/28/2005 and 06/09/2014. 21 of the 143 AEs (15%) found with strontium ranelate were either the indication ("Osteoporosis", "Bone loss", "Osteopenia" or "Osteoporosis postmenopausal") or diseases linked to or increasing the risk of osteoporosis. These 21 AEs represented 51% (524) of the 1,021 couples found with strontium ranelate in total.

21 AEs were considered as signals applying all the decision rules. 33 percent of these 21 AEs were from the SOC "Musculoskeletal and connective tissue disorders" and 19% from the "Neoplasms benign, malignant and unspecified (incl cysts and polyps)" SOC.

Among the 21 statistical signals, three (14%) were the direct indication ("Osteoporosis", "Bone loss" and "Osteopenia"), 10 (48%) were diseases linked to or increasing the risk of osteoporosis (among them: "Cystic fibrosis", "Breast cancer", "Psoriasis", "Neoplasm malignant", "Multiple fractures", "Multiple sclerosis", and "Rheumatoid arthritis"), and eight (38%) were AEs among which three were unexpected: "Atrial fibrillation", "Rhabdomyolysis" and "Toxic epidermal necrolysis" representing five, three and three couples respectively. These 11 couples corresponded to eight posts reporting two lists of drugs recommended to avoid, one from a consumer advocacy association (UFC-QUE CHOISIR) in March 2011, and another from a national association for patients suffering from ADR.

Discussion

This retrospective study allowed us to identify 47 pharmacovigilance cases concerning strontium ranelate among 387 posts extracted from French language forums reviewed by pharmacovigilance experts.

Although the average number of ADRs per post/case was the same in the forums and the FPVD (2.3 vs 1.9), forums' posts were significantly less informative than FPVD cases concerning patient's information (age, sex), treatment's dose and duration as well as the AE's evolution. Only the indication of the treatment was significantly more frequently known in forums than in the FPVD. This result was also found in a larger scaled study that we previously achieved for six drugs [12].

Patients from both data sources were mostly women. Based on the 34% of posts containing gender information, patients in forums were younger than those in the FPVD (mean age of 60 *vs* 72). These results are concordant with published studies: women and young patients are more prone to publish posts on social media [6, 12].

The proportion of non-serious cases reported in web forums was significantly higher than those reported in the FPVD (95.7% vs. 53.5%) which confirms the results found in the medical literature [6, 7, 12], but no significant difference was found between both sources for the number of cases containing at least one unexpected ADR.

The distribution of the SOCs was significantly different ($p < 0.0001$) between the two sources and was more diverse in the FPVD than in the forums: the three most frequent SOCs represented 60% of those in the FPVD vs. 72% in the forums. This could be due to the collaborative aspect of web forums: a first post could lead to several others reporting the same type of ADR in the discussion topic.

If tools have already been developed to evaluate posts from social media [13-15], none gave the possibility to evaluate the medical history, pregnancy status, indication, rechallenge, TTO, drug causality, seriousness or expectedness of the AE. Moreover, no graphical user interface has previously been described in the medical literature to facilitate the application of signal detection methods on social media data.

A major bias of the quantitative study is that the NLP tool could not detect causality – thus, three unexpected severe ADRs considered as signals by the signal detection algorithms were actually false positives - while the qualitative study identified 47 cases showing causality relations from 387 posts (12%). Three AEs identified in forums in the qualitative approach and not reported in the FPVD were not detected as signals in the quantitative approach. However, these AEs may bring interesting information complementary to data available in spontaneous reports. Moreover, the quantitative evaluation also showed that indications were captured as AEs in some cases: 51% of the 1,021 AEs found were either the indication, either diseases linked to or increasing the risk of osteoporosis.

Another limitation was that information concerning strontium ranelate and other drugs was probably under-estimated, as we used a perfect match to normalize drug terms. This study illustrates current limitations of using social media to complement spontaneous reports for signal detection.

Conclusions

We developed two tools to facilitate the evaluation of web forums' posts for pharmacovigilance purpose and used them in a case study focusing on one drug. We found that these tools are complementary. Findings of the quantitative study may be biased by false positives. A qualitative study is difficult to perform on a large number of drugs and posts as it requires important time and workforce. This is the reason why a qualitative approach is usually restricted to signals detected by the quantitative approach.

Future work will focus on reducing bias related to the absence of detection of causality at the linguistic level, implementing other statistical methods (logistic regression, change-point analysis, etc.), and exploring the complementarity of the two approaches on a larger scale, prioritizing the posts that should be manually evaluated after having applied appropriate signal detection methods.

Acknowledgements

This work was funded by grant AAP-2013-052 from the ANSM, the French Agency for Drug Safety (*Agence Nationale de Sécurité du Médicament et des Produits de Santé*) through the Vigi4MED research project and Convention n° 2016S076 through the PHARES project.
Damien Leprovost implemented the tool used for the qualitative study. Rim Aboukhamis evaluated the posts in the qualitative study.
We acknowledge ANSM for providing the FPVD extraction, CHU of Rouen, CISMeF team for providing RacinePharma, Vidal for linking it to the ATC, classification and CNRS-LIMSI for detecting mentions of drugs and AEs in posts.

Abstract

Since the eighties, case mix evaluation methods based on diagnosis-related groups (DRG) were gradually introduced in developed countries. These methods of assessing the costs of diseases to measure the productivity of the hospital have been introduced in management softwares that are not accessible to low-income countries. In this study, the authors applied these methods to an open source hospital management information system (HMIS) implemented in three university hospitals in Great Lakes Africa. A comparative study of the financial burden of five major diseases, monitored as part of a universal health coverage (UHC) analysis, was carried out. The level of coverage of patients in the hospitals was evaluated and the impact of UHC policies demonstrated. Although the financial protection of patients treated in the three hospitals had improved, HIV and tuberculosis treatments that ought to be free, remained a considerable financial burden for the patient.

Diagnosis-Related Groups; Hospitals, University; Africa

Introduction

Knowing the financial burden of disease remains a challenge in sub-Saharan countries. In this study we focused on three countries in the Great Lakes region: Rwanda, Burundi and DRC. WHO and the WB [1] evaluated the coverage of the population for the treatment or prevention of tracer health services and Boema et al. [2] estimated coverage for five diseases as a metric for the UHC progress in countries. The evaluation mainly used household surveys from the Demographic and Health Survey (DHS). The indicators of health coverage focused on maternal and newborn care, the traitement of HIV infection, hypertension, tuberculosis (TB) and diabetes. Health coverage diminishes when household income is lower [3; 4]

Tuberculosis treatment was highly covered in Rwanda, Burundi and DRC (between 80 and 90%) thanks to the national TB programs. ARV therapy was accessible to 67%, 40% and 20% of population with advanced HIV infection in Rwanda, Burundi and DRC respectively. But values for diabetes coverage remained particularly low in the three countries (<10%). The evaluation focused on the general framework of health services accessibility and coverage, without zooming in on the individual patient's financial situation in health facilities. Questions such as “What is the patient's financial coverage for the treatment of these diseases monitored in the context of the UHC?”, “What is the patient's ability to pay for the treatment?”, “What role does health insurance play?” remained unanswered.

According to the DHS [5], UHC policies in the three countries in the Great Lakes region are very different. Rwanda opted for a community based health insurance (Mutuelle de santé) which covers more than 90% of the population. Burundi has strengthened its UHC policy with free healthcare for pregnant women and children under five years old, reaching coverage of 23-30% of the population. In the DRC, we observe a low level of population health coverage (2%). In DRC, patients nearly pay for the full costs of health services they consume.

Alternative methods, based on health facility data, have been developed with the same purpose of measuring financial burden of diseases and to promote better quality of care. These methods are at the basis of the case mix concept introduced in the USA around the 1980s [6] This concept is based on DRGs (Diagnosis Related Groups), and was developped by a team of researchers at the Yale University and consequently introduced in the *MEDICARE* prospective payment system [7]. The DRG is defined as the first “health management tool” to group patients in clinically meaningful categories with homogeneous resources consumption [6]. The DRG-based payment systems have been introduced in Europe in the mid-nineties [8]. The first evaluation of the use of the case mix tool in Africa is found in private health facilities in South Africa in the early 2000s [9] . These were pilot experiments introduced in *3M* software which used the ICD-10 classification for diagnostics and CPT for medical procedures in service pricing. The challenge in sub-Saharan health facilities remained to find affordable tools that integrated these international standards, were easy to use and better adapted to the local context.

In 2009, we worked out a set of disease grouping codes in an attempt to enable efficient evaluation of clinical activity in a typical sub-Saharan health facility [10]. This classification was called the KHIRI Pathology Grouping Set (KPGS). KPGS is a bi-classified grouping system, based on ICD-10 and ICPC-2 classification standards. The KPGS classification aimed to be a simplified sub-Saharan implementation of DRG codes, addressing clinical conditions that better matched local sub-Saharan health management reality [11]. We introduced this classification in an open source hospital management information system (HMIS) called *OpenClinic GA* [10; 12]. *OpenClinic GA*-HMIS was developed by a research team of the Vrije Universiteit Brussel (VUB) and has been put in the public domain (https://sourceforge.net/projects/open-clinic/). The first implementation was at the university hospital of Kigali (CHUK), where the KHIRI (Kigali Health Informatics Research Institute) was established [13]. At a later stage, a data warehouse enabling fully automatic extraction of KPGS coded health indicators from *OpenClinic GA* hospital databases worldwide, named the *Global Health Barometer* (GHB, http://www.globalhealthbarometer.net), was added to the project.

This study attempts to use the KPGS classification to provide case mix evaluation extracted from OpenClinic GA databases

for estimating the financial burden of diseases and the level of patient coverage provided by health insurance schemes.

Methods

The study was conducted during a 6-year period from 2010 to 2016 in three university hospitals of Rwanda, Burundi and DRC by collecting data through *the OpenClinic GA* software. Data related to patient identification, ADT (admission, discharge, transfer), patient- and insurance invoicing, diagnostics and other clinical medical records content.

The following hospitals participated in the study:

1. The University Teaching Hospital of Kigali (CHUK) in Rwanda where the first implementations of OpenClinic GA started in 2007.
2. The University Teaching Hospital of Kamenge (CHURK) in Burundi where the OpenClinic GA implementation started in 2014, and
3. The Provincial General Reference Hospital of Bukavu (HPGRB) in DRC where the OpenClinic GA implementation started in 2011.

The process of *OpenClinic GA* implementation included the setup and configuration of the software, staff training, follow-up, quality control, monitoring and evaluation.

In each of the hospitals, we analysed and compared:

1. The main disease groups encountered in the hospitals. Data were extracted from the GHB data warehouse. We focused on the five disease groups monitored within the framework of UHC: Maternal and new-born health, diabetes, hypertension, tuberculosis and HIV.
2. The financial burden was calculated in terms of care costs generated by each of the five disease groups and split up into patient out-of-pocket and health insurance payments. This information was directly extracted from the hospital OpenClinic GA databases. Disease cost factors have been furthermore identified using the CALCO method. This approach takes into account the amounts of health services consumed and, the disability and mortality weight factors of a disease group compared to associated pathologies (comorbidity) recorded during one and the same encounter [11] [14]. Care deliveries and medical procedures had been registered using local coding schemes. Diagnoses were coded using ICD-10 and ICPC-2 and have been mapped onto the KPGS classification.
3. Levels of patient coverage were derived from average amounts paid by patients and reimbursed by insurer schemes. We calculated the patient health service payment rate (PHSP) by dividing the patient out-of-pocket payment (POOP) by the total amount of health services consumed. The PHSP defines the level of the patient share in the health services consumed and should, in the light of UHC, not exceed 25% of the total cost of health services consumed. To avoid ruinous expenses for the patient, the POOP should also not exceed 25% of the GDP per capita in the country.

Results

Main KPGS-disease groups monitored

Table 1 shows the top 10 of disease groups registered in the three university hospitals during the year 2016. These disease groups represent respectively 58%, 66% and 59% of all cases at CHUK, CHURK and HPGRB. At CHUK in Rwanda, the first in-patient disease group is related to the complications of pregnancy, childbirth and the puerperium (1679 cases). This disease group (KPGS code 15B) covered 13% of all cases in 2016 at CHUK and was also found in the top 10 of disease groups at CHURK (10th group, 2.1%) and HPGRB (3rd group, 8.1%). Genitourinary system diseases (KPGS code 14O) constituted another disease group that found its way to the top 10 disease groups recorded in each of the three university teaching hospitals.

Malaria (KPGS code 1V) was the first disease group encountered at CHURK in Burundi. This pathology group did not appear in the top 10 pathologies group encountered either at CHUK or HPGRB.

Figure 1 presents the disease group overlap for the top 10 disease groups (KPGS codes) in the three hospitals.

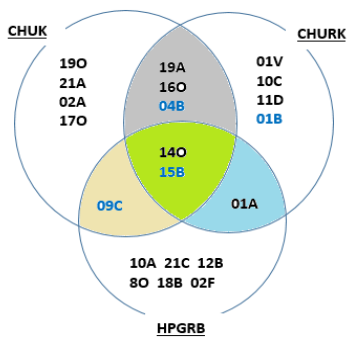

Figure 1- Top 10 KPGS codes overlap in three university hospitals of Rwanda, Burundi and DRC (2016)

If we focus on the five disease groups monitored as indicators of UHC progress, we see that:

1. 15B (Other complications of the pregnancy, childbirth and the puerperium) is found in the top 10 of pathologies in the three hospitals.
2. 04B (Diabetes mellitus) is encountered in the top 10 of diseases at CHUK of Rwanda and CHURK of Burundi.
3. 09C (Hypertensive diseases) is encountered in the top 10 of diseases at CHUK (Rwanda) and HPGRB (DRC).
4. 01B (Tuberculosis) is encountered in the top 10 of pathologies treated at CHURK in Burundi only.

HIV, the fifth treatment intervention monitored by the health coverage at global level was not among the top 10 disease groups in any of the three hospitals in 2016. In 2010, HIV still represented a morbidity rate of 4.5% (1594 in-patient cases, ranked at the third place) at CHUK in Rwanda.

Financial burden per pathology group

Table 2 shows the disease weight scores used from the CALCO method and the number of in-patient cases related to the five disease groups monitored in the framework of health coverage analysis during the period of study.

The data analysis period was different in the three hospitals. For each hospital, we only took into account the period during which financial information and diagnostics have been recorded in the *OpenClinic GA* system.

Figure 2 illustrates a graph of financial burden by disease group. It also shows a table of the POOP and the health insurance share in disease treatment costs. We have expressed the money values in the three countries in international dollars for the sake of consistency and comparability.

Table 1- Top 10 of disease groups in three university hospitals of Rwanda, Burundi and DRC (2016)

Top 10 of pathologies (CHUK)			
Code	Pathology	# Cases	%
15B	OTHER COMPLICATIONS OF THE PREGNANCY, CHILDBIRTH AND THE PUERPERIUM	1679	13.1%

	Insurance	$ 69.51	$ 81.37	$ 52.64
Other complications of pregnancy	POOP	$ 67.97	$ 0.19	$ 53.06
	Insurance	$ 227.24	$ 135.09	$ 50.65

Figure 2- Financial burden (in Intl$) per patient and per insurance for five disease groups at CHUK, CHURK and HPGRB (2010-2016)

The financial burden for treating diabetes, tuberculosis and hypertension are the highest in CHURK. Treatment of HIV is most expensive in HPGRB (Intl$394), three times the cost of CHUK (Intl$123). In contrast, the treatment of "other complications of pregnancy" is twice as high in the CHUK (Intl$295) compared to the two other teaching hospitals. There is not much difference in the financial burden of tuberculosis treatment in the three university hospitals. The average treatment costs vary between Intl$355 and Intl$405.

The patient share (POOP) for tuberculosis treatment (Intl$352) and HIV disease (Intl$293) are the highest at HPGRB and represent respectively 95.8% and 74.5% of the total amount of treatment costs. POOPs for the treatment of diabetes (Intl$ 251) and hypertension (Intl$152) are the highest in CHURK and represent respectively 52.3% and 65.1% of the total financial burden for treatment. The POOP for "other pregnancy complications" (Intl$68) is the highest at CHUK, while it is around zero at CHURK thanks to the free health care policy applied in Burundi for children under five years and pregnant women.

Health services coverage per disease group in the three hospitals

Figure 3 illustrates the average level of health service coverage for each disease group in the three university hospitals.

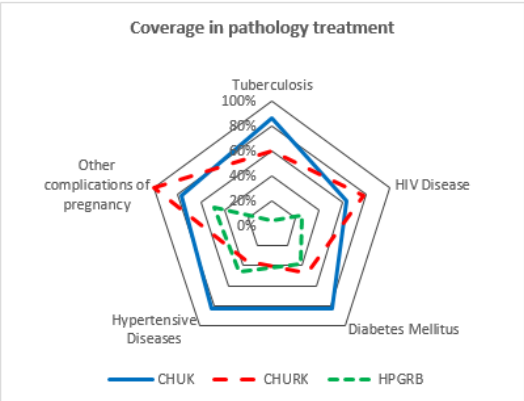
At CHUK, the financial health service coverage of the studied disease groups varies between 63.1% (for HIV) and 86.8% (for tuberculosis). In CHURK, this coverage is close to 100% for "other complications of pregnancy" and remains low (34.9%) for hypertensive diseases. Finally, in HPGRB, the treatment costs of tuberculosis seem to remain predominantly uncovered (only 4.2% coverage) for the patient, and also other groups of diseases have a low coverage rate (between 25.5% and 48.8%) compared to the two other sites.

Discussion

Our study of the financial burden of diseases showed that the situation of case mix in the three university hospitals in the Great Lakes region was not homogeneous both for disease costs and for patient coverage. For tuberculosis for example, the health coverage varied between 87% at CHUK and only 4% at HPGRB.

The patient's financial burden (PHSP) depends on the cost of the health services consumed on the one hand and the level of health coverage on the other hand. It varied between

37% (for HIV) and 13% (for tuberculosis) in CHUK, 65% (for hypertensive diseases) and 0% (for other complications of pregnancy) in CHURK. It was very high in HPGRB (between 96% for tuberculosis and 51% for other complications of pregnancy). Even if the patient share in the health service costs (PHSP) is low in CHUK, it still exceeds the 25%-threshold of health services consumed for the HIV treatment. HIV treatment is not well covered in the CHUK and HPGRB in spite of the free ARVs treatment. The PHSP remains above the 25%-threshold for all disease groups studied in HPGRB



Code	Pathology group	CHUK	CHURK	HPGRB
01B	Tuberculosis	86.8%	59.8%	4.2%
01M	HIV Disease	63.1%	77.5%	25.7%
04B	Diabetes Mellitus	82.1%	47.7%	38.5%
09C	Hypertensive Diseases	83.1%	34.9%	46.3%
15B	Other complications of pregnancy	77.0%	99.9%	48.8%

Figure 3- Health care coverage for five disease groups in CHUK, CHURK and HPGRB

and CHURK, expect for other complications of pregnancy where the PHSP was 0% in CHURK thanks to the policy of free healthcare for pregnant women. Patients may be pushed into poverty if they have to be treated for these diseases not well covered by health insurance schemes.

Treatment of tuberculosis and HIV is supposed to be "free" for the patient, thanks to the specific health programs set up in the countries to fight against these diseases. However, there always remain uncovered costs associated to these treatments. Our findings match the results of several studies that have also found sometimes high associated costs of health care for patients receiving 'free' HIV and tuberculosis treatment [15] [16; 17]. There are indirect costs related to transport, food and waiting time; direct costs due to the treatment of opportunistic infections, self-medication, extra medical exams and traditional healers' services. Chimbindi estimated annually expenditures to USD200 for patients suffering from tuberculosis and USD270 for HIV patients receiving public care in rural KwaZulu-Natal [15] while Laokri estimated tuberculosis associated costs to USD101 in six rural districts of Burkina Faso [16]. On our side, the average POOP associated to these two pathologies varied between USD20 and USD217 for tuberculosis treatment and between USD19 and USD182 for HIV treatment in the three university hospitals of the Great Lakes region. In the HPGRB in DRC, the POOP is more than 50% of the GDP per capita, which could financially ruin the treated patient.

POOPs are related to the treatment of the main disease plus comorbidities that increase the financial burden and add up their disability and mortality weight factors. We have not included the costs of external factors, such as transportation, unproductivity due to time-loss, treatment in the private sector... that may furthermore increase the POOP for the studied diseases.

Although we have noted the important role of health insurance in the coverage of health expenditures in Burundi and Rwanda, appropriate policies should further ensure the management of comorbidities of HIV and tuberculosis to reduce the financial burden for patients and reach total coverage for the two pathologies.

Conclusions

KPGS codes derived from ICD-10 and ICPC-2 classifications integrated into the HMIS software enabled comparison of financial burden and coverage of five disease groups in three university teaching hospitals (CHUK, CHURK and HPGRB) in Great Lakes Africa. Coverage for these diseases is used to monitor UHC progress in countries. The evaluation using case mix methods shows that the situation is quite different in the three hospitals, in terms of total financial burden of disease as well as financial patient coverage.

Our analysis method allowed to detect effects of the free health care policy for pregnant women applied in Burundi in covering pregnancy related problems and the role of CBHI in health services coverage in Rwanda. The method also enabled measuring the financial burden of comorbidity related to treatments for diseases such as HIV and tuberculosis. The same method could also be applied in other low-income countries through an implementation of adequate ICT infrastructure for health information management. Additional broader studies involving more health facilities are needed in order to further evaluate the role of health insurance in covering the financial burden of diseases.

Racial Representation Disparity of Population-Level Genomic Sequencing Efforts

Isaac E. Kim, Jr., Indra Neil Sarkar

Center for Biomedical Informatics, Brown University, Providence, RI

Abstract

To develop personalized treatments for diseases, it is essential that they reflect the population of individuals that may be affected by a given disease. Amidst claims that there may be racial disparities in research populations, there have been no direct studies to explore this disparity in disease incidence and research projects that involve genomic sequencing. The precise relationship between underrepresentation of certain races in genomic sequencing studies and health outcomes relative to these races is unknown. Here, we examine the disparities in racial representation of national datasets pertaining to clinical data, mortality rates, and a major initiative involving genomic sequence analysis (The Cancer Genome Atlas [TCGA]). The results suggest that black Americans are underrepresented for most cancers in TCGA compared to clinical and mortality datasets, whereas Asian Americans are overrepresented. These findings accentuate the importance of targeted efforts to recruit representative patient populations into studies involving genomic sequencing.

Keywords:

Precision Medicine; Healthcare Disparities; Cohort Studies

Introduction

Genomic sequencing initiatives such as The Cancer Genome Atlas (TCGA) aim to catalogue cancer-associated genetic mutations towards the overall goal to diagnose, treat, and prevent cancer through better genetic understanding. While different genetic variants may result in similar symptoms, they could lead to diseases that require distinct, "personalized" treatments [1]. Genomic sequencing studies have led to major breakthroughs in the understanding of various types of cancer. In particular, research using TCGA has revealed that the genetic mutations responsible for breast cancer can be categorized into four major subtypes.

As precision medicine initiatives are embarked upon, such as the All of Us Research Program in the United States, it will be essential to be aware of the potential gaps in genetic knowledge. The All of Us Research Program is designed to treat patients based on individual differences in lifestyle, environment, and biology including factors such as race. Studies have shown that genetic makeup across races can impact treatment regimens as well as outcomes. For example, some patients with localized prostate cancer are prescribed active surveillance as opposed to immediate treatment. Other studies have shown, however, that Black American candidates for active surveillance had worse clinicopathological features on final surgical pathology than their white counterparts, suggesting that the criteria for active surveillance should be more rigorous for Black Americans [2].

The advancement of precision medicine requires genetic information on patients of all races [3]. Adequate racial representation in these studies will lead to more effective targeted therapies and at least address the issue of racial disparities in national health measures. Previous studies have shown a disparity between genomic databases and population demographics [4].

This study aimed to quantify the level of representation of racial minorities such as Black Americans and Asian Americans in the genomic sequencing study, TCGA, relative to clinically reported populations in three publicly available epidemiology databases: (1) Health Care Utilization Program [HCUP] from the Agency for Healthcare Research Quality; (2) mortality data from the Centers for Disease Control and Prevention [CDC]; and (3) the National Cancer Institute's Surveillance, Epidemiology, and End Results Program [SEER]). A major goal of this study is to provide data to compel researchers leading cohort-based studies to actively ensure appropriate balance of racial minorities.

This study sought to address the knowledge gap in the representation of racial minorities in genomic studies compared to incidence databases. To quantify and assess the proportional relationships between the racial groups examined in this study, we introduce the Sinuosity Index as a measure to quantify racial discordance.

Methods

Datasets

Four datasets were analyzed and compared: (1) the 2012 National Inpatient Sample (NIS) from the Healthcare Cost and Utilization Project (HCUP), (2) 2012 mortality data from the Centers for Disease Control and Prevention's (CDC) National Vital Statistics Report, (3) genomic sequencing data from TCGA, and (4) 1973-2014 incidence data from the National Cancer Institute's Surveillance, Epidemiology, and End Results Program (SEER). Based on the Clinical Classifications Software (CCS) disease codes that aggregate International Statistical Classification of Diseases and Related Health Problems, patient race information was extracted according to cancer groups from HCUP and SEER.

HCUP included the races White, Black, Hispanic, Asian or Pacific Islander, Native American, Other, and Invalid, while SEER catalogued a patient's race as White, Black, American Indian, as well as a range of ethnicities belonging to the Asian or Pacific Islander demographic, Other, or Unknown. The CDC's mortality data were analyzed from its corresponding website, while TCGA's genomic sequencing data was retrieved from the National Cancer Institute's Genomic Data Commons Data Portal. CDC divided race into White, Black, American Indian or Alaska Native, and Asian or Pacific Islander, whereas TCGA listed the races White, Black or African American, Asian, American Indian or Alaska Native,

Native Hawaiian or Other Pacific Islander, Other, and Not Reported. As a result of the different race variables and data formats across the four databases, the data extraction code required mapping tailored to each database. Tallies were graphed according to overall cancer and cancer, gender, and race for white, black, and Asian Americans using the Plotly.jl Julia package. This study included 16 cancers in total, specifically cancers of the head and neck (CCS code 11), esophagus (CCS code 12), stomach (CCS code 13), colon (CCS code 14), liver and intraheptic bile duct (CCS code 16), pancreas (CCS code 17), bronchus/lung (CCS code 19), skin melanomas (CCS code 22), breast (CCS code 24), uterus (CCS code 25), cervix (CCS code 26), ovary (CCS code 27), prostate (CCS code 29), bladder (CCS code 32), kidney and renal pelvis (CCS code 33), and brain and nervous system (CCS code 35). For certain cancers, data only existed in a single incidence dataset, SEER, leading to the omission of the following codes in the plotted graphs: Other non-epithelial cancer of skin (CCS code 23), Cancer of other female genital organs (CCS code 28), Cancer of other male genital organs (CCS code 31), and Cancer of other urinary organs (CCS Code 34). Analysis of Variance (ANOVA) calculations were done based on the total number of individuals for each race in each dataset using the Tukey honest significant difference test.

Sinuosity Index

Sinuosity index, which is a measure of steepness of a curve commonly used to assess the straightness of geographic features [5] was used as a measure for racial discordance across the examined databases. The relative difference was quantified as the slope between the relative lowest and highest occurrence of a given population group, with higher sinuosity indices suggesting greater variation across the databases.

For each given cancer and race in which at least three datasets were represented, percentage values were sorted in ascending order into an array. The highest value was then assigned an adjusted value of 1, while all other values were divided by the highest value. For the adjusted sinuosity index of each examined cancer and race, in traversing a sorted array of three values, the lowest value was given an x-value of 1 and set to the front index of a new 2D array, the second an x-value of 3 and set to the last, and the third an x-value of 2 and set to the middle index. In traversing a sorted array of four values, the lowest value was given an x-value of 1 and pushed to the front index of a new 2D array, the second an x-value of 4 and set to the last index, the third an x-value of 2 and to the second index, and the fourth an x-value of 3 and set to the third index. The euclidean distance between the first and last points in the sorted 2D array was calculated and designated as the B value. The sum of the euclidean distances between neighboring points (i.e., first and second, second and third, third and fourth, etc.) in the sorted 2D array was calculated and designated as the A value. The sinuosity index was calculated as A/B.

For the adjusted slope angle of each cancer and race, the lowest value was given an x-value of 1, the second lowest an x-value of 2, and so forth. Then, the euclidean distance was calculated between the points with the lowest and highest y-values and designated as the D value. Next, the difference between the points with the lowest and highest x-values was calculated and designated as the C value. The slope angle was

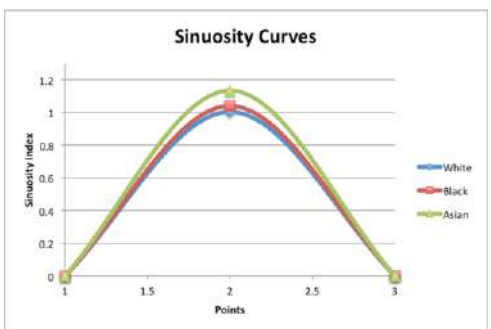

Figure 1 – Sinuosity Curves. Disproportion between sinuosity indices for White, Black, and Asian Americans can be seen as relative differences between the curves.

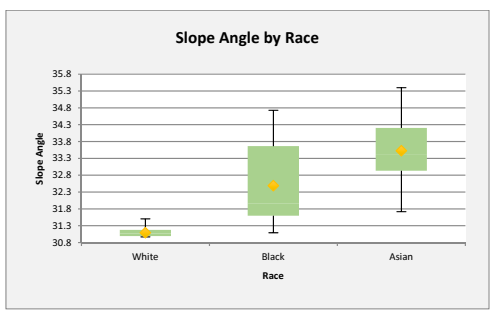

Figure 3 – Distribution of Slope Angle By Race. A distribution of slope angle is shown for each race examined across the datasets: White, Black, and Asian

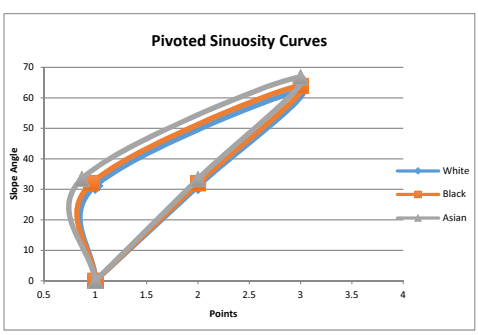

Figure 2 – Pivoted Sinuosity Curves. The relative slope differences between the White, Black, and Asian Americans shows disparity between genomic and epidemiological data sources.

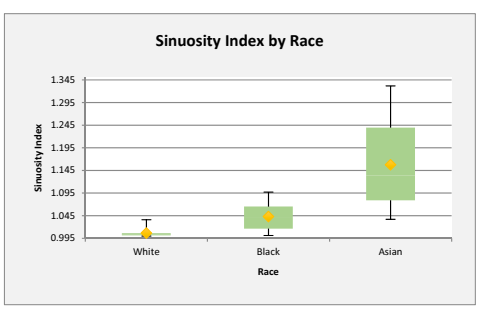

Figure 4 – Distribution of Sinuosity Index By Race. A distribution of sinuosity index is shown for each race examined across the datasets: White, Black, and Asian

calculated using cos(C/D).

The sinuosity curve was plotted for each racial grouping based on the median sinuosity index and then pivoted according to its respective median slope angle. The sinuosity curve was graphed by assigning two points with coordinates (1,0) and (3,0) and a third point with an x-value of 2 and y-value of the median sinuosity index. The sinuosity curves were pivoted so that the line connecting the points (1,0) and (3,0) corresponded to the median slope angle.

Results

For the cancers included in TCGA, Black Americans comprised less of the total sample population in TCGA as compared to HCUP, CDC, and SEER for 15 out of 19 cancers; White Americans and Asian Americans were underrepresented in 11 and 4 out of 19, respectively. Prostate cancer showed the most underrepresentation in TCGA across all examined races, and certain female-dominated cancers such as breast and uterus showed the highest representation of Black Americans in TCGA compared to HCUP, CDC, and SEER. An Analysis of Variance test using Tukey's honest significant difference test for the entire populations in each database revealed statistically significant differences (P=0.0000) between each race group for each dataset, except for Black Americans versus Asian Americans in SEER (P = 0.4001).

For the 16 cancers in which data in TCGA and at least two other datasets were listed, the mean sinuosity indices for White Americans, Black Americans, and Asian Americans respectively were 1.00642±00879 [1.00023-1.03608], 1.04298±02936 [1.00128-1.09715], and 1.15744±09114 [1.03703-1.33156]; the mean slopes were respectively 31.0961±0.1401 [30.9656-31.5034], 32.4931±1.22428

Table 1 – Sinuosity Indices and Slope Angles by Cancer and Race. Percent-adjusted sinuosity indices and percent-adjusted slope angles are shown for each cancer and race.

Cancer (CCS Code)	Race	Percent-Adjusted Sinuosity Index	Percent-Adjusted Slope Angle (Degrees)	Cancer (CCS Code)	Race	Percent-Adjusted Sinuosity Index	Percent-Adjusted Slope Angle (Degrees)

The individual sinuosity indices for each cancer examined are shown in Table 1.

Discussion

The discordance of racial or ethnic groups in genomic sequencing projects potentially exacerbates racial disparities in U.S. health care, especially for complex genetic conditions. As a step towards overcoming these challenges in developing genetically informed healthcare regimens, it is of the utmost importance that the research community actively recruit racially proportional cohorts into national genomic sequencing efforts [3] such as the All of Us Research Program. Efforts such as TCGA require patient consent in the procurement of tissue samples, which implies that non-White Americans tend to withhold their samples from researchers.

The sinuosity index was adapted for this study to understand the relative differences between genomic sequence and epidemiology databases. In geography it is commonly used to study the "straightness" of an earth feature (e.g., a river). In this study, this metric was chosen as a proxy to compare the relative "straightness" of the curves that characterize the difference between the analyzed sources. To our knowledge, this is the first use of the sinuosity index in the context of biomedicine, where higher index values indicate greater dispartity. The differences between sinuosity (which quantifies shape) are more pronounced than slope alone (which measures overall difference) provide a unique persective to compare the general patterns of disparity between the races analyzed in this study.

Previous studies have shown that Black Americans are significantly less likely than their white counterparts to participate in research that used their DNA, share their DNA with a private company, and permit their DNA to be used to generate cell lines for future research [6]. Moreover, as has been noted with clinical trial studies [7], racial minorities are much less likely to want the results of their genetic testing [8] and have diverse views on the utility of genetically targeted treatments [9].

It is important to acknowledge the potential problems associated with using race as a label, especially since racial disparities in genomic sequencing may either be related to or are the direct results of the perception of how healthcare systems and research communities interest. Previous studies connecting race and variable risk for certain diseases have generated considerable controversy, as the correlation between these two factors has long been disputed among members of the scientific community and the general public.

In an effort to direct researchers away from the preconceived notion of race in genetics research, Yudell et al. noted that "the use of biological concepts of race in human genetic research - so disputed and so mired in confusion - is problematic at best and harmful at worst. It is time for biologists to find a better way." [10] In contrast, David Reich suggested that the scientific community legitimize and incorporate these claims into genetic studies while working to provide the same freedoms and opportunities to individuals irrespective of their race [11]. Reich notes that genetic studies have shown distinct differences across populations in traits such as bodily dimensions and susceptibility to diseases. Reich specifically suggests that "it will be impossible - indeed, anti-scientific, foolish, and absurd - to deny the differences [between populations]".

In contemporary medicine, treatment for cancer is usually based on the type, the size, and whether it has metastasized. As our results suggest, however, patients are at higher risk for different cancers based on their race. The results of this study further underscore that the promise of precision medicine must accomodate attributes such as race alongside pre-existing chronic conditions and environmental factors.

This study reinforces the growing wave of support for precision medicine by the government and academic institutions, specifically the United States National Institute for Minority Health and Health Disparities's aim to understand disease mechanisms that lead to differential health outcomes in minorities. This study suggests that the genetic component associated with race that affects the kinds of cancer that patients are at risk for.

For results of initiatives like the All of Us Research Program to have practical meaning to the general population, the scientific community must intently ensure that large-scale genomic sequencing efforts are representative of the range of racial backgrounds. For example, the adequate representation of female Black Americans relative to their male counterparts in TCGA indicates that these recruitment efforts into genomic sequencing studies should especially target male Black Americans. For prostate cancer, the sinuosity indices for White Americans, Black Americans, and Asian Americans were 1.01355, 1.08430, and 1.23926, indicating that Black Americans were more underrepresented in TCGA compared to White Americans (Figure 5). Interestingly, prostate cancer mortality for Black Americans is more than twice the rate observed in White Americans [5]. In contrast, Asian Americans showed overrepresentation in genomic sequencing studies, leading to disproportionately high sinuosity indices across examined cancers. This finding suggests that recruting efforts to target Asian Americans in genomic sequencing studies may not be nearly as vital as those seeking Black Americans.

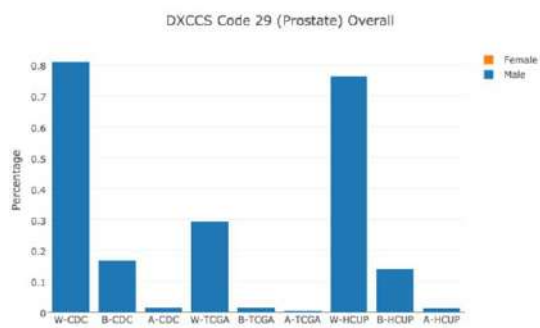

Figure 5 – Percent Representations in CDC Mortality, TCGA, and HCUP By Race for Prostate Cancer. Percent representations of prostate cancer are shown for each race (White [W], Black [B], and Asian [A]) examined across the datasets: CDC, TCGA, and HCUP.

A notable limitation of this study was being unable to examine representation for other races and some cancers due to a lack of sufficient data in at least two of the following datasets: CDC, TCGA, HCUP, and SEER. Such cancers included those of the other GI organs and peritoneum (18) and other urinary

organs (34). Thus, future work should also entail assessing adequate representation of races besides White Americans, Black Americans, and Asian Americans as well as these cancers. Relatedly, there was little to no documentation on how race data was collected in each database. This absence of documentation is relevant in that Mersha et al. found that self-reporting African Americans can have drastically different levels of African or European ancestry. Moreover, genetic analysis of individual ancestry revealed that some self-identified African Americans have significant European ancestry and vice versa [12]. Therefore, that race might be self-reported by patients in these databases would suggest that racial disparities in healthcare are largely due to factors other than genetics. Further work should be done on determining the socioeconomic and genetic basis for why race seems to play an important factor in the onset of different types of cancer. Additionally, data analysis was limited to one genomic database, so future work should incorporate genomic databases other than TCGA.

The challenge in ensuring diversity in large scale initiatives has been acknowledged. For instance, the 1000 Genomes Project analyzed the genomes of 1,092 individuals from 14 populations ranging from people with African ancestry in Southwest United States to Han Chinese in Beijing, China to British from England and Scotland. Given the importance of racial makeup in patient treatment and health outcomes, all genomic sequencing studies should follow suit to initiatives such as the 1000 Genomes Project and contain racial diversity [6]. However, it is important to note that as initiatives like All of Us launch into recruitment efforts, diversity alone is not sufficient. Diversity must be complemented with ensuring that it is with comparable frequencies relative to actual population. Otherwise, the research and clinical community risk the challenge of arriving at putative treatments that are of little utility to significant portions of the population who would benefit the most from personalized medicine approaches.

This study shows that, while race is acknowledged as an important component to consider risk for cancer, cohort studies to date are disproportionate relative to the actual occurrence of cancer by race. Thus, while genomic sequencing studies have led to novel discoveries of disease progression, they may inevitably biased by the races represented in these studies. As our results show, there has been a shortage of minorities in genomic sequencing studies, thereby potentially exacerbating racial disparities in health outcomes. Minimally, from findings of this study, we conclude that researchers must actively recruit Black Americans in genomic sequencing efforts.

The development of personalized treatments for diseases is increasingly plausible due to the increased availability of genomic data. For such efforts to be impactful, it is essential that they reflect the population of individuals that may be affected by a given disease. Despite claims of racial disparities in research populations, there have been no direct studies on such disparities in disease incidence and research projects that involve genomic sequencing. As a result, the relationship between the underrepresentation of certain races in genomic sequencing studies and health outcomes relative to these races is thus unknown.

Conclusions

This study explored the disparities in racial representation of national datasets pertaining to clinical data, mortality rates, and of a major initiative involving genomic sequence analysis (The Cancer Genome Atlas [TCGA]). The results suggest that Black Americans are underrepresented for most cancers in TCGA compared to clinical and mortality datasets, whereas Asian Americans are overrepresented. Additionally, male Black Americans tend to be especially underrepresented in such genomic sequencing studies compared to their female counterparts. These findings highlight the importance of targeted efforts to actively recruit representative patient populations into studies involving genomic sequencing.

Abstract

With the characteristics of high incidence, high prevalence and high mortality, stroke has a serious impact on residents' health and imposes a heavy ecomomic burden on China. In order to simulate the economic burden of stroke in the next 20 years, we construct a simulation platform for Chinese stroke economic burden based on the national stroke screening data. We use the Leslie model for population prediction and the equilibrium model to simulate the stroke economic burden in the platform. The platform constructed in this study can dynamically simulate the stroke economic burden during 2020-2040 by computing the incidence, prevelance and mortality rates from the national stroke screening data or as customized by the user. Based on this platform, we can further develop a warning mechanism at the national level, and provide a guide for the planning and allocation of national health resources.

Keywords:

Stroke, Cost of Illness, Computer Simulation

Introduction

In recent years, with the economic development, changes in people's lifestyles and the aging population of China, the incidence of chronic diseases has surpassed that of infectious diseases. With the characteristics of high incidence, high prevalence and high mortality in China, stroke has a serious impact on the health of residents and imposes a heavy burden on society and families. An accurate simulation of stroke economic burden can provide and estimate of stroke burden at the national level, guide the planning and allocation of national health resources—including the required number of beds in hospitals and medical investment, and develop a reasonable intervention strategy for people with high risk of stroke. Researchers have conducted successful studies on disease economic burden. Tomaskova H et al.[1] used system dynamics to predict the number of patients with Alzheimer's disease based on data from the Census Bureau and the U.S. Surgeon General's Smoking Report. Miotto R et al.[2] derived a general-purpose patient representation with unsupervised deep feature learning method to predict disease such as diabetes. Liu J et al.[3] further used the unstructured notes and free-text medical notes to improve the accuracy of the prediction results. Chen M et al.[4] applied machine learning algorithms for prediction of chronic disease based on real-life hospital data collected from central China in 2013-2015. However, these machine learning methods require a long time span cohort data. Keoghbrown M R et al.[5] simulated Alzheimer's disease prevalence, morbidity and mortality for 2011–2050 and analyzed related economic and non-economic impact on Chinese economy. Charlson F J et al.[6] drew upon burden of mental disorders and population data to estimate disability the quality adjusted life years from 2010 to 2050 for the Pacific region. Xu J et al. [7] used regression model and dynamic general disequilibrium model based on data from multiple sources to predict the total annual economic costs of dementia in China in 2020 and 2030. Bommer C et al.[8] predicted the economic burden of diabetes in 180 countries upto 2030, using the epidemiological and demographic data, as well as recent GDP forecasts with three assumed scenarios. Rossi A et al.[9] predicted Parkinson's disease prevalence upto 2040, considering the correlation between Parkinson's disease and smoking. They obtained age and gender.stratified smoking prevalence from the published reports. However, there are very few studies on the simulation platform of the economic burden in China due to stroke. The data used in these simulations are either focused on a certain area [10] or a certain stroke subtype [11], and some studies are based on old data [12]. Most of the research results are presented in a report which is difficult to share and update.

In order to investigate and reduce the incidence, prevalence, recurrence, mortality and disability rate of stroke in China, the Ministry of Health of the People's Republic of China launched a stroke screening and intervention program. The program established stroke centers in the hospitals, which are responsible for screening the risk factors for stroke among residents over 40 years of age in China. Since the launch of the project in 2011, more than 7 million stroke screening cross-sectional data and follow-up cohort data have been accumulated nationwide. Due to the short construction time of the screening cohort, it is not suitable to use regression models, machine learning and other simulation methods that require cohort data over several years. We propose an equilibrium model based on stratified population to simulate the stroke economic burden. We have calculated the age and gender stratified incidence, prevalence, and mortality of stroke based on the national screening big data. Combined with the predicted population structure, we can simulate stroke economic burden and its trends in the next 20 years. At the same time, by adjusting the incidence, prevalence and mortality of stroke, we can simulate the economic burden and provide decision support to develop scientific indicators for stroke prevention and control.

In this paper, we construct the platform for simulating the stroke economic burden, which can dynamically simulate and display the changes in the economic burden of different population groups in China in the next 20 years. The second section describes the main technologies used in the platform,

combined with the usage scenarios, the third section illustrates the results, and the fourth section discusses these results.

Methods

The stroke economic burden is related to the population structure. Based on the sixth national census data in 2010, we predict the population structure of China. And then an appropriate model is selected to simulate the stroke economic burden for the next 20 years.

Population Prediction

The methods for predicting population mainly include the Malthus population model [13], the Logistic model [14], the Leslie model [15], the BP neural network model[16], and the Bayesian model [17]. Economic and health policy in China has impacted the population. The birth and mortality rate have changed greatly in recent decades. The national census is conducted every ten years and as a result, the available national census data for population projections is limited. Among these population prediction models, only the Leslie model does not require long-term cohort data. And we choose the Leslie model to predict the population structure in China. Introduced by Leslie PH. in 1945, the Leslie matrix groups population by age and gender. It overcomes the drawbacks of the Malthus model and the Logistic model, which cannot predict the population structure. Considering the birth rate and mortality of the population, Leslie model can dynamically predict changes in population structure.

Considering the difference in survival rates of different provinces and urban/rural areas, we group the population by the province, age (5-year age as a group), gender, and urban/rural areas for the prediction. The population forecast is based on the 2010 national census data, from which the survival rate of each population group is taken. We assume that the survival rate remains unchanged during the prediction period.

Stroke Economic Burden Simulation

In this paper, equilibrium simulation model is used to predict epidemiological indicators of stroke, including incidence, prevalence, and mortality. The equilibrium model, also known as static model, assumes the epidemiological indicators of stroke in certain population groups do not change over time, and the total changes in the epidemiological indicators are only related to changes of population size and structure. Giving hospitalization rate and average hospitalization expenses as parameters, the changes of stroke economic burden are mainly related to the population structure changes.

Epidemiological Indicators Simulation

Firstly, the population is regrouped by age (10-year age as a group) and sex. We assume that in the next 20 years, China will maintain the current health conditions and the risk factors of stroke will not change, namely, the incidence, prevalence and mortality of stroke will remain at the current level. The default stroke incidence, prevalence, mortality included in the platform are calculated with the national stroke screening cohort data during 2013-2015 and the results from paper [9], which the user can choose as needed. In addition, users can customize the stroke incidence, prevalence, and mortality for each group. Taking the calculation of the incidence cases as an example, the number of incidence cases in each group is the product of the predicted population of that group and the incidence rate. The incidence cases of all groups are increased to obtain the national stroke cases of that year. The calculation method for incidence cases is as follows:

$$\text{cases}_{i,j} = \sum_{j}^{10} pop_{i,j} * inci_{i,j}$$

where i indicates the year, j is the group number, pop is the predicted population, and $inci$ is the incidence of stroke. The incidence of stroke of that year is the incidence cases divided by the total predicted population. The number of stroke patients, the number of deaths, the prevalence, and the mortality rate is calculated in the same way.

Hospitalization Expenses Simulation

The total hospitalization expenses for stroke patients is defined as the product of the number of incidence cases, hospitalization rate, and the average hospitalization expenses (in billion yuan). The hospitalization rate and average hospitalization expenses in a certain year can be customized by users.

Indirect Economic Burden Simulation

The World Bank and the World Health Organization (WHO) proposed the disability adjusted life year (DALY) in 1993 [18] as a comprehensive indicator for assessing indirect economic burden of disease. Widely used in various countries and regions, DALY is used to calculate the premature death caused by various diseases and consequent loss of healthy life. One DALY is defined as a loss of one healthy life year. It consists of two parts: the year of life lost with premature death (YLLs), and the other is the year of lived with disability (YLDs). The calculation formula for DALY is as follows:

$$DALY=YLLs+YLDs$$

The calculation of YLD requires the disability weight (DW) due to stroke. According to GBD, the DW of the first ever stroke is 0.92, and the DW of the surviving case after 28 days is 0.266. The calculation of disability adjusted life years in the platform is based on a computational template provided by the GBD.

GDP Loss Simulation

The GDP loss caused by short-term disability, long-term disability, and premature death is calculated using human resource model. The definition of GDP loss is as follows:

$$GDP\ loss=PPP\ *DALYs*\ pw$$

where PPP indicates GDP per capita (in international dollars, purchasing power parity adjusted), and pw indicates productivity weight, which is related to the productivity of the age of people. The productivity weight of people aged 40-44 years is 0.75, 45-59 years is 0.8, and that of people over 60 years is 0.1. In the platform, users can customize the GDP per capita.

Results

First, we experimented the prediction accuracy of the Leslie model. Using the Chinese fifth census data in 2000, the national population structure in 2010 is predicted. The results are compared with the data of Chinese sixth census in 2010. The error rate of the prediction results is shown in Table 1.

We do not consider the immigration and migration of the population while using the Leislie model, which may bring certain deviation between the prediction results and the actual population data.

Table 1– Prediction error rate (%) of the Leslie model

Age range	Male	Female
40-49	13.84	10.24
50-59	-9.85*	-11.53*
60-69	11.98	10.18
70-79	13.58	13.69
80-	2.70	8.14
Total	6.40	4.77

* Negative sign indicates negative deviation.

At the same time, the increase in the incidence of chronic diseases in the past decade[19-21] may also bring deviations. The population size of people in 40-49 years old is larger than the prediction results of the model. The baby boom in the 1960s may explain this phenomenon. Overall, the population prediction using the Leslie model is basically reliable. Since China has entered an aging society, the actuall population size in 2020-2040 will be theoretially smaller than the prediction results.

The platform is implemented using Visual Studio 2015 based on the MVC framework. The initial interface of the platform is the user input interface, which can be used to set the parameters, as shown in Figure 1.

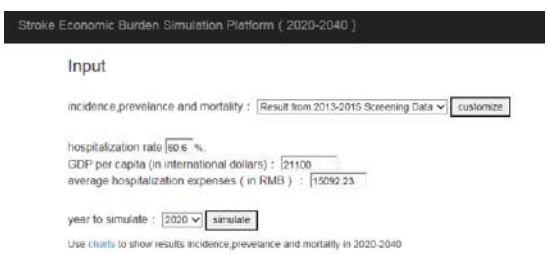

Figure 1– The initial interface of the platform

In the platform, users can choose the incidence, prevalence, and mortality calculated based on the national stroke screening data of a certain year, or use the results of other research papers. The following result acts as an example of simulation using the incidence, prevalence, and mortality calculated using national screening data in 2013-2015. The simulation results of average incidence, prevalence and mortality of stroke in China from 2020 to 2040 is shown in Figure 2-4.

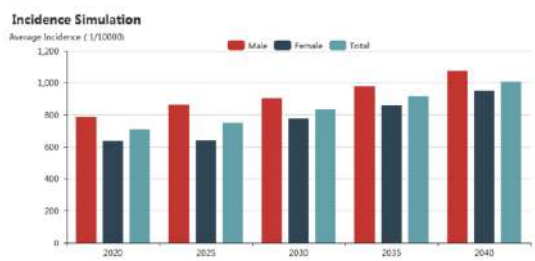

Figure 2– Simulated stroke incidence of China from 2020 to 2040

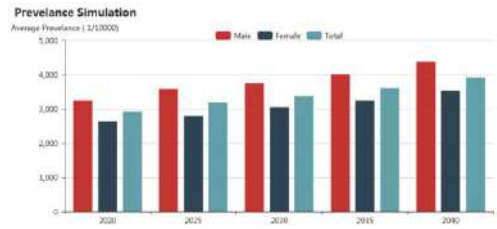

Figure 3– Simulated stroke prevelance of China from 2020 to 2040

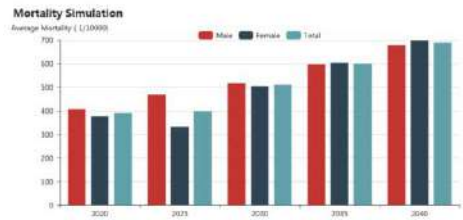

Figure 4– Simulated stroke mortality of China from 2020 to 2040

When simulating the indirect economic burden, we choose the average hospitalization cost and hospitalization rate of stroke patients calculated from the national stroke screening data in 2013-2015. The GDP per capita in 2020 is set to 21,100 international dollars, in reference to the prediction results in paper [22]. The simulation results of the indirect economic burden of stroke in 2020 are shown in Figure 5.

Figure 5– Stroke economic burden simulation results

Stroke incidence, prevalence, and mortality are associated with age [17]. The stroke prevalence is highest in people aged 70-79, and the incidence and mortality are highest in people 80 years and over. The results show that as the aging population in China increases, the stroke incidence, prevalence and mortality will increase anually. In order to further control the economic burden of stroke in China, the risk factors of stroke should be controlled through health education for residents to reduce the incidence and recurrence rate of stroke. And the medical care condition should be improved to reduce the mortality rate of stroke.

Discussion

While using the platform, users can customize the stroke incidence, prevalence and mortality. By changing the parameters, the economic burden of stroke under different conditions can be simulated. The simulation results of

economic burden are more timely and intuitive than the traditional reports. With the advancement of stroke screening and intervention project and increased control of stroke risk factors, the incidence, prevalence and mortality of stroke will change. These values can be entered in this platform to dynamically simulate the future changes in stroke economic burden. Also by setting the warning value of stroke economic burden, the threshold of incidence, prevalence and mortality in each population group can be explored, which can be used as a guide for the national health policy.

In the future, we can predict population structure of various regions based on their population structure and simulate their respective stroke economic burden in order to make different health policies for different regions.

Conclusions

The stroke economic burden simulation platform based on the national screening data constructed in this paper can share the simulation results in time. According to the user's custom input, changes in the stroke economic burden caused by changes in the incidence, prevalence, and mortality will be simulated. Policy makers can further explore the threshold of stroke incidence, prevalence and mortality by calculating the "blowout" or "inflection point" of the economic burden. Rational use of this stroke economic burden simulation platform can help create a guide for planning and national health resource allocation. This would include the required number of beds in hospitals and medical investment needed. Based on the simulation results an early warning mechanism can be developed at the national level and the timing of warning for the onset of stroke can be further explored.

Abstract

Despite U.S. federal agencies increasing their investment since 1999's release of To Err Is Human, recent reports suggest there is a lack of measurable outcomes in patient safety research. The present study sought to explore the associations between federal incentives of patient safety research and the outcomes from 1995 to 2014, in which the two historical events – the release of To Err Is Human and the American Recovery and Reinvestment Act – were considered in the analysis. We employed Poisson distribution models to provide a longitudinal picture of (1) how the federal incentives drove sponsored research projects; (2) how hot research topics changed over time. Our findings suggested a positive outcome in patient safety research. We also found trending health information technology (HIT) related topics including "natural language processing", "user-computer interface", and "clinical decision support systems" that are prevalent approaches to patient safety research.

Keywords:
Patient Safety, Medical Errors, Quality of Health Care

Introduction

Patient safety is the first priority for healthcare quality. Its significance had been lost for a long period of time in the public and healthcare professions' attention until the release of the Institute of Medicine's (IOM) report *To Err Is Human* on November 29, 1999 [1]. The report disclosed 44,000 to 98,000 patient deaths of medical errors every year. Nevertheless, errors that resulted in patient harm are preventable, to a great extent [2].

Nationwide collaboration is key to patient safety. Immediately after the IOM's report, several collaborations among hospitals, research institutes, and healthcare organizations were called on. Among these collaborations, patient safety research was an integral component [3]. Meanwhile, financial incentives were offered to motivate the systematic study of better understanding patient safety challenges and solutions. At the direction of Congress and the Agency for Healthcare Research and Quality (AHRQ), strategies were made during the first decade since the IOM's report to (1) develop a solid evidence base, (2) develop useful strategies and tools, and 3) implement the strategies and tools. These efforts made notable progress and were highlighted in a number of AHRQ reports and scholarly publications [4,5].

In 2009, the American Recovery and Reinvestment Act (ARRA) became another notable factor that triggered an influx of research awards to spur patient safety research. Because of this economic stimulus, the National Institute of Health (NIH) received a total of $10.4 billion in funds for patient safety research [6].

Despite the federal government and institutions making more investments than ever, there are recent reports on worsening patient safety [2,7]. Most of the critiques come directly from the statistics of patient harm in the hospitals. As of 2013, the annual patient deaths of preventable medical errors increased to 210,000 ~ 440,000 [2]. Patient safety still poses serious challenges nationwide.

Measuring the efforts and progress of patient safety plays a vital role in the framework of patient safety research [8]. A wide variety of measurements have been used for such a purpose, including clinical study, literature review, and survey on patient safety culture [5]. However, there is a missing perspective on how the activities and outcomes of patient safety research changed under the influence of federal incentives. The awareness of such an association is necessary to sustain the improvement of patient safety. Recommended by IOM, patient safety research was included in the national collaboration on enhancing the knowledge about safety and developing tools for reducing medical errors. Among many other efforts, research is one of the most supported efforts by the federal government and stakeholders.

We investigated the activities of patient safety research in the U.S. from 1995 to 2014, which consisted of fifteen years since *To Err Is Human* and five years before it as a baseline. Data of federally sponsored research projects and publications on health sciences were used as the gauge for the national priority, research activities, and outcomes of patient safety [3]. We included two remarkable events, *To Err Is Human* and ARRA, in the data analysis to assess their influence in a longitudinal view. Specifically, we developed Poisson regression models to provide longitudinal pictures of (1) how federal incentives drove sponsored research projects, reflected in the quantity and cost of grants and the quantity of publications; (2) how hot research topics changed over time.

Methods

Data sources

To track federal funding in patient safety research, we used the Research Portfolio Online Reporting Tools Expenditures and Results (RePORTER) provided by NIH to download research projects funded by U.S. national institutions. These projects were archived in the ExPORTER format. The data underlying

RePORTER contains detailed information for each project. See Table 1 for a dictionary of the data we used. We retrieved the projects from the fiscal year (Oct. 1 – Sep. 30) 1995 to 2014. Note that data for the cost of projects are not available before 1999. To track the publications affiliated with the sponsored projects, we performed a literature search in the Medline database from 1995 to 2014 via PubMed. To extract hot topics of sponsored patient safety publications, we incorporated MeSH major topics and PMID in the search of RePORTER and Medline.

Table 1 – RePORTER data dictionary

RePORTER Database	RePORTER Entity	Definition
Project Data	Application_ID	A unique identifier of the funded project.
	Activity	A 3-character code identifying the funded project.
	FY	The fiscal year appropriation from which project funds were obligated.
	Project_Terms	Prior to the 2008 fiscal year, terms are assigned by NIH CRISP indexers. From the 2008 fiscal year, terms are mined from the project's title, abstract, and specific aims using an automated text mining tool.
	Project_Title	Title of the funded project.
	Total_Cost	Total project funding from NIH for a given fiscal year.
Project Abstracts	Application_ID	A unique identifier of the funded project.
	Abstract_Text	An abstract of the research being performed in the project.
Publication Link Tables	PMID	A PubMed unique identifier.
	Core Project_Num	An identifier of the research project either cited in the publications' acknowledgements section or reported to have provided support in the NIH Public Access manuscript submission system.

Data analysis

Identification of thesaurus terms related to patient safety

Five domain experts developed a list of thesaurus terms related to patient safety. Thereafter, these terms were used to retrieve sponsored projects on patient safety. The decision-making process took three criteria into account: (1) terms that had been documented to determine the patient safety literature were used as a pool of candidates [3], (2) the NIH Computer Retrieval of Information on Scientific Projects (CRISP) thesaurus (1972 – 1995) were used as a source of candidate terms, and (3) MeSH terms were used to substitute candidate terms identified by criteria (1) and (2) when available. We used CRISP because it was a long-lasting database of NIH funded projects before the implementation of RePORTER in 2009.

Finally, we compiled a list of terms: "medical errors" (MeSH ID: D019300), "medical mistakes" (MeSH entry term of "medical errors"), "surgical errors" (MeSH entry term of "medical errors"), "medication errors" (MeSH ID: D008508), "drug use errors" (MeSH entry term of "medication errors"), "patient safety" (MeSH ID: D061214), "patient harm" (MeSH ID: D064406), "iatrogenic disease " (MeSH ID: D007049), and "diagnostic errors" (MeSH ID: D003951).

Trend analysis: Change of grants in patient safety over time

The trend analysis was intended to disclose the change in the number and cost of patient safety grants over time. Within a timeframe from 1995 to 2014, we assumed two historical events may remarkably impact the trend. The first event denotes the release of *To Err Is Human* in 1999. The second event denotes ARRA enacted in 2009.

Sponsored patient safety projects were retrieved by searching the project data from ExPORTER using the thesaurus terms. Table 1 shows the definitions of the fields in ExPORTER we used. We searched in the selected fields of project data consisting of Project_Title, Project_Terms, and Abstract_Text. A project is labeled as a patient safety project if the text in any of these fields contains one or more terms.

We constructed Poisson regression models to evaluate the trends of grant number and cost in patient safety on a longitudinal scale. In the Poisson regression models, two interventions corresponded to the two events [9]. These models accounted for the instant effect and the lasting effect of the interventions. The model for the number and cost of patient safety grants is:

$$\log(Patient\ safety\ grant\ number\ (or\ cost)) = \beta 1 + \beta 2 * time\ + \beta 3 * intervention1 + \beta 4 * time\ after\ intervention1 + \beta 5 * intervention2 + \beta 6 * time\ after\ intervention2 + e$$

where $time$ denotes the year of a grant; $intervention1$ and $intervention2$ are dummy variables denoting the events of *To Err Is Human* and ARRA, respectively; $time\ after\ intervention1$ denotes the year of a grant since *To Err Is Human*; $time\ after\ intervention2$ denotes the year of a grant since ARRA; $\beta 1 \sim 6$ and e are coefficients.

Trend analysis: Change of publications in patient safety over time

Similarly, we accommodated two historical events in the analysis. In the Medline database via PubMed, we retrieved all articles from January 1, 1995 to December 31, 2014, by specifying the following query:

> "Medical errors"[mh:noexp] OR "Medication errors"[mh:noexp] OR "Patient safety"[mh:noexp] OR "Patient harm"[mh:noexp] AND (("1995/01/01"[PDAT] : "2014/12/31"[PDAT]) AND "humans"[MeSH Terms] AND English[lang])

To model the trend of quantity of patient safety publication, we included the number of Medline documented publications per quarter, obtained from Medline Trend [10], and the number of Medline documented patient safety publications per quarter for analysis. The model is:

$$\log(Patient\ safety\ publication\ number) = \beta 1 + \beta 2 * time\ (quarter) + \beta 3 * intervention1 + \beta 4 * time\ after\ intervention1 + \beta 5 * intervention2 + \beta 6 * time\ after\ intervention2 + e$$

Lag effect

To evaluate the possible lag effect of the number of patient safety publications in acknowledgement of the number of

patient safety grants, we assumed the lag time could be 0 ~ 4 year(s). For example, a 2009 grant would start to show its impact on the number of publications in 2012, which indicates 3 years of lag time. We compared the Bayesian Information Criterion (BIC) by applying these candidate lag times [11]. BIC is a measure of the relative quality of models given the existing data. Higher BIC value refers to a better fit of the model.

Hot topic tracking: Change of MeSH major topics in patient safety publications over time

We identified hot topics of the publications sponsored by funded patient safety projects. The MeSH major topics (i.e., MeSH major headings and MeSH major subheadings) were used to track the hot topics since they were designed to identify focusing research subjects, methodologies, fields of interest, etc. To extract MeSH major topics from the patient safety publications, we followed these procedures: (1) we identified PMIDs of publications associated with the patient safety projects in the RePORTER, (2) we retrieved bibliographical information of these publications by searching the PMIDs in Medline, and (3) we extracted MeSH major topics from the bibliographical data.

Results

Identification of patient safety grants and publications

We identified 3,358 (0.28%) patient safety-related projects in a total number of 1,208,188 documented projects from the RePORTER between the fiscal year 1995 and 2014. We identified 21,441 (0.16%) patient safety publications from 13,278,113 publications documented in Medline between January 1, 1995 and December 31, 2014.

Trend of patient safety grants

Table 2 shows the estimated coefficients of the Poisson regression model are statistically significant, which indicates a good fit of the model to the actual number of patient safety grants.

Table 2 – Model parameters for the number of safety grants

Effect	λ	95% CI	z
Time	0.040	[0.026, 0.054]	5.63**
Intervention1	1.280	[1.129, 1.432]	16.58**
Intervention2	0.158	[0.049, 0.262]	2.83*
Time after intervention2	-0.054	[-0.081, -0.027]	-3.93**

* $p < 0.01$; ** $p < 0.001$

Table 3 shows the estimated coefficients of the Poisson regression model are statistically significant, which indicates a good fit of the model to the actual cost of patient safety grants.

Table 3 – Model parameters for the cost of safety grants

Effect	λ	95% CI	z
Time	0.1870	[0.1870, 0.1871]	13000.00**
Intervention2	0.2434	[0.2432, 0.2436]	2847.02**
Time after intervention2	-0.2173	[-0.2174, -0.2173]	-9578.03**

* $p < 0.01$; ** $p < 0.001$

Figure 1 shows the number of grants reveals an overall ascending trend from 1995 to 2014. We observed two rapid momentums in 1999 and 2009, respectively. A similar pattern was observed on the project cost.

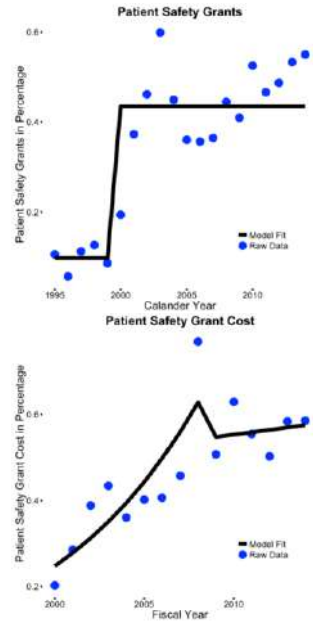

Figure 1 – Trends of patient safety project number (top) and grant cost (bottom)

Furthermore, we categorized the number and cost of awarded projects, respectively, by NIH research award activity codes. Figure 2 shows there is a significant effect on the number of the awarded projects ($F(17,342) = 43.57$, $p < .05$). NIH Research Projects increased by 10.1% ($p < .001$), leading to a significant contribution to the number and cost of the awarded projects.

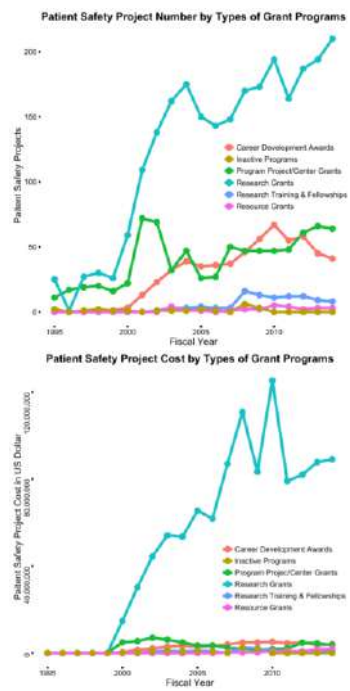

Figure 2 – Trends of patient safety project number (top) and cost (bottom) by NIH activity codes

We presented 24 major MeSH topics that have the highest frequency of occurrences out of 6,472 in total from 1995 to

2014 (see Figure 3). MeSH terms that were used for identifying publications were excluded since they naturally occur in every publication. Due to the limited space, we only demonstrated the hot research topics in 1999 and 2009, respectively, in Table 4.

Figure 3 – Frequencies of hot research topics in the publications of sponsored patient safety projects over time

Table 4 – Examples of hot research topics and frequencies

1999 Hot topics	*f.*	2009 Hot topics	*f.*
Risk Management/ *methods	19	*Safety Management	101
Malpractice/ *legislation & jurisprudence	13	Safety Management/ *organization & administration	93
*Drug-Related Side Effects and Adverse Reactions	10	Safety Management/ *methods	41
Medication Systems, Hospital/*standards	8	*Quality Assurance, Health Care	31
*Quality of Health Care	7	*Attitude of Health Personnel	29
*Clinical Pharmacy Information Systems	6	*Clinical Competence	28
*Truth Disclosure	6	Drug Prescriptions/ *standards	27
*Patient Care Team	6	*Medication Systems, Hospital	24
Nursing Staff, Hospital/*legislation & jurisprudence	6	*Quality of Health Care	24
*Attitude of Health Personnel	6	*Safety	24

The two historical events are associated with the trends of research topics. Notably, we observed an immediate increase of a research topic, "hospital mortality trends", following the release of *To Err Is Human*, suggesting that hospital mortality was one of the earliest research foci since 1999. Immediately following are "adverse drug reaction reporting systems", "needs assessment", "safety management", "quality improvement", "natural language processing", "electronic health records", "medical order entry systems", and "user computer interfaces". Among these topics, health information technology (HIT) related techniques received increasing attention. This finding is in line with the complex origins of HIT-related errors [12,13]. "Natural language processing", "electronic health records", "user computer interfaces", and "medical order entry systems" have maintained a relatively high frequency through the release of ARRA. Research topics such as "quality of healthcare", "computer simulation", and "artificial intelligence" did not show a clear upward trend until the release of ARRA.

Trend of patient safety publications

The estimated coefficients are statistically significant in the model for the number of publications, indicating a fit for the actual data (Table 5). Patient safety publications revealed a similar pattern as compared to the number and cost of patient safety grants, where two rapid momentums were observed in 1999 and 2009 on an ascending trend (Figure 4). The baseline increase was 8.6% by quarter. After the release of the IOM report, patient safety publications instantly increased 11.8% by quarter, and 2.6% thereafter. After the release of ARRA, publications instantly increased 74.5% by quarter, and 0.8% thereafter.

Table 5 – Model parameters for patient safety publications

Effect	λ	95% CI	*z*
Time	1.086	[1.079, 1.093]	24.68**
Intervention1	1.118	[1.035, 1.207]	2.83*
Time after intervention1	0.940	[0.934, 0.947]	-17.99**
Intervention2	1.745	[1.648, 1.848]	18.99**
Time after intervention2	0.982	[0.972, 0.992]	-3.56**

* $p < 0.01$; ** $p < 0.001$

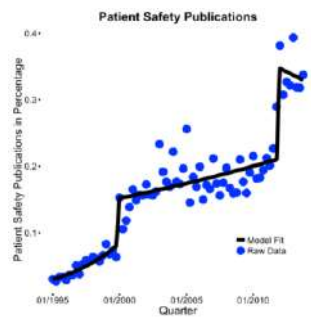

Figure 4 – The trend of patient safety publications

We calculated the BIC for 0 - 4 years of lag time. BIC peaked (BIC = -11.4) when the lag time was 3 years, indicating the trend of patient safety publications has a three-year lag of time as compared to the trend of patient safety grants (Table 6).

Table 6 – Bayesian Information Criterion values

Lag time (year)	0	1	2	3	4	5
BIC	-15.18	-30.37	-13.64	-11.40	-17.26	-13.39

Discussion

Building on a data-driven approach, this study underscores how patient safety research has evolved since 1999. The efforts during the fifteen years since the release of *To Err Is Human* have shown an ascending trend in patient safety research reflected in the volume and cost of federally sponsored projects and scholarly publications. This finding can serve as one of the measurable outcomes that gauges the nationwide endeavor on patient safety research over two decades. It also implies a positive change of priority and cultural attitude toward patient safety. Our findings also confirmed the prominent influence of *To Err Is Human* and ARRA on patient safety research.

The change in topics of patient safety research has provided important insights. One observation is research interests have advanced from the general assessment of preventable medical errors to specific domains (e.g., HIT) that may contribute to errors in the US hospitals. The "hospital mortality trends" was the first topic that caught the researchers' attention since 1999 because hospital mortality rate has been a common measure of healthcare quality. Soon after, researchers started to focus on adverse drug reaction and clinical or patient safety educational needs assessment. Notably, IOM has now identified adverse drug events and medication errors as a national priority in the U.S. [14].

The other observation pertains to the emergence of novel methods. There has been an increasing number of patient safety studies on exploring new knowledge from electronic health records (EHR) [15]. Researchers have identified Human-computer interaction (HCI) as a crucial contributing factor to data quality and data entry during event reporting [16,17]. Natural language processing (NLP) has also emerged in many studies because patient safety event reports consist of considerable free text data [18]. In our view, health informatics is a promising future direction along with new data challenges. Recent studies have shown the application of advanced data analytics, e.g., machine learning, to address the ever-increasing volume of patient safety event reports [19,20].

Our findings need to be discussed in light of limitations. First, our data sources provided only a few facets of patient safety research. *To Err Is Huamn* has led to actions from many governmental agencies and professional groups that were not included in this paper. In 2000, the U.S. congressional hearings directed $50 million funds to establish a patient safety center at AHRQ. Additionally, our study paradigm may be used to gauge efforts on patient safety research in Europe, Asia, etc. when data is available. Secondly, our findings are not intended to explain the latest estimate of increasing patient deaths, between 210,000 and 400,000 [2]. The proliferation of patient safety research and measurable clinical outcomes are separate processes. Nonetheless, we believe the ultimate goal for patient safety research is to reduce preventable deaths. Future studies are needed to investigate the translational outcomes of patient safety research that make measurable changes to patient harm.

Conclusions

We have identified an ascending trend of activities of patient safety research during the 15 years since *To Err Is Human*. We also identified trending research topics in which shifts of research foci, challenges, and future directions were discussed.

Abstract

Pre-eclampsia is a pregnancy condition affecting 5-10% of pregnancies, and it is the leading cause of death in pregnancy associated with increased risk of cardiovascular disease later in life. Despite research, the pathogenesis of pre-eclampsia is still poorly understood. In this paper, we investigate the overlapping pathogenic mechanisms between pre-eclampsia and adult hypertension using an integrative biomedical informatics strategy that combined text mining techniques to identify genes and proteins, with geneset analyses, generating knowledge on the pathways and mechanisms involved in these conditions. We identified several overlapping pathogenic pathways/systems including metabolic pathways, developmental biology pathways, immune system, haemostasis, tyrosine kinase pathways, extracellular matrix and oxidative stress pathways. This bioinformatics approach could be applied for investigating mechanistic pathways of other disorders.

Pre-Eclampsia, Computational Biology, Data Mining

Introduction

Pre-eclampsia is a condition affecting 5-10% of pregnancies. It is clinically characterised by the new onset of hypertension and proteinuria or other organ damage after 20 weeks' gestation [1]. There are different types of pre-eclampsia diagnosed according to the time of onset in pregnancy, i.e. early (before 34 weeks' gestation) and late (after 34 weeks' gestation) or according to the severity of the symptoms [2]. Pre-eclampsia is a leading cause of mortality and morbidity, claiming approximately 80,000 maternal and 500,000 foetal deaths every year [3]. Long-term complications associated with pre-eclampsia include type 2 diabetes mellitus and cardiovascular disease (CVD) for both mothers and adult offspring, later in life [4,5].

During the early stages of pregnancy, a group of differentiated cells forming blastocysts, become implanted in the lining of the uterus. The outer layer of the blastocyst consists of foetal trophoblast cells which invade the spiral uterine arteries after implantation [6]. The invasion of trophoblast cells into the lining of the uterus results in remodelling of spiral uterine arteries to allow an unlimited supply of oxygen and nutrients to the foetus. These changes involve the replacement of maternal endothelial cells with invasive trophoblasts, which develop to form a large section of the placenta, leading to irreversible dilation of blood vessels and loss of elastic tissue, therefore preventing restriction to blood flow and vasomotor control which regulate blood pressure [7]. Impaired trophoblast invasion has been implicated in the pathogenesis of pre-eclampsia. This results in the absence of uteroplacental remodelling of spiral arteries leading to placental ischaemia and causing insufficient perfusion and delivery of the oxygen and nutrients to the foetus which can affect the foetal growth [8]. In an attempt to overcome the lack of blood and nutrient supply to the foetus, maternal blood pressure becomes gradually elevated. The restricted blood supply to the placenta causes the release of chemical mediators and hormones into the maternal circulation, altering endothelial cell activity and resulting in endothelial cell dysfunction. This suppresses the release of vasodilatory factors such as nitric oxide (NO) and increases the production of vasoconstrictors while inhibiting anticoagulant synthesis and increasing procoagulant production [9]. Dysbalance of vasodilatory and vasoconstrictive factors increases the risk of blood clotting and can lead to an increase in blood pressure. Endothelial dysfunction has been implicated in the pathogenesis of pre-eclampsia [10,11], however endothelial dysfunction following pregnancy complicated by severe pre-eclampsia appears to also persist 10-20 years after pregnancy [12].

As mentioned above, women who have pre-ecplampsia and their children born from such pregnancies have increased risk of CVD later in life, particularly if pre-eclampsia was severe (blood pressure ≥160/110 mmHg, thrombocytopenia, impaired liver function, progressive renal insufficiency, pulmonary oedema, and cerebral or visual disturbances). Based on a meta-analysis of prospective and retrospective cohort studies including 198,252 women with pre-eclampsia, the relative risks of developing hypertension, ischaemic heart disease and stroke were 3.70 after 14.1 years, 2.16 after 11.7 years, 1.81 after 10.4 years, respectively [13]. Furthermore, children born to mothers who suffered pre-eclampsia in pregnancy were also at increased risk of hypertension and stroke in later life [14].

Pre-eclampsia and cardiovascular disease are affected by similar risk factors such as hypertension, obesity, insulin resistance, diabetes, a family history of CVD, and genotypes related to CVD, suggesting that similar pathogenic mechanisms could be present in both diseases [12,15]. Biomarker discovery and characterisation is an important area of research both in pre-eclampsia and CVD that led to the identification of a number of important markers. However, despite research in this field, there is still a lack of knowledge in relation to the mechanisms underpinning the pathogenesis of pre-eclampsia and future increased risk of CVD.

Scientific literature presents the knowledge generated in research and practice. It is a continuously growing wealth of data that is enriched on a daily base with new publications. These data represent an opportunity for the development of research strategies aiming to generate new biomedical knoweldge that is hidden in this vast amount of information, or the generation of new research hypotheses. Therefore, it has

attracted the interest of biomedical informatics, especially the development of methods and tools designed to mine it. An important element of these methodologies has been focused on the identification of diseases, genes or proteins cited in scientific texts and the identification of interaction networks. Biomedical relation extraction is an approach that has shown precedence in similar studies providing cross-sectional and domain-specific views of biomedical research literature [16–18].

In this study, we investigated an *"in silico"* approach, which uses the information embedded in the literature to integrate relevant biomarkers identified in pre-eclampsia and hypertension. Furthermore, we sought to contextualise these in terms of significant biological pathways which are common denominators in both conditions. The approach presented here provides a mechanistic interpretation of the commonalities between pre-eclampsia and hypertension, but it could be applied to study pathogenesis of any other disorder.

Methods

The methodology applied in this work consisted of three sequential stages including: i) document search and retrieval, ii) document annotation and gene/protein extraction and iii) mechanistic analysis. These steps are further detailed below.

The first step in our analyses included the definition of the relevant Pubmed queries, which were used to identify the relevant elements in the literature associated with the two conditions of interest for this study:

- Pre-eclampsia query was built as "("pre-eclampsia"[MeSH Terms] OR "pre-eclampsia"[All Fields] OR "preeclampsia"[All Fields]) AND ("biomarkers"[MeSH Terms] OR "biomarkers"[All Fields] OR "biomarker"[All Fields])". This query aimed to retrieve a broad range of elements that could be associated with this condition.
- Hypertension query was built as "(Hypertension[MeSH] NOT ("pre-eclampsia"[MeSH Terms] OR "pre-eclampsia"[All Fields] OR "preeclampsia"[All Fields])) AND Biomarker". This query focused on the retrieval of documents annotated as hypertension as a MeSH term while excluding pre-eclampsia.

We used the R package *RISMed (2.1.7)* designed to retrieve and download contents from the NCBI databases into R. For this purpose, both of these queries were then passed as arguments to the function "EUtilsSummary" to identify the relevant documents in Pubmed that were subsequently downloaded using the "EUtilsGet" function. This resulted in two R data frames containing information associated with these documents and in particular the relevant Pubmed IDs that were used as input in the second stage for annotation of the literature.

The second stage of the analysis consisted of the annotation of the biological terms of relevance (genes/proteins); for this purpose, rather than developing a new methodology, we relied on the annotations provided by Pubtator [19]. Pubtator annotates Pubmed documents using different "named-entity-recognition" algorithms around four bioconcepts Gene; Chemical; Disease; Species. Although Pubtator was initially developed as a web service at the NCBI ftp site we used the downloadable version of the results from its annotations.

The third and the final stage consisted of the mechanistic analysis of the identified biomarkers. In this analyses we selected two knowledge bases to analyse the enrichment in certain biological processes or functions: DAVID [20], broad and containing multiple annotations such as gene ontology terms, Uniprot keywords or KEGG terms for multiple organisms; and Reactome [21], a highly curated database of biological reactions in humans. Reactome identifies the enrichment in its contents using an overrepresentation analysis based in the hypergeometric test and using a FDR (Benjamini-Hochberg) *p*-value correction to adjust the significance for multiple comparisons. DAVID uses EASE, a modified version of the hypergeometric test and allows the selection of multiple *p*-value correction methods. In both cases the input provided was a list of NCBI Gene IDs that were translated into their own internal IDs to match their contents.

Results

An overall overview of the methodology developed and the results obtained are presented in Figure 1.

The literature search allowed us to identify and retrieve almost 9000 documents in total, 3167 for preeclampsia and 5675 for hypertension. As a quality control we compared the PMID between these two datasets to ensure that there was no overlap

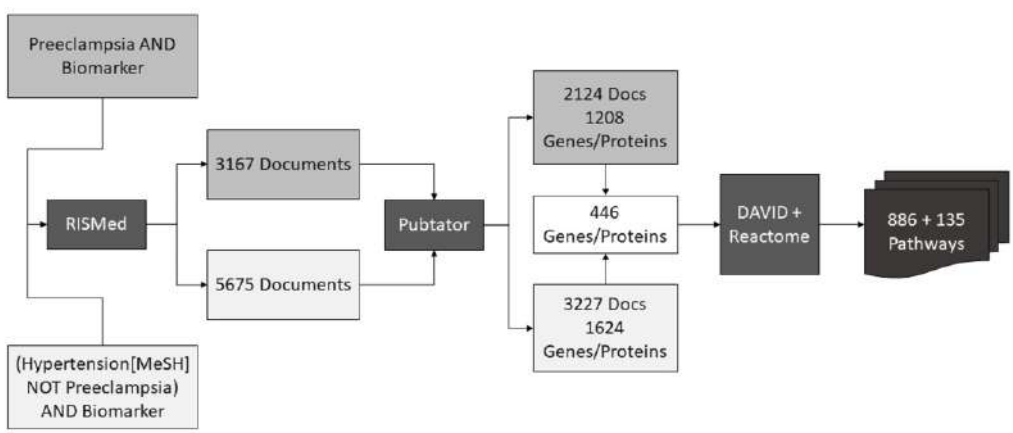

Figure 1 – Overview of the methodology and the results from the the query terms to the final and total number (sum of Reactome and DAVID results) potentially shared pathways and genesets between preeclampsia and hypertension

and that the results would not be misled by publications present in both datasets.

The annotation of these two sets of Pubmed documents allowed us to identify approximately 5,000 different documents that were annotated with at least one gene or protein providing 2,124 in the pre-eclampsia dataset and 3,227 in the hypertension dataset. These documents contained 2,386 genes/proteins of which 446 were present in both datasets (19% of the overall gene list and 37% of the genes identified in the pre-eclampsia dataset; Figure 2).

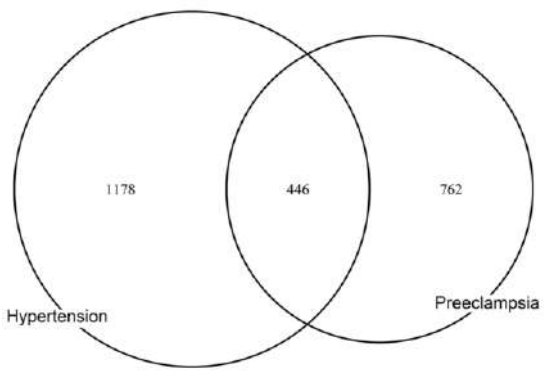

Figure 2 – Number of genes/proteins identified for each dataset and the set of 446 shared genes proteins that were used in the geneset analyses

Once we identified the relevant gene lists the next step was to perform the geneset analyses of the identified genes. As the significance is determined by the number of elements in the genelist we initially run three different analyses using Reactome with the following three subsets: 1- All genes (1624) identified for hypertension (HT.a); 2- All genes (1208) identified for preeclampsia (PE.a); 3- the 446 genes present in both hypertension and preeclampsia (Both). The significance threshold for enriched pathways was set as an adjusted *p*-value < 0.05. The number of significant pathways identified in each of these analyses are presented in the Table 1 and the shared pathways across these comparisons are visualised in Figure 3.

Table 1 – Number of Reactome pathways significantly enriched for each of the three genesets analysed.

Gene Subset (Number of Genes/proteins) (code)	Number of Pathways	Unique Pathways
All genes in Hypertension (1624) (HT.a)	20	7
All genes in Preeclampsia (1208) (PE.a)	107	21
Genes present in both Preeclampsia and Hypertension (446) (Both)	129	42

The set containing the genes/proteins present in both conditions ("Both" set) was the most enriched one with 129 significant pathways (Figure 4) whereas the hypertension set, which was the largest, was the least enriched with 20 different reactome pathways identified. An overlap analysis of these results allowed us to identfy 12 pathways in common for the three different genesets (Table 2).

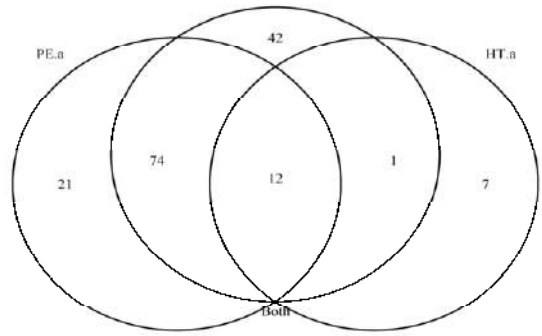

Figure 3 – Pathway enrichment for the three analysed sets, hypertension (HT.a), pre-eclampsia (PE.a) and the intersection between hypertension and pre-eclampsia (both)

Table 2 – List of the 12 statistically significant (adjusted p-value <0.05) pathways identified in Reactome for the three genesets analysed.

Pathway Name
Regulation of Insulin-like Growth Factor (IGF) transport and uptake by Insulin-like Growth Factor Binding Proteins (IGFBPs)
Platelet degranulation
Response to elevated platelet cytosolic Ca2+
Post-translational protein phosphorylation
Platelet activation, signaling and aggregation
Integrin cell surface interactions
Chemokine receptors bind chemokines
Peptide ligand-binding receptors
Interleukin-10 signaling
Syndecan interactions
Formation of Fibrin Clot (Clotting Cascade)
PI5P, PP2A and IER3 Regulate PI3K/AKT Signaling

As different resources contain different information and annotations for the different genes we submitted the "both" (shared) dataset to DAVID for a complementary analysis. In this case we limit the query to the 446 shared elements between both pathologies. And set a significance threshold of benjamini adjusted *p*-value < 0.05. This resulted in the detection of significant enrichment in 886 different genesets made of pathways, gene ontology terms (Table 3) and other annotations.

Table 3 – List of the top 12 statistically significant (adjusted p-value <0.05) Gene Ontology Biological Process terms identifed in DAVID for the intersected gene list

	Pathway Name		Pathway Name
1	Inflammatory response	7	Response to drug
2	Response to hypoxia	8	Platelet degranulation
3	Leukocyte migration	9	Aging
4	Positive regulation of nitric oxide biosynthetic process	10	Positive regulation of smooth muscle cell proliferation
5	Positive regulation of gene expression	11	Positive regulation of angiogenesis
6	Angiogenesis	12	Regulation of blood pressure

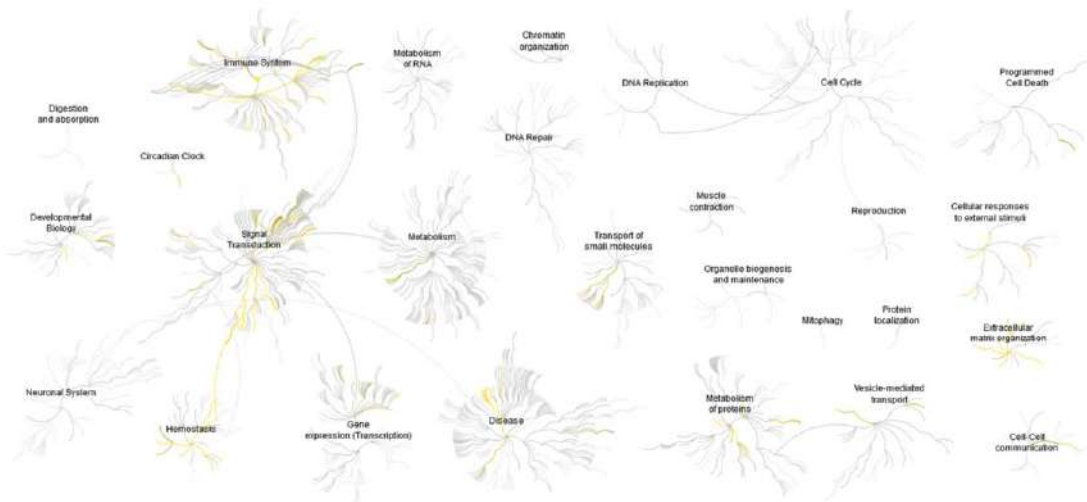

Figure 4 – Results from the Reactome analysis using the shared elements between pre-eclampsia and hypertension. The statistically significant elements are highlighted in yellow in the image.

Discussion

Using an integrated strategy we have been able to retrieve biomarkers (gene/proteins) that are shared between pre-eclampsia and hypertension. Our strategy allowed us to also identify genes from other organisms commonly used to model human diseases such as rats and mice. Although it would have been possible to map those genes to their human orthologues we decided not to do this therefore keeping our focus just on human biomarkers.

The identified genes were transformed into gene lists that were analysed using two different resources. As we mentioned before we were focused on human disease or models and, for this reason, we chose to run initially a more restrictive search using Reactome, as this is a highly curated database used to generate results from high-quality and restricted sources facilitating their biological interpretation. Overrepresentation analyses, similar to what we carried out here, are dependent on the size of the query lists and the size of the background available in the resource they are compared with. Therefore, finding differences in the composition and number of significant pathways identified between the lists containing the whole set of biomarkers for each condition and their intersection, was not completely unexpected. However, it was surprising that the smallest list containing the conserved biomarkers was the one showing the highest enrichment. From a biological perspective, this list, derived from the intersection of biomarkers identified in both pathologies, is expected to contain genes/proteins positively associated with the diseases. These genes would therefore be more biologically meaningful and would better capture the common underlying biological processes in both conditions.

The identified pathways for the shared set of genes are related to metabolism, developmental biology, immune system, haemostasis, tyrosine kinase, extracellular matrix and oxidative stress signalling. All these aspects provide coherent and meaningful biological information in the context of these pathologies. Interestingly, we have identified using DAVID analyses, the GO terms associated with “Regulation of blood pressure” showing up as statistically significant and highly ranked. This is an expected result as both conditions show changes in blood pressure, which validates our methodology as both conditions share a high blood pressure phenotype. In relation to the other enriched pathways identified, for example, it is well recognised that inflammation (associated with the immune system) plays a significant role in hypertension [22,23]. Furthermore, pre-eclampsia is a pregnancy-related condition therefore developmental biology plays a key role [6, 7].

Limitations and future work

The limitations of this study include some aspects of methodology which assume a perfect gene/protein identification in the annotation process not taking into the account the effects of potential false positive and negative biomarker hits. The second limitation is associated with the assumption of treating equally all the terms identified and not considering potential negations contained in the abstracts. An example of this is that we are including a gene in our analysis that could appear in the text as “gene XXX does not have an effect in pre-eclampsia.” However we tried to minimise this by basing our approach on relevant pathways and disease mechanisms.

As part of the future work, we are planning to address specifically the effects and quantity of false positives and negatives potentially present in the current version and we will try to develop new approaches that can help us identify and successfully manage negations found in literature used as input.

In addition to this, as part of the future work, we plan to develop an R package that will seamlessly integrate the methodology and processes that have been described in this work.

Finally, we plan to biologically validate some of the findings derived from this work.

Conclusions

There is a wealth of data and inforamtion available in public repositories that could be mined and analysed to generate new knowledge and research hypotheses. In this work, we combined different biomedical informatics tools, to retrieve

and identify biomarkers in hypertension and pre-eclampsia and then analysed these to identifiy common underlying molecular mechanisms linking these two conditions.

This data-driven approach enabled us to identify the specific aspects and reactions associated with metabolic pathways, developmental biology, immune system, haemostasis, tyrosine kinase pathways, extracellular matrix and oxidative stress pathways as the most prominently involved in the pathogenesis of these two important conditions.

Our bioinformatics approach described in this paper is therefore applicable to any other similar diseases for the purpose of identifying overlapping or individual pathogenic mechanisms.

Patient-Reported Outcomes of Utilising Person-Generated Health Data in Simulated Rehabilitation Technology: Perceptions of Stroke Survivors

Gerardo Luis Dimaguila[a], Kathleen Gray[a], Mark Merolli[b]

[a] Health and Biomedical Informatics Centre, University of Melbourne, Melbourne, Victoria, Australia,

Abstract

Patient-reported outcome measures (PROMs) contribute to improving the evidence base in many areas of clinical care. An area where PROMs can help build the evidence base is in person-generated health data (PGHD) that is available to people who engage with many health technologies. An important use case for PGHD outcomes is in simulated poststroke rehabilitation that use body-tracking technologies. This study gathered stroke survivor perceptions—through 2 focus groups and 5 interviews—on PGHD effects from a leading poststroke simulated rehabilitation technology. Deductive thematic analysis was performed. The findings show that PGHD outcomes of utilising PGHD can be measured. Moreover, the findings provided a deeper understanding of PGHD effects and broadened the scope through the perceptions of stroke survivors themselves. This work will further refine and validate the development of a PROM for utilising PGHD for poststroke simulated rehabilitation systems, and has wider relevance and application.

Keywords:

Patient reported outcomes, stroke, telerehabilitation.

Introduction

Patient-reported outcomes are independently self-reported status of a patient's health condition or experience [1-3]. Instruments that measure patient-reported outcomes are patient-reported outcome measures (PROMs). PROMs allow patients to contribute to more precise evaluation of the effects of a variety of health interventions, and their contribution to improving the evidence base in many areas of clinical care is well recognised [4]. The important role PROMs have in assessing and improving health care services are marked by key national projects that sought to develop suites of PROMs for different health domains or conditions. In the US, the National Institutes of Health sought to produce a suite of PROMs for various chronic conditions [5]; in Europe, the Netherlands is leading the push to include outcomes data in clinical registries; and closer to home, the Australian Commission on Safety and Quality in Health Care commissioned scoping studies, towards supporting the use of PROMs to improve quality of health care at a national level [6].

One area where PROMs could contribute to building the evidence base is in understanding person-generated health data (PGHD). PGHD are available to people who engage first-hand with a range of ubiquitous, user-friendly health information technologies such as mobile apps, wearable sensors and interactive computer games [7]. Various kinds of positive effects have been reported on patients who used PGHD in controlled settings [7], e.g., encouraging positive health behaviour change [8] and increasing patients' interest in their care processes [9-11]. However, there is currently no systematic way for patients to measure and report health effects that they experience from utilising their PGHD – whether positive, negative or nil. This hinders building the evidence base about the value of PGHD in conjunction with clinical care. Currently, PGHD outcomes are not integrated into existing clinical workflows [7]. If PGHD outcomes can be systematically measured and clinically integrated, similar to patient-reported outcomes of health conditions [5], PGHD may lead to more efficient and beneficial home-based health care services [12-14].

An important use case for measuring PGHD outcomes is in home-based poststroke rehabilitation, that uses body-tracking technologies [15]. Stroke is a pertinent area for applying rehabilitation systems due to its high global burden, and the complexity of care involved [16; 17]. Rehabilitation can be costly and availability may be scarce for some patients [18], hence the need for convenient and more practical rehabilitation choices for patients. Simulated rehabilitation systems offer a potentially effective option, with some benefits for stroke therapy previously documented [19-22]. These systems offer simulated activities of daily living [20], and – relevant to PGHD – may allow for a semicontrolled, consistent method of recording and assessing patients' therapeutic progress data [20; 21].

Implementing PGHD tools could further optimise these systems [15], by making performance data more accessible to patients at home – and their effects documented and available to therapists. More specifically, a PROM of utilising PGHD (PROM-PGHD) for simulated poststroke rehabiltiation technologies could measure self-reported outcomes of patients' access and use of health data they generate. Similar to how PROMs provide a more precise evaluation of the effects of health interventions [4], a PROM-PGHD could more precisely evaluate the effects of PGHD from poststroke simulated rehabilitation systems, and lead to a better understanding of their impact on the health status of patients.

This study presents the perceptions of stroke survivors, on the effects of PGHD from a poststroke simulated rehabilitation technology in order to refine a PROM-PGHD that has wider relevance and application.

Methods

Focus groups and semi-structured interviews were conducted with stroke survivors who have used a leading poststroke simulated rehabilitation technology [15]. Focus groups and interviews are a key step in a larger study of developing a PROM-PGHD, following the Qualitative Item Review (QIR) process of patient-reported outcome item development [5]. The entire process is described elsewhere.

Ethics Approval

This study was approved by the Deakin University Human Research Ethics Committee (Deakin HREC, ID 2017-087).

Participants

Stroke survivors with experience of utilising PGHD were recruited for convenience from participants in a randomised controlled trial (RCT) called STRIVE, which sought to determine the efficacy of a selected poststroke simulated rehabilitation technology, Jintronix [23]. These participants used Jintronix which utilises Kinect, a leading body-tracking technology [15, 23], and generates PGHD, see example in [15]. Participants were from the Melbourne metropolitan Area, Victoria, and Launceston, Tasmania (Australia). After the RCT lasting 8 weeks, participants in the intervention arm were invited to participate in focus groups of 3-6 people (or semi-structured interviews for participants who could not meet at the same day and time as other participants). There were 3 males and 7 females. All interviewees (5) were females.

Procedure

Participants were asked two categories of semi-structured questions: the first for the purposes of the STRIVE study and the second for the purposes of this study.

The first category for the STRIVE study gauged perceptions for the whole trial in terms of system usability, patient engagement, and intervention impact. Sample questions participants were asked included what parts of Jintronix were easy or difficult to use; whether use of Jintronix resulted in any behavioural changes to daily tasks; and whether Jintronix helped them in understanding and achieving their rehabilitation goals. Participant responses to the questions in this category, if they were also relevant to the second category of questions below, were included in our analysis.

The second category of questions was to conceptualise patient-reported outcomes of PGHD and ask participants to comment on any outcomes their PGHD may have had. Questions included what emotions or reactions they may have from seeing their PGHD; whether they felt more or less engaged after seeing their PGHD; and if any of their rehabilitation goals changed. Participants were also asked to comment on sample patient-reported outcome items. These questions and sample patient-reported outcome items were developed from steps 1-3 of QIR [5], where different effects of PGHD were identified:

1. Influence health-related behavioural changes in patients [8].
2. Change feelings about health status [10].
3. Influence interest in their care processes [9-11].
4. Facilitate personal care goals [10; 24].
5. Influence relationship with care providers [10; 11; 25; 26].

These effects were also used to guide the deductive thematic analysis conducted, as described in the next sub-heading. Steps 1-3 of QIR involved a literature review to scan established PROMs within the areas of interest; and selecting, categorising, and revising relevant PROM items to form initial themes that would guide the discussion with the target cohort.

All focus groups and interviews were held in meeting rooms at Deakin University at days and times that suited the participants. Participants who could meet at similar days and times were organised into focus groups, everyone else was organised into semi-structured interviews. In total there were 2 focus groups with 3 and 2 participants each. In each group, there was one participant who could not make it on the day. Additionally, there were 5 semi-structured interviews. All focus groups and interviews were audio-recorded.

Data Analysis

Nearly 10 hours of focus groups and interviews were transcribed verbatim; the former by GLD and the latter by a research assistant of the STRIVE project. GLD checked all transcriptions for accuracy, and de-identified them. The transcriptions and data management (including coding) were done using NVivo 11 (QSR International Pty Ltd, Melbourne, Australia).

Deductive thematic analysis was initially conducted independently by all authors on a few transcripts. Once common understanding was achieved for how themes are applied, GLD proceeded to analyse the rest of the transcripts; using a coding journal to clarify contentious quotes with the co-authors. Themes were derived deductively from the identified PGHD effects from the literature. The different themes are presented in the results below as subheadings.

Results

The results below show perceptions of stroke survivors on the effects of PGHD from a poststroke simulated rehabilitation technology.

Health-Related Behaviours

While stroke survivors mentioned some improvement with their ability to do some daily tasks as a result of their use of Jintronix, few of them mentioned any behavioural changes as a result of their PGHD. One of them did mention adjusting movement based on the scores they received at the end of an activity: “I automatically adjust what I was doing, if I couldn't burst every balloon I, I had to adjust.. To work out what I was doing wrong” (FG1_STC2-3). Seeing an improvement in performance data encouraged a stroke survivor to do more of the activities: “if I can see the improvement I'm making then it would…encourage me to maybe have more of those sessions” (INT1_STC3). However one stressed that positive health data was not enough, and would not have done the exercises “that long if there hadn't been somebody driving me” (INT1_STC1).

Feelings About Health Status

Most stroke survivors felt either “disappointed” (FG1_STC2-3) or pleased with themselves depending on their PGHD. Seeing their performance data go down, or “wanting to achieve and not achieving, or you not doing it the way you want” (INT2_STC1) resulted in feelings of being “disheartened” (INT2_STC1), with one going as far as describing the experience as “offensive” (INT1_STC1). “Levels of frustration” were also experienced when their data fluctuated: “sometimes you went backwards, sometimes you went forwards” (INT2_STC1). It could also be

discouraging, making one think that they may have reached their limit: “I would think well surely this is the benchmark, and so I probably thought, would have thought nah, I’m probably not gonna to [sic] get any better” (INT1_STC1), with the same survivor cautioning that “it would depress me”. Positive feelings such as “happy” and “satisfying” (INT2_STC3) abound where their PGHD were also positive. One described the experience as feeling “good about yourself” when the data was “improving” (FG1_STC2-1). Positive PGHD was also “reassuring” (INT2_STC3) and “exciting” (INT1_STC1). It could make them feel “hopeful” and “confident” because “it was encouraging,” (INT2_STC3) “saying okay you can perform” (INT3_STC1). A survivor humorously shared that it gave the assurance that “you’re not totally dead” (INT3_STC1). It can therefore be observed that positive or negative PGHD correlated respectively with positive or negative emotions.

There were however a few stroke survivors who were neither disappointed nor pleased based on their PGHD, with one saying “it doesn’t really matter”, and that the data neither “encouraged (n)or discouraged” (FG2_STC1_1). There was a sense of acceptance that their performance can go up or down: “I was very, very upbeat about my progress, I was very pessimistic about my progress. And different times I felt, different” (FG2_STC1_1). Meanwhile one survivor described seeing gains in their PGHD as “kind of surprising how much you can achieve, you know you kind of surprise yourself what you can achieve” (INT3_STC1).

Finally, while some stroke survivors associated their PGHD with their performance: “Yeah you'd know if you didn't get a hundred” (FG1_STC2-3), others relied on their own feelings about their health to assess their performance: “numbers on the screen isn't going to tell me the other, one thing or the other” (INT1_STC1). However one had lesser trust on their PGHD and more on other people describing their improvement for them: “when they say, oh, you're doing this a lot better than you were, that you actually, realise that you have improved” (FG1_STC2-3).

Interest in Care Processes

Stroke survivors reported interest in how the exercises contributed to the progress of their therapy, as a result of seeing their PGHD. They wanted “to see whether there were any gains” (FG1_STC2-3), or some “improvement” (FG2_STC1_2); asserting that “there must be some things that have, that have improved from that, even if” (FG2_STC1_1) they were tired. Others expressed interest in “having an indicator of previous performance” (FG1_STC2-3), a “comparison point” (INT2_STC1), and see how they would “stack up at the end” (FG1_STC2-3). Still others liked “tracking” (FG2_STC1_1) their progress, whether good or bad: “because I understand it, um, some days are bad, some days are good” (FG2_STC1_1). A few survivors also wanted to see when they “weren't so good” (FG1_STC2-1) that week, and when they were: “it told me when you were right it’s, it’s um.. If you are doing okay or or not” (INT2_STC3). They also wanted to know why: “because you realise that you know you're not going as far because you have the disability part of it” (INT3_STC1); and whether “there's a bit more to do” (INT2_STC3) to improve. Some of them especially remarked on things they could have done better, with one remarking that “I should have been standing up, hmm, longer for weeks” (FG1_STC2-1). As such, their PGHD could “be helpful” to know what they needed “to do (to) improve” (INT2_STC3), comparing it with teacher-student feedback: “it’s like uh, you know student getting feedback from…their teacher or something…it's important to get feedback” (INT2_STC3). One described the experience as “a bit like having a physio visit you at home, or having an OT visit you at home” (FG1_STC2-3).

Some stroke survivors also reported interest in understanding where they “were at in the program” (INT2_STC3), to see “how far there was to go if you can, by what percentage was showing” (FG1_STC2-3), and feel better when they were close to finishing an exercise: “I see the percentage, and when I was getting to seventy percent, I would think uh, this is good I'm getting towards the end” (FG1_STC2-1). This could be important for self-management, as described by one survivor: “It was certainly something that I watched, to see where I was at. 'Cause um, y- you need to think about this, we have some sort of a budget of energy that you have to manage yourself, and you can't afford to get to empty” (FG1_STC2-3).

There were a few survivors who didn’t “really care” (FG2_STC1_1), didn’t “take that much notice” (FG1_STC2-1) of their PGHD, and that they were just “going with the flow” (FG2_STC1_1). A survivor described seeing their data but not perceiving any benefit from it: “it was just information…I didn't feel I was involved in any way” (INT2_STC3). This lack of feeling involved was also true even when the PGHD was informative: “You knew what you had to do to improve or not, but I I didn’t feel involved really” (INT2_STC3).

Interestingly, a few stroke survivors reported how seeing their PGHD affected their perceptions towards their therapy. Positive PGHD gave the impression that the therapy was effective, and “the confidence of actually doing the exercises” (FG1_STC2-3); whereas negative PGHD could imply that the therapy was “pretty useless” (INT1_STC1). However there was also one stroke survivor whose perceptions of the exercises was unaffected: “I wouldn’t say I was more engaged or less engaged by it, I took it for what it was” (INT2_STC1). Finally, another survivor found that the data helped with self-assessment: “I'm good in this game but I'm not good in the other game, it gives that sort of feeling you know” (INT3_STC1).

Personal Care Goals

Stroke survivors reported receiving “an extra percentage of motivation” (FG1_STC2-1) and an “incentive to do better” (FG1_STC2-3) when they see their PGHD. Seeing how their data changed over time would make therapy more “motivational”, because it “feels like a bit of a competition? To see if we can do better” (FG1_STC2-3). It helped them develop “short term and long term goals” or a new “benchmark to try and achieve next time”, and kept one “focused to some extent” (INT2_STC1). However, it was cautioned that a downward slope could be detrimental: “you can get hard on yourself or feel ‘Oh I didn’t get that right’ and if you keep doing that and you're not achieving 100% and the score keeps flashing at you, that can be a positive motivator, but can also (be) a negative one” (INT2_STC1). There was one survivor however whose motivation remained unchanged: “I know when I haven’t done well. And numbers on the screen isn't going to tell me the other, one thing or the other” (INT1_STC1). Meanwhile, some survivors reported being motivated to simply finish the therapy, “to get to somewhere in time” and to concentrate on trying to “achieve it” (FG1_STC2-3).

Relationship with Care Provider/s

Some stroke survivors were prompted to ask their therapists when they “haven’t been doing well,” and why so they can improve: “what [sic] reason to it, and then they tell me off for certain things” (INT3_STC1). However, while they “wanted to know why it was so different so…low” (INT2_STC3), they were less prompted to ask about their performance when it was

good: "when it was good I didn't ask questions" (INT2_STC3). Surprisingly good data however prompted one to ask how it could have happened: "a couple of times I was surprised that I had a higher score when I thought I'd done badly" (INT1_STC1). Regardless, one survivor reported being prompted to ask for more assistance: "If they were always bad then I would need uh more assistance and even if they (were) good um, they (are) not perfect, right so I would want to have more, more assistance to um, to to improve" (INT2_STC3).

Discussion

This study is the first to gather perceptions of stroke survivors on the effects of PGHD for PROM development. In fact to our knowledge, this is the first study that gathered patient-reported outcomes of utilising PGHD. While there have been studies presenting patient-reported outcomes of a health condition [3, 27] such as quality of life as a result of using a PGHD-enabled device [28], and patient-reported experiences or satisfaction with health interventions and technologies [29-31], there have been no studies systematically soliciting patient-reported outcomes of utilising PGHD. This study begins to understand how PGHD may affect the health outcomes of people who use them, from their own perspective. More specifically, this contributes to the missed opportunity of the poststroke simulated rehabilitation literature to engage patients in their own health care [15].

The findings of this study demonstrate that we can measure outcomes of utilising PGHD, and have shown some similarities with PGHD effects reported in the literature. Moreover, the findings have also provided a richer understanding of the effects, and at times broadened the scope. This is a strength of conducting qualitative data collection for patient-reported outcomes of a health domain of interest [3].

The findings show that while in general patients are affected positively or negatively based on their PGHD, some are not affected at all. First, while stroke survivors' perceptions confirm previous findings that PGHD may influence positive behavioural changes [8], it has also shown that some patients may only be influenced when encouraged personally by their therapists. Second, the findings confirmed that PGHD could increase patient satisfaction with their health [10], but for the most part only when they are positive. Negative PGHD can, in the stroke survivors' own words, be offensive or depressing. Still, other survivors reported indifference to their PGHD. This emphasises the need to utilise patient-centered design when developing health technologies [32], particularly when PGHD is produced [15].

Third, this study affirms reports that direct access to PGHD can increase patient engagement [9-11]; however, we have learned that for some stroke survivors PGHD is just information that does not make them feel involved. Fourth, development of new goals or benchmarks as a result of their PGHD were also reported by stroke survivors, supporting assertions that PGHD facilitates personalised health strategies [10, 24], but others relied on their own feelings about their health to formulate their goals and were neither motivated nor demotivated by their PGHD. Finally, while the literature showed that PGHD may improve health management coordination between patients and their care providers [10, 11, 25, 26], stroke survivors using a simulated rehabilitation system may only ask questions when their PGHD shows poor results, or when their results surprise them.

These findings have direct implications for PROMs to utilise PGHD. As mentioned before, this paper is part of a larger study to develop a PROM-PGHD with poststroke simulated rehabilitation systems as a use case. For example, we noted that previous literature on effects of PGHD have not addressed "levels of frustration". This will be added as an item to accommodate for stroke survivors' experience of seeing their PGHD go up and down. This study demonstrates how the focus groups and interviews will be used to broaden the coverage of the PROM.

One limitation to our study is that all of the focus groups and interviews were moderated by the same person (GLD), which has the risk of a narrower array of themes and ideas. However, this method's advantage is that it increases the chance of thematic saturation, as GLD would have learned relevant themes as the discussions progressed [3]. Additionally, our sample was never intended to represent all stroke survivors; it was meant to elicit the input of survivors who have used a leading poststroke simulated rehabilitation technology to guide the development of the PROM-PGHD. The PROM will be refined and validated further as per the next step of QIR [5].

Poststroke simulated rehabilitation systems were selected as the use case for measuring PGHD outcomes because of the global burden of stroke and the potential benefits of simulated rehabilitation systems. However research into applicability of a PROM-PGHD for the wider spectrum of health technologies are ongoing. The authors will report elsewhere on how these PROMs are proving their validity in other cases of technology and health domains.

Practitioners and developers of health technologies need to understand how PGHD affect people differently. Therefore, when considering PGHD-enabled devices the patient perspective has to be given priority [15, 32]. Future studies should consider relevant health domain and technology use cases for applying a PROM-PGHD and evaluate their implications on the care process.

Conclusions

This study has described the importance of patients self-reporting the effects of utilising PGHD through a PROM. It has identified a pertinent use case in poststroke simulated rehabilitation systems, and gathered perceptions from stroke survivors. The findings highlight five key themes that demonstrate that PGHD outcomes of utilising PGHD can be measured. Moreover, this study has provided a deeper understanding of those effects and broadened the scope through the words of the stroke survivors themselves. The perceptions gathered here will further refine and validate the development of a PROM-PGHD for poststroke simulated rehabilitation systems and has wider relevance and application.

Acknowledgements

We would like to thank Marie-Louise Bird, Wei-Peng Teo, and Jessica Freeman for assisting with recruitment and administration of the discussions, and Cecily Gilbert for assisting GLD during the discussions. GLD would also like to acknowledge the support of his organisational sponsor, Newman College (University of Melbourne).

IoT, Cloud Computing and Big Data: Integrated Framework for Healthcare in Disasters

Samaneh Madanian[a], Dave Parry[a]

[a] Department of Computer Science, AUT University, Auckland, New Zealand

Abstract

Currently, healthcare in disaster management context faces a number of challenges mostly due to the lack of availability of reliable data from diverse sources required to be accessible by appropriate authorities. Therefore, the main objective of this study is the introduction of a framework based on the integration of three technologies, Internet of Things (IoT), cloud computing and big data to solve this issue in all disaster phases and provide precise and effective healthcare. This framework supports healthcare managers by enabling data sharing among them and assists them in performing analytical calculations to discover meaningful, logical and accurate trend(s) required for strategic planning and better preparedness in the face of disasters. Also, the outcome of the framework may help decision makers to identify and predict the health consequences of the disasters for any specific geographical location in any country based on its geographical properties and disaster background.

Keywords:
Medical Informatics, Disasters, Disaster Planning

Introduction

Disasters (natural, manmade, or epidemic) have detrimental effects and annually force huge expenses on governments nationwide in terms of economical, social, environmental, and human conditions and life. According to the statistics from Centre for Research on the Epidemiology of Disasters, the number of disasters and their complexity and severity (damage to life and property) shows an upward trend over recent decades. Only in 2017, 536 disasters occurred causing 16,458 deaths, affecting 95,979,187 people and costing USD 337,542,768,000 globally [1].

Regardless of disaster types and sources, their consequences mostly threaten people's health and wellbeing to varying degrees. This includes injuries or deaths of the affected people or even disrupting the healthcare systems that affects both disaster injuries and people with chronic healthcare conditions who still require care. Therefore, the greatest challenge to healthcare systems is probably when it is to deal with disasters; they should change swiftly from their everyday activities to adjust to the conditions of great uncertainty that, at the same time, may exceed their available resources and their ability to attend to a large number of casualties in a short time [2].

Although most disasters are not preventable, having a proper healthcare preparedness plan in advance can significantly lessen the harmful effects of disasters and diminish their adverse consequences. For such a plan and addressing citizens' healthcare requirements more effectively, reliable data from diverse sources are needed to be shared among different authorities and parties in disaster management. In this regard, effective data gathering and sharing is the building block leading to more accurate data analysis and information extraction required for a disaster healthcare plan. This issue is a challenging task and has not been effectively addressed yet.

The attempt in this paper is to introduce an integrated framework of three technologies. This framework aims to address challenges in data collection and sharing that are faced by different authorities, including healthcare, within Disaster Management Cycle (DMC). The framework enables automatic data collection and sharing that can be categorized for each region and the whole country before, during and after disasters. Also, it can further be used for real-time decision making, discovering trends, and possibly forecasting healthcare consequences of disasters on communities, or predicting epidemics outbreak. Moreover, it is expected that authorities will be able to prepare customized healthcare disaster management plans based on the geographical location properties, disaster history and the healthcare background of their inhabitants.

The rest of this article is organized as follows. First, the research methods and motivations are explained. Then, a brief background of the utilized technologies is provided. After that, the proposed model is presented followed by detailed explanations of its layers and its implications.

Research Methods and Motivation

As a part of Disaster e-Health (DEH) project (see [3] and [4]), a comprehensive scoping study in three fields of disaster management, disaster medicine, and healthcare was conducted. The scoping study was carried out in two different phases of controlled and uncontrolled search in 13 different databases including Scopus, CINAHL, ProQuest, IEEEXplore, Science Direct, and PubMed. In these databases, keywords or combination of keywords such as disaster, healthcare, technology, e-health and challenges, were used to extract relevant studies. Among 3956 captured articles in uncontrolled search and 925 articles in controlled, after considering the exclusion factors, 264 and 328 articles in each method, respectively, were selected for review.

Citizens' health requirements and demands following disasters are varied and highly depend on the disaster types, location, and intensity. Therefore, efficiency and effectiveness of healthcare disaster response activities are of prime importance due to finite resources compared to the number of affected population. In most disasters, preventing further life loss has a direct relation to the level of preparedness and readiness of different organizations in a community. Thus, pre-disaster phases, that is, preparedness and mitigation, are key elements of effective

response; however, their importance may be hidden or underestimated unless a major disaster occurs [5]. By managing pre-disaster phases wisely and properly in their planning, there will be no, or less need to run response and recovery phases as the disaster risks are prevented or reduced and appropriate systems, procedures, and resources are in place to assist affected population [6]. Consequently, rather than a reactive system, governments can shift to a proactive system.

However, most healthcare centers are still struggling to prepare an appropriate disaster management plan. According to the results of the scoping review, some of the identified root cause challenges are:

- Data gathering (considering data quality and reliability)
- Data sharing (which data, how to share and with whom)
- Data analysis (healthcare risk analysis to prepare for disaster threats, respond to and recover from them)

Data gathering and availability can be the greatest challenge for preparing an effective disaster management plan for healthcare centers most of which suffer from a lack of reliable and relevant data. This deficiency forces most countries, especially developing ones, to have a general, or national, disaster management plan mostly prepared and designed based on the assumptions for the whole country with no or a very few customizations for different regions [7]. However, based on regions' backgrounds, having some customization is a must. It is expected that disaster healthcare plans would be more effective if created for each geographical region by considering the number of its inhabitants and its disaster background information, including type, frequency, severity, and consequences. This information helps healthcare authorities to prepare region based and customized disaster healthcare plans, which are possibly more effective and efficient, and they may result in a better and effective healthcare response.

For a precise and effective disaster healthcare plan, it is necessary to have information regarding past disasters, and the effectiveness, success or failure rates of healthcare response activities. However, many countries have little information regarding the real effectiveness and efficiency of their healthcare response activities or their challenges and deficiencies [8, 9]. Therefore, healthcare response shortcomings have not been identified properly, and consequently, learned lessons from past disasters are poorly considered for future healthcare planning. This issue results in having mitigation and preparedness plans mostly based on the assumptions and not on the real data or information. This not only wastes a lot of valuable resources, but it also results in not being able to meet some of the demands of disaster casualties, specifically the healthcare related demands [10].

Technology Background

Information Technology (IT) utilization could be a viable solution for the identified challenges. It has the potential to improve overall disaster management, better prepare against disasters, facilitate response when disasters occur, enhance support after disasters, and keep records for better future preparedness.

In the proposed framework, three different technologies are utilized. These technologies have already revolutionized other fields/industries such as supply chain, healthcare and military. Therefore, it is believed that they may offer a huge potential for healthcare within disaster DMC. Although these technologies by themselves are powerful, it is expected that they may exploit further potential if they integrate with each other.

Internet of Things (IoT)

IoT is a technological phenomenon that stems from new advances and ideas in ICT, and it is related to ubiquitous communication/connectivity, ambient intelligence, and pervasive computing [12]. It comprises sensing devices and technologies such as sensors, Radio Frequency Identification (RFID), and Global Positioning System (GPS) [12] and network and communication components such as Wireless Sensor Network (WSN), 4/5G communication, and Wide Area Network (WAN). IoT integrates humans, physical objects and digital devices by making use of distributed sensors in environments [13]. IoT enables people to automatically gather all sorts of data and information such as location, movement, sound, and heat. Since IoT encompasses different types of technologies and components, its scope covers a broad range of applications in different fields such as healthcare, military, supply chain, and agriculture. IoT Devices are already starting to appear in the consumer space in the form of wearable devices and smart appliances so that it may be possible to both use data from these devices and the infrastructure being built to support them.

Cloud Computing

Cloud computing is a framework of "abstracted, virtualized, dynamically scalable, managing, computing, power storage platforms and services for on-demand delivery over the Internet." [14]. It consists of both hardware and software that offer various services in different levels of infrastructure, platform and software [15]; it has revolutionized IT resources utilization in different industries. Cloud services are available anywhere at anytime and bring flexibility and scalability of IT services and resources while enhancing their employment in different levels and organizations. Cloud computing provides a series of advantages for the organizations as mentioned by [16] including scalability, reliability, efficiency, and data storage.

Big Data

The "Big data" concept has emerged as a result of a massive increase in data with regard to its quantity, type and speed of generation. Big data can be defined as "high volume, high velocity, and/or high variety information assets that require new forms of processing to enable enhanced decision making, insight discovery and process optimization" [17]. Big data is used in different organizations for analytical purposes. Its data are from diverse sources, and sometimes in real-time manner, fueled by the latest development in technologies such as mobile devices adoption, social media, IoT, and RFID [18].

Related Studies And Research Objectives

Although the applications of the discussed technologies in other fields are increasing, only in recent times have the researchers started exploring the role of these technologies for disaster management purposes. However, there are some gaps in these studies. A significant number of solutions concentrate on utilizing only one technology: ([19, 20] on IoT, [21, 22] on big data, and [23] on cloud computing). Some others have utilized these technologies for a specific disaster phase: ([24] on disaster recovery, [22, 25-27] on disaster response, [28] on disaster response and preventive monitoring). Still, some other studies look into a specific activity in a specific disaster phase ([21] on big data for disaster relief activities and supply chain

management). Only a few research studies proposed their solutions based on technology integration for addressing the disaster management challenges ([29] integrated big data and cloud computing, [30] proposed big data and IoT integration, and [25] integrated cloud and IoT). Among the identified studies, only, [31] integrated all the mentioned technologies for the purpose of event detection and sending alerts, and coordinating rescue and medical operations. Therefore, it can be said that among all the recent research, little attention has been paid to technology integration and healthcare operations, specifically for pre-disaster phases.

In this context, in this research, the proposed framework has the potential to be used in supporting and assisting healthcare and governmental authorities in their decision making and disaster healthcare planning for any disaster type, in different phases and for different regions. The objectives of the framework are:

- automatic gathering precise and real-time or near real-time data at all disaster phases
- aggregating the captured data to facilitate data sharing among different parties
- identifying and revealing any meaningful trends in the captured data that can be utilized for forecasting future disasters and the required healthcare actions resulting in accurate disaster healthcare planning and precise response
- enabling authorities to customize and localize disaster healthcare planning based on regions' precise data.

Technology Integration and Proposed Model

One of the greatest challenges for preparing an effective disaster management plan for healthcare is the lack of reliable and relevant data. It is believed that a great number of issues can be prevented in healthcare by having better and quality data. These data can be a great source for healthcare disaster planning and management as we cannot manage something when we cannot measure it.

Therefore, the proposed framework in this research integrates and utilizes three advanced technologies in three layers (Figure 1) to facilitate data gathering, sharing and analysis which are necessary for an effective disaster healthcare plan and management, as these areas have been identified by several researchers as barriers [10, 32-34].

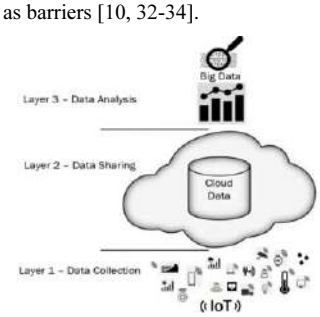

Figure 1 – Proposed Technology Integration Model

Layer One: IoT

The aim of this layer is to solve the problem of data availability and reliability by utilizing different IoT devices. The IoT devices are able to precisely capture different types of data for a particular case (object or human) with no or minimum human intervention in a periodic or continuous form in a specific location. These data can be people's vital signs or location, environment temperature, humidity, location of the objects, etc. The variety in the data types makes IoT suitable for monitoring purposes and transmitting or receiving real-time data regarding different conditions in the implemented environment. Furthermore, as most of the IoT devices have embedded memory and are battery powered, if network and power are disrupted by disasters, they can save data in their memory and upload them whenever their connection reestablishes. Therefore, the effects of disruptions in network communication after disaster could be mitigated.

Based on IoT functionalities and by giving digital identity to the objects, IoT sensors are able to be context-aware, sense the monitoring environmental conditions, communicate with neighboring nodes and even sometimes perform some basic computations on the collected data [35, 36]. These unique features of IoT can integrate the objects in the real world with the digital environment which, eventually, brings an integration, and relevant and quality data/information for healthcare planning at all phases of disasters. IoT also provides a cooperative monitoring environment either for environmental conditions or physical objects. Moreover, as IoT sensors require no or little human intervention, they can be used in harsh or infectious environments where conditions are not suitable for human work [35]. In such situations, the sensors can be set to execute processes to activate specific actions or create services [36].

Layer Two: Cloud Computing

Although in disaster healthcare planning, data availability and quality are crucial, sharing these data with right authorities is vital. Otherwise, even having quality datasets, may lead us to thousands of silos of fragmented data. While data sharing is the other common problem in healthcare planning. Therefore, the second layer of the framework attempts to address this problem by utilizing cloud computing technology. Furthermore, to apply the full potential of IoT, it seems that utilizing cloud computing in parallel with IoT is vital [37].

Cloud computing can provide the required virtual infrastructure for integrating the monitoring devices [37]. As it is required to store a wide range of data types, cloud facilitates deployment of a system for data sharing across different platforms and through a unified framework for a fast and easy access with unlimited data storage [16, 37]. This technology is an efficient and reliable solution for data sharing among different parties and authorities and supports collaborative work and access anywhere. Moreover, it is potentially more resilient and scalable in terms of physical locations.

In this layer, the captured IoT data available in a single cloud repository ultimately facilitate sharing of data and enhance collaboration and cooperation of people, programs, processes and services [36]. This issue is particularly important in healthcare as all the parties will be able to work on a common and aggregated data and establish a network to coordinate and exchange data more effectively and efficiently that, in turn, also supports strategic planning and research. Moreover, different authorities and governmental agencies, including healthcare, monitor different types of objects, locations and environmental conditions in a way that if any significant issues happen, they can respond swiftly.

Layer Three: Big Data

The outcome of the lower two layers is an integrated repository of data of differing quality, provenance and or reliability which disaster management and planning can use for evidence-based

plans and responses. For this purpose, the analysis and validation of all the captured data from monitoring devices are required. In this context, big data algorithms and analytics can be considered since they have the potential to make use of those data and extract the available trends and evidences. As in the previous layer cloud computing has been used, big data sharing and exchange becomes possible without further investing in big computing assets [38]. Big data algorithms and analytics can be used to visualize the connected IoT objects, make sense of them and help IoT for acceptance, usage and influence [18]. For this purpose, big data analytics tools and applications can be used to exploit the full potential of the proposed framework by converting the data into information and knowledge. In other words, big data "takes the amount of intelligence within the network to another level where devices reason and take action in ways that aren't necessarily preprogrammed or even initially understood by humans" [18].

This layer's outcome could facilitate supplying information and knowledge required for disaster healthcare planning as well as enhancing the quality of the plans and decisions in both normal and disaster situations. The generated information can be real-time for immediate decision making in any alarming situations [2], such as epidemics outbreak, or about the past disasters to support healthcare resilience and prevention research.

Discussion

Appropriate and precious healthcare planning, for normal or disaster situations, relies on past together with real-time data from various sources. If these data are available and reliable, their aggregation in a single repository with further processing and analysis may result in extracting important information and trends that have the potential to enhance the quality of disaster healthcare planning and preparedness. Hereof, it is believed that integrating the discussed technologies can support governments and authorities to provide a more accurate, robust and customized disaster preparedness and response plans based on the geographical locations by considering their geographical conditions, healthcare and disaster backgrounds. The proposed framework can be seen as a possible solution to the identified challenges in the disaster healthcare. The following paragraphs discuss the contribution of each technology.

IoT connects the physical objects with the digital world and makes objects identifiable and traceable. It also can collect and disseminate data from the monitoring areas to the control centers. Besides this offered convenience, these connected and intelligent devices could have the life-saving applications during disasters and be considered critical applications [39] as they can capture and then disseminate accurate data with minimal human interventions.

However, for a complete realization of the IoT potential, an efficient, secure and scalable storage is required. Consequently, in the proposed framework, cloud computing is suggested that can also provide a reliable and ubiquitous access to the dynamic IoT objects [37]. Therefore, the large amount of the collected data from IoT devices are aggregated and shared among different centers through cloud computing. In this way, collaboration among parties is improved, and critical data are swiftly distributed to the top decision makers [36].

This integrated repository can be considered as an easily accessible platform for using data mining models to discover new facts and trends. For this purpose, big data approaches such as large-scale visualizations, stream processing, machine learning, etc. can be used to generate knowledge and discover trends. This information can be employed by decision makers and other authorities for a quality strategic planning and predicting future requirements and demands in the face of disasters.

As a result of adopting this framework of interconnected sensing devices, sharing data across different platforms through a unified framework becomes possible. Therefore, healthcare decision-makers will be able to use the real-time and precise data for real-time decision making [36, 37] and for better understanding the impact of disasters and reacting more appropriately [40] with respect to the healthcare consequences. Additionally, every healthcare center is able to be integrated into the disaster plans, along with its critical components of the response efforts [41], and its situations can be assessed by using big data and cloud computing. This framework can also make data and information available for the wider and authorized access that may enhance data processing and sharing.

This approach may also enhance and facilitate decision making in the healthcare response missions as different objects in the monitoring environment are inter-connected via their properties [13]. Therefore, IoT for the disaster management application not only can be seen as a data acquisition technology, but it can also facilitate establishing a more effective, intelligent and goal-oriented communication [11]. Moreover, information regarding medical resources availability and location can be tracked and shared among related organizations automatically and without any human intervention that, in turn, results in enhancing tasks efficiency and accuracy. Consequently, matching the available medical resources and staff with the region population can be performed in disaster preparedness, and the chance of overwhelming different systems and organizations can be decreased in the disaster response.

Conclusions

IoT, cloud computing and big data are powerful on their own but together can potentially improve disaster healthcare. The combination of these technologies will require work to assure privacy and safety. However, research in these areas may produce synergistic benefits. Frameworks for integration of these approaches are vital for effective implementation.

Abstract

Influenza is an important public health problem with consequences on the health of people, but also at the state level with social and health costs due to the morbidity and mortality produced. Vaccination is an act of care of high clinical complexity, which can be learned and trained, so that decision-making in vaccination requires elements of judgment that act logically in a cascade. The creation of algorithms and their implementation in computer systems will identify susceptible people more quickly and improve the competence in the administration of vaccines. For the creation of the algorithm, the variables and their relationships were identified through mathematical formulation. As a result, the nine variables for vaccination that result in 47 different clinical situations were identified (29 "non-vaccination" and 18 "vaccination" situations). The formalization of algorithms in vaccine administration allows to represent the process by which the professional carries out the decision making process.

Keywords:

Algorithms; Decision Support Systems, Clinical; Influenza Vaccines

Introduction

The present study starts from the following reseach aim: to design an algorithm that describes the decision-making process in influenza vaccination. Influenza is an acute respiratory infection caused by RNA-virus that encompasses different groups (mainly groups A, B and C) with type A being the most prevalent [1]. This infection appears in the form of epidemic outbreaks and because of the high rate of virus mutation (especially H3N2) [2], annual vaccination is necessary (with an effectiveness of 70-90% if there is concordance between the strains) [3,4]. The virus is transmitted by air, and transmission period may begin from one day before the symptomatic phase to seven days after symptoms start [5]. Influenza is characterized by high fever, cough, muscle and joint pains, headacheand and intense discomfort. In people with poor health, the flu and its complications can be fatal, due to pneumonias caused by secondary bacterial invaders [1].

Worldwide, influenza accounts for about 300,000 to 600,000 seasonal influenza-associated respiratory deaths annually [2]. In Spain, the flu surveillance report indicates that 5,977 severe hospitalized confirmed cases of influenza were reported, of which 21.8% were admitted to the ICU and 17.3% died in the 2017/2018 season [6]. In the Community of Madrid, an accumulated incidence of 1,540.33 cases per 100,000 inhabitants was estimated in the same season [7]. In conclusion, influenza is a major public health problem worldwide related to a high rate of morbidity and mortality, increase in social and health costs, potentially preventable and whose management and control of risk should continue to evolve and improve to increase the level of health of the community [2,7].

Vaccination is one of the main acts of care in primary prevention, definid as health behaviors aimed at avoiding the health problem, or reducing the probability of it appearing [8]. In particular, it is essential for the prevention of health problems of infectious origin worldwide [9]. Fernandez Batalla et al. indicate that vaccination is an act of care of high clinical complexity, which can be learned and trained, so that decision-making in vaccination requires elements of judgment that act logically in a cascade. The first assessment should be based on the characteristics of the individual (vaccine selection) and then the administration decision according to the context [10]. In addition, the computational implementation of decision-making in care allows a better identification of the population to which vaccination is recommended. This allowed us to design tools for specific distance recruitment and increase vaccination rates, which has been progressively decreasing in recent years [11].

Methods

For the identification and description of variables, the methodology used was deductive, based on:

- Extraction of knowledge through text analysis
  - Scientific and technical regulations of the Public Health services, in relation to the indication of influenza vaccination for the 2017-2018 influenza campaign of the Community of Madrid.
  - Instructions for use and technical data sheets of the influenza vaccines available in said campaign.
- Education throught expert's knowledge.

The expert group consists of a nurse doctor in computer science, mathematical doctor in computer science, a nurse specialist in community health, and two master's degree nurses in multidisciplinary informatics.

Establishment of existing relationships between variables: algorithm creation.

- Mathematical formulation through bivalued logic: Identification of relevant clinical variables and definition of possible values for each variable[12-14].

Results

Extraction and Definition of the Variables.

A total of 9 variables relevant to influenza vaccination were selected.

Age

Time a person has lived at the time of the valuation. It was classified into 6 stages: less than 6 months (e0), 6 - 35 months (e1), 3 - 8 years (e2), 9 – 59 years (e3), 60 - 64 years (e4) and 65 years or more (e5).

Life Process

Indicates the presence of factors that indicate risk group for vaccination. Three main groups were identified:

- Processes that increase the risk of complications from the flu
- People who can pass the flu to those who are at high risk of complications
- Essential public service workers

With the presence of one factor it will be considered posive (r) while the absence of all of them will be considered negative (¬r)

First Vaccination

Indicates that the person has not been vaccinated against the flu in previous years (p).

Interval Between Doses

When vaccination with several doses is necessary, it indicates that 4 weeks have passed after the first dose (i).

Initial Dose

When vaccination with several doses is necessary, it indicates that the vaccine proposed constitutes the first dose to be administered in this anti-flu campaign.

Influenza Vaccination Completed

Indicates the correct vaccination in the current anti-flu campaign (c)

Health Situation

Indicates the presence of factors that contraindicate the administration of the vaccine at that time. Three main situations were identified: fever, acute infection, allergy to some components of the vaccine.

With the presence of one factor it will be considered posive (s) while the absence of all will be considered negative (¬s).

Anticoagulation

Indicates that the patient is at increased risk of hemorrhage by intramuscular puncture (a).

Vaccination Action

It is the result variable. Indicates whether the vaccine is indicated (v) or not (¬v) and complementary information (type of vaccine, dose, route of administration, cause of non-vaccination).

Order of Variables

For decision making in vaccination, a hierarchy of the variables is necessary to indicate when to ask for each variable.

The final formalization of the variables is presented in Table 1.

Table 1 – Description and Formalization of Variables

Variable	Order	Code	Range
Age	1	e	e0 –e5
Life process	2	r	r/¬r
Influenza vaccination completed	3	c	c/¬c
First vaccination	4	p	p/¬p
Initial dose	5	d	d/¬d
Interval between doses	6	i	i/¬i
Anticoagulation	7	a	a/¬a
Health situation	8	s	s/¬s
Vaccination action	9	v	v/ ¬v

Establishment of the Relationships Between Variables

With the identified variables, a total of 47 different clinical cases were obtained leading to a specific vaccination action (Table 2).

- 29 "non-vaccination" situations. The algorithm has five different causes that indicate "no vaccination" (distribution in Figure 1).
- 6 situations in which to vaccinate with inactivated vaccine (0.25ml)
- 11 situations in which to vaccinate with inactivated vaccine (0.5ml)
- 1 situation in which to vaccinate with inactivated vaccine with adjuvant (0.5ml)

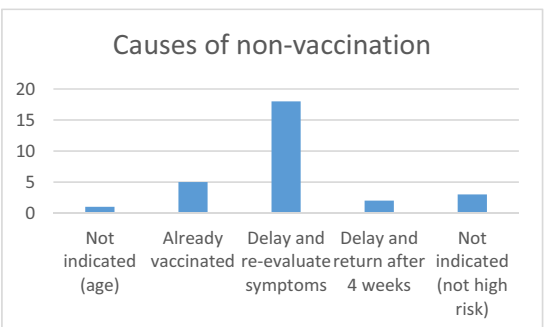

Figure 1 – Distribution of Reasons for Non-Vaccination

Table 2 – Coding of the Algorithm

Discussion

In relation to the use of Information and Communication Technologies, the CDC indicates logic specification for ACIP Recommendations in Clinical Decision Support for Immunization (CDSi). The variables used in this research work resemble the variables defined by the CDC (Target dose, patient series)[15].

In the context of primary health care, Martín-Ivorra indicates that the development of this type of tools would improve to identify the people of being vaccinated who attend the scheduled consultations in Primary Care[16]. On the contrary, it has found different publications that indicate that the use of ICTs are useful to determine and increase vaccination coverage[17,18].

Gerard et al. developed a system of influenza vaccination reminders in a hospital's information systems to increase the rate of influenza vaccination in patients hospitalized in internal medicine. Although the system was effective, it did not discriminate the indication of the vaccine based on their clinical features[19]. In relation to decision making in vaccines, Jacobson describe the development, of a software tool, introduced to assist health care professionals and public health administrators in managing pediatric vaccine purchase decisions and making economically sound formulary choices[20]. In relation to the methodology, Shiffman and Greenes used this methodology with with logic and decision-table techniques to improve cinical guidelines applicates to prevention of perinatal transmission of hepatitis B by immunization[12].

Conclusions

The formalization of algorithms in the vaccination allows to represent the process by which the professional carries out the decision making process, in this case, in the influenza vaccination. In addition, the algorithms serve as a guide for the professional. The hierarchy of variables is not the most computationally efficient but it represents in a better way the process of decision making. To measure progress in vaccination decision-making training, it is proposed to incorporate a case generator into the application in the future. Thanks to the development of the algorithm, all the variables have been coded to generate these cases.

Abstract

Even though Adverse Drug Reactions (ADRs) constitute a significant public health issue, there is a lack of Information & Communication Technologies (ICT) tools supporting Pharmacovigilance activities at the point of care. In this paper, we present the rationale of a Web-based platform to address this need. The driving user scenario of the proposed platform refers to a clinician who investigates information for a possible ADR as part of a specific patient treatment. The goal is to facilitate this assessment through appropriate tools for searching various relevant data sources, analysing the acquired data, aggregating the obtained evidence, and offering follow-up ADR monitoring over time in a systematic and user-friendly way. In this regard, we describe the adopted user requirements engineering methodology and illustrate the use of Knowledge Engineering (KE) as the platform's main technical paradigm to enable heterogeneous data integration and handle the complexity of the underlying information processing workflow.

Keywords:

Pharmacovigilance; Drug-Related Side Effects and Adverse Reactions; Knowledge Management

Introduction

Pharmacovigilance (PV) is defined as "the science and activities related to the detection, assessment, understanding and prevention of adverse effects or any other possible drug-related problems" [1]. As Adverse Drug Reactions (ADRs) cause a significant social and financial burden [2], PV is widely recognized as an important public health priority. An estimation by the US Office of Disease Prevention and Health Promotion has recently calculated that Adverse Drug Events (ADEs)[1] are responsible for 1 in 3 of all hospital adverse events, related to about 2 million hospital stays each year, and increased hospitalization by 1.7 to 4.6 days[2]. Thus, the detection and prevention of ADRs at the point of care rise as a major clinical issue as the probability of benefit should balance the possibility and cost of potential harm [4].

The assessment of potential new or incompletely documented ADRs (called "signals") is typically performed by national and international drug monitoring/regulatory organizations (e.g., the Food and Drug Administration [FDA] in the US, the Uppsala Monitoring Centre [UMC], World Health Organization collaborating centre for international dug monitoring). These organizations perform statistical analysis of individual case safety reports (ICSRs) gathered in Spontaneous Reporting Systems (SRSs), in order to identify indications of a causal relationship between the drug administration and the adverse effect based on the measures of disproportionality [5], taking also into account other sources of evidence (e.g., scientific literature, clinical trial databases, etc.).

While SRSs are the dominant data source for PV, recent advances in Information and Communication Technologies (ICT) enable the exploitation of new, emerging data sources that can expand the real-world evidence base for PV (e.g., observational healthcare databases, social media, internet search logs). Thus, the need for comprehensive and knowledge-intensive ICT tools supporting the systematic and efficient exploitation of diverse data sources for PV is evident, in order to accommodate the entailed big data challenges [6].

To this end, we develop a Web-based platform aiming to facilitate the early identification and assessment of potential ADRs at the point of care. The main objective is to contribute at "active", post-marketing drug safety surveillance [7], focusing on the timely assessment of potential drug safety risks, supporting clinicians (as well as PV experts and researchers) to explore diverse data sources of interest and obtain actionable insights via knowledge-intensive analytics [8]. The proposed platform is currently in its "user requirements analysis" and "design" phase, which is driven by the real-life scenario according to which a clinician investigates information for a possible ADR as part of a specific patient treatment. The ultimate goal is to facilitate the integration of ADR assessment in routine clinical practice (Figure 1), by introducing tools that facilitate the search of diverse data sources, the analysis of the acquired data, the aggregation of the evidence to conclude with ADR assessment, and follow-up ADR monitoring over time in a systematic and user-friendly way.

In this paper, we present the methodology applied and the main challenges identified during the "user requirements analysis" phase of our development, which were in turn mapped to relevant user goals. We also illustrate the main elements of the platform design through the respective information processing workflow. In this regard, we elaborate on how a Knowledge Engineering (KE) based approach can accommodate the re-

[1] ADEs include side-effects that may or may not have a causal relationship with the respective drug, also referring to cases of adherence failure. ADRs refer only to side-effects caused after legitimate drug use, therefore implying a possible causal relationship between the drug and the adverse effect [3].

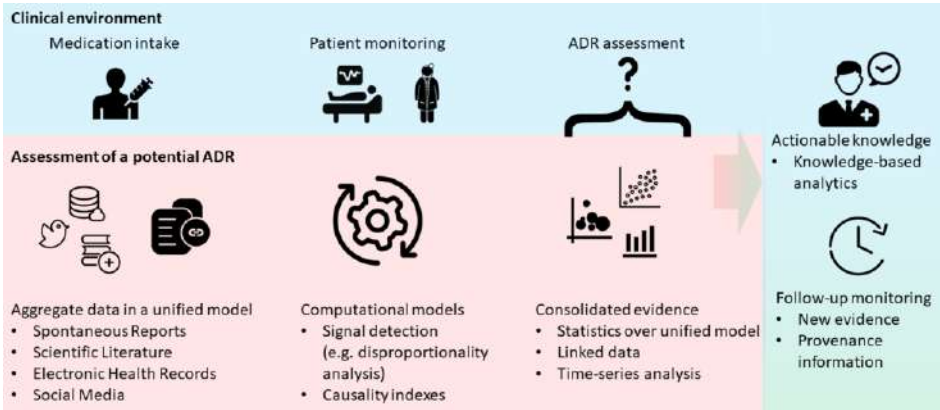

Figure 1 - Integrating the ADR assessment process in the clinical context.

spective design and development challenges. We further discuss practical implications of our work and outline directions for future work, aiming to support a comprehensive learning health system for active, post-marketing drug safety surveillance at the point of care [9].

Compared to relevant works, like the SALUS platform [10], which focused on exploiting Electronic Health Records (EHRs) for ADR detection, or the platform developed in WebRADR [11], which exploited social media for new insights on drug safety, our work relies on multiple, diverse data sources, increasing the search space for real-world evidence with an explicit focus on the clinical environment.

Methods

The employed "user requirements analysis" process is an adjusted version of the methodology described in [12]. It can be summarized as follows:

1. Analysis of the currently applied *Business Processes* (BPs) based on the respective user scenarios.
2. Definition of *User Goals* upon the elaborated BPs based on end-user input.

A *Business Process* (BP) is defined as a collection of relevant and ordered structured activities/tasks aiming to produce a specific outcome [13]. ADR assessment can also be considered as a BP conducted in the context of a hospital, as part of other parallel BPs (e.g., patient treatment, administrative processes). We envisage that the use of the proposed platform could reform the current process of ADR assessment, typically conducted manually and without systematic ICT support, to a well-defined sequence of information processing steps, supporting the overall clinical treatment processes. The ultimate goal is to optimize this BP model by satisfying the so-called *User Goals*. User goals are defined as "abstract user requirements, not directly referring to specific technical solutions or components" [12], associated with specific user actors or roles and facilitating timely identification and resolution of potential conflicts between actors. For the optimization of the ADR assessment process, user goals were elaborated based on feedback provided by clinicians and PV experts in the "user requirements analysis" and the "design" phases.

Regarding the presented platform design, the main BP of interest refers to the assessment of a potential ADR by a clinician. However, other BPs could also interact with it, e.g., concerning the patient's treatment. Given that patient treatment is the topmost priority in the clinical environment and that it is a personalized process, highly dependent on the local context (e.g. the way the specific clinic/hospital is organized), the modelling of these "interacting" BPs is very important and could be rather complex. The proper modelling and early identification of such BP interactions could be critical as they may substantially affect the identified goals and, thus, the platform design.

We model the identified BPs using flowcharts based on a notation similar to Business Process Management Notation (BPMN), in order to identify decision points, possible information processing bottlenecks, interactions with other BPs, etc. These flowcharts are further refined collectively by ICT experts, healthcare professionals (i.e., clinical doctors) and PV professionals (i.e., scientists who investigate potential ADR signals). Furthermore, interviews and workshops among researchers and end users were conducted as part of the overall "user requirements analysis" phase to analyse the established BPs, identify the *User Goals* and refine the platform's information processing workflow accordingly. Meetings were also held in the clinical environment (i.e., in the two hospitals which will host the platform in its pilot phase) to validate these goals and also address deployment issues in practice.

All types of current and emerging data sources considered in PV [6], were found interesting to explore by the end users. These include the local EHR systems, national and international SRSs, reference bibliographic databases as well as social media. From a technical viewpoint, programmatic data access is considered of high priority, as it enables systematic data gathering (e.g., spontaneous reports from the FDA Adverse Event Reporting System via openFDA [14], articles via the PubMed Central Application Programming Interface).

In order to successfully accommodate the imposed challenges regarding the synthesis and analysis of the vast data available, *Knowledge Engineering* (KE) is adopted as the main technical paradigm for our platform development. KE refers to methods, tools and theories for developing knowledge-intensive applications [15], and includes *knowledge extraction*, *knowledge integration*, *knowledge representation*, *knowledge dissemination*, and *knowledge elicitation* as its subdomains.

In the scope of our work, which concerns the systematic exploitation of all the available evidence from multiple PV data sources for the assessment of possible ADRs, we employ two technology artefacts tightly related with KE, namely, "*Linked Data*" [16] and "*Semantic Web*" [17]. Linked Data refer to a group of standards which facilitate the interconnection of data

over the existing Internet infrastructure, while Semantic Web refers to the vision of semantically annotated publicly available data interlinked via Linked Data standards.

The use of Semantic Web and Linked Data standards provides two main technical benefits: (a) *Interoperability:* The use of the Linked Data paradigm provides syntactic and semantic interoperability tools to interlink heterogeneous data sources and unify them in one processing realm. (b) *Reasoning capabilities:* The well-defined semantics upon a robust mathematical infrastructure, i.e., Description Logics [18], enable automatic reasoning through specific software, a.k.a. "reasoners".

Results

Based on this methodology and the choice of KE as the main technical paradigm, several challenges were identified from the end user perspective, leading to concrete user goals and the design of the platform's information processing workflow. In particular, given the characteristics of the clinical environment, the following challenges (enumerated with Cx) regarding the adoption of an ICT-based ADR assessment process were identified:

C1 | *Lack of time*: While the assessment of potential ADRs is identified as an important task, it is often neglected by clinicians due to lack of time.

C2 | *Lack of expertise*: PV entails specialized knowledge, which may not be available in clinical settings. While this argument supports the need for ICT-based support tools, it could also be conceived as a barrier for their adoption as their value might not be evident for the end-users.

C3 | *Adaptation to the clinical workflow*: Workflow diversity among various clinical environments (different hospitals, or even different clinics in the same hospital apply different BPs) could hinder the definition and the adoption of a "one-size-fits-all" workflow of PV information processing.

C4 | *Inadequate evidence*: While spontaneous reports are the dominant source of evidence for PV, other data sources such as EHRs, bibliographic databases, and even social media platforms are interesting for clinicians during ADR assessment. However, systematic access to multiple data sources shall be facilitated through appropriate tools.

C5 | *Coping with "big data"*: Expanding the search space for PV does not only provide a broader evidence space, but it also imposes "big data" challenges.

Overall, challenges C1-C5 have been discussed in the conducted workshops and the following user goals (enumerated with Gx) were identified and mapped to the respective challenges:

G1 | *Flexibility and Unobtrusiveness (mapped to C3):* The ADR assessment process should be flexible and tolerant to interruptions by tasks directly related with patient treatment. Thus, an important feature would be the ability to easily recover from such interruptions. Practically, this can be interpreted as the need to "save" the ADR assessment workflow and continue later. In addition, clinicians stressed that the patient's treatment should not be disrupted. Thus, the designed process should be as unobtrusive as possible, minimizing "alerts"/ "warnings".

G2 | *Balance between assessment depth and speed (mapped to C1 and C5):* As the clinician's time is valuable, the platform should enable both "in depth" assessment capabilities, while also supporting a "quick look" which could provide rigorous information. Although the information provided this way would obviously be more superficial than an "in depth" assessment, it could still provide value for clinicians.

G3 | *Semantic enhancement (mapped to C1, C2 and C5)*: Since the expression of the drug and condition of interest can be ambiguous (e.g., active substances, trade names, synonyms etc., could be used as drug terms), the overall process should be supported by curated standard terminologies and lexicons (e.g., with automatic synonym matching) to accelerate and facilitate information search and synthesis.

G4 | *Heterogeneous data synthesis (mapped to C4 and C5):* Clinicians identified the need to synthesize various and heterogeneous data sources (e.g., scientific literature, drug-information databases, clinical trial information, SRS data, observational healthcare databases). Overloading the end user with incomprehensible data was identified as a major risk and, thus, the need for knowledge-based analytics emerged.

G5 | *Data sharing (mapped to C2):* The need to share data to further elaborate on the collected ADR information and assessment results was also identified. Moreover, the value of data provenance was highlighted, especially for the process of reporting assessment outcomes to regulatory organizations.

G6 | *Follow-up monitoring over time (mapped to C4):* Typically, an ADR assessment produces a report with the conclusion and the supporting evidence. However, the time dimension is critical in PV, especially regarding newly marketed drugs. Thus, a follow-up mechanism for monitoring potential ADRs over time is important and is currently missing.

The main information processing workflow supported by the proposed platform (Figure 2) that was defined based on the abovementioned challenges and user goals are organized in 5 steps. These steps are summarized next, describing the use of the KE methods that are applicable in each case:

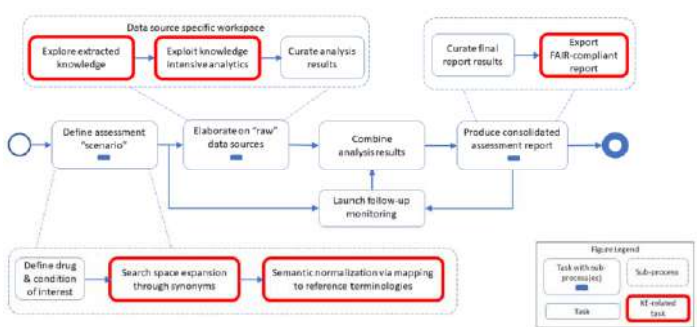

Figure 2 – Outline of the main information processing workflow supported by the proposed platform (tasks related with Knowledge Engineering are highglihted in red).

Step 1 | *Definition of "ADR assessment scenario"*: When the user launches an ADR assessment, the platform shall support the definition of the drug and the condition of interest by automatic suggestions of synonyms and relevant terms obtained from reference terminologies, e.g., the Anatomical Therapeutic Chemical (ATC) classification for drugs, and the Medical Dictionary for Regulatory Activities (MedDRA®) and the International Classification of Diseases (ICD) for the conditions of interest. The use of such well-defined knowledge structures expands the search space, enables the semantic normalization of the overall process, prevents ambiguities, and facilitates automatic information interlinking in the next analysis steps.

Step 2 | *Browse/analyse raw data from each data source*: Each raw data source has its own characteristics. For example, SRS data could be used for disproportionality analysis, while EHR data could be explored through observational healthcare data analytics [14]. KE approaches will be exploited for the analysis of each data source, e.g., text mining techniques can be used to extract and semantically annotate information from unstructured data sources such as the literature or social media. Thus, the end user can browse or analyse the respective data source in a dedicated workspace, providing suitable features and analysis capabilities.

Step 3 | *Combine analysis results from raw data sources*: The results/analysis outcome obtained from each data source workspace shall be integrated in one common processing realm, where all the analysis results could be integrated, compared and evaluated by the end user. Knowledge integration is based on semantic annotations produced in the previous steps and the use of Linked Data standards. Moreover, semantic reasoning can be applied to further elucidate knowledge from the already extracted analysis results.

Step 4 | *Produce a consolidating assessment report*: The overall analysis outcome shall be generated as a consolidated report, facilitating further analysis in collaboration with other clinicians, or even reporting to PV regulatory agencies. The produced report shall be available in both human-readable (e.g., in text form as a PDF document) and machine-readable (e.g., an RDF document) formats. Knowledge dissemination approaches can be used to facilitate the respective information exchange in a way that could promote the automatic reuse of this information. For example, the recently developed OpenPVSignal model [19] could be used in this regard, to enable compliance with the FAIR data principles [20].

Step 5 | *Launch follow-up monitoring*: The end user can launch a monitoring follow-up process, in order to receive potentially new information regarding the assessed ADR from the available data sources. This process would notify the end-user based on his/her notification preferences to avoid over-alerting. Ontology models such as the *Time Ontology* [21] and the *PROV-O Ontology* [22] can be used to enrich the obtained information with semantically enhanced time and provenance annotations, and thus, facilitate further processing/reasoning regarding the time aspects and the origin of the information collected regarding the ADR under assessment.

It should be noted that the presented workflow defines an independent BP, which can be adapted to each organizational context. Furthermore, in each assessment process, the end-user may decide the time spent on each BP step, either selecting to use the automatically retrieved information, drill-down to investigate further or manually curate the produced outcomes, and save or share his/her work with others at any time.

Discussion

Drug safety is an important issue in the clinical environment. Among the common tasks that are routinely performed in PV centres/departments in hospitals, the collection and review of all the available data for a potential ADR of interest is vital. However, there is a lack of comprehensive tools to support PV activities, specifically tailored for use at the point of care. For example, a clinician may ask for a timely evaluation of the respective patient case after a new drug administration, and the PV centre/department shall provide a documented answer with a medical advice about the case, after assessing the eventuality of an ADR [8]. To respond to this challenge, current available sources of information about the drug–event pair have to be searched by PV experts separately and in many cases without using appropriate support tools.

To address this need, we are currently developing a Web-based, knowledge-intensive platform aiming to support the assessment of potential ADRs, experienced during routine patient treatment. In the current paper, we presented the entailed challenges and the goals for such a development from the user perspective. We also presented the platform's main information processing workflow (Figure 2). Its design relies on exploiting various KE-based methods, employed in each step of the workflow.

In particular, the use of Linked Data and Semantic Web technologies provides the following key benefits:

- *Information linking* can be improved and automated by reducing the need for manual data exploration and discovery as data could be automatically retrieved.
- Rich *semantics* enhance information processing capabilities, which are typically limited in the PV domain to statistical measures of disproportionality. The already established statistical methods could be combined with semantically-enhanced knowledge sources to improve outcomes via automatic reasoning capabilities (e.g. regarding causality assessment).
- *Evidence can be strengthened* through the knowledge-intensive, concurrent exploitation of multiple data sources, eliminating false positive findings [6].
- KE-based automatic information linking enables the use of *provenance information* to annotate the generated analysis outcomes. This is important as full supporting evidence shall be explicitly available, e.g. when reporting results to regulatory organizations.

Despite the abovementioned benefits, the implementation of KE-oriented techniques entails complex challenges, both in methodological and technical terms, e.g.:

- Automatic reasoning capabilities based on the Description Logic defined semantics are one of the most prominent features of Semantic Web technologies. However, "reasoners" require significant computational resources and their efficient use in large datasets remains a challenge.
- Various reference knowledge sources (e.g. terminologies/thesauri/vocabularies) are available and can be applicable in the scope of this work. However, since these sources are constantly evolving and refined, their alignment is a complex task as it can lead to semantic inconsistencies.
- Integrating all the collected evidence under one unified knowledge model can be very challenging. This

process engages many heterogeneous data sources, which could be available via standard data exchange interface or not. For example, using proprietary EHRs to retrieve observational healthcare data would typically require specific interface implementations.

To this end, besides the ultimate goal of delivering a robust and evaluated ADR assessment platform, our mid-term goals are: (a) the design of a unifying semantic model enabling the integration of heterogeneous data sources in one information processing realm, and (b) the modelling of ADRs in one ontological model, facilitating advanced reasoning operations upon the collected information.

Conclusions

There is a clear need for comprehensive tools to support PV activities at the point of care. The proposed platform aims to support the assessment of potential ADRs in routine clinical practice, relying on the concurrent exploitation of multiple data sources for appropriate evidence. This entails the analysis of the acquired data, the aggregation of the obtained evidence, and the support of follow-up ADR monitoring over time in a systematic and user-friendly way. In this paper, we presented the main challenges and the goals from the end-user perspective for such a development, identified during the "user requirements analysis" phase of our development. We also presented the main elements of the platform design, i.e. its main information processing workflow, and illustrated the use of KE as the platform's main technical paradigm. Our work contributed to the development of a learning health system for active, post-marketing drug safety surveillance at the point of care.

Abstract

Despite similar policy goals, the adoption of eHealth practices took different paths in Austria (AT), Switzerland (CH), and Germany (GER). We seek to provide a rigorous analysis of the current state of hospitals by focusing on three key eHealth areas: electronic patient records (EPR), health information exchange (HIE), electronic patient communication. For validation and in order to gain better contextual insight we applied a mixed method approach by combining survey results from clinical directors with qualitative interview data from eHealth experts of all three countries. Across countries, EPR adoption rates were reported highest (AT: 52%, CH: 78%, GER: 50%), HIE-rates were partly lower (AT: 52%, CH: 14%, GER: 17%), and electronic patient communication was reported lowest overall (AT: 17%, CH: 8%, GER: 19%). Amongst others, results indicate patient awareness about eHealth to be equally weak across countries, which thus may be an important focal point of future policy initiatives.

Keywords:

Electronic Health Records, Health Information Exchange, Health Policy

Introduction

Widespread diffusion and usage of electronic health records across care settings are a major issue on health policy agendas worldwide [1–3]. Also, Austria (AT), Switzerland (CH), and Germany (GER) aspire to improve continuity of care by fostering eHealth. Although, there are similarities between the major German-speaking regions in Europe, there are also crucial differences (Tab. 1).

Table 1 – Country characteristics

	AT	CH	GER
Population (2013)*	8.5 Mill.	8.1 Mill.	80.6 Mill.
Federal States	9	26	16
Welfare type	SHI	Public/Private	SHI
Hospitals (2016)*	273	283	1,951**
Expenditure on hospitals (2016)*	4.0% of GDP	4.3% of GDP	3.2% of GDP

SHI: Social Health Insurance, GDP: Gross Domestic Product
*see www.stats.oecd.org, **see www.destatis.de (accessed 10/25/2018)

Correspondingly, eHealth legislation took different paths in the three countries (Fig. 1). For instance, Germany has seen a rather long process of eHealth legislation with changing goals and approaches, dating back to 2003 but medically useful applications are not available up to this point. In Austria, the introduction of the Electronic Health Record ("ELGA") has already started, allowing health care providers and patients to access selected structured patient documents. In Switzerland, the federal government regulations of the Electronic Patient Dossier (EPD) stipulate that health professionals in hospitals are technically able to store essential patient information required for further treatment until 2020 (see Tab. 2).

Table 2 – Recent eHealth legislation

AT	**ELGA** *(Electronic Health Record Act)*
	• Focus on the "Elektronische Gesundheitsakte" (ELGA) to exchange discharge letters, laboratory data, medical imaging, medication data
	• Mandatory participation for health care providers
	• Citizens participate unless they object (Opt-Out)
	• Defined structure, format and standards for ELGA data
CH	**EPDG** *(Federal law on the electronic patient dossier)*
	• Focus on the "Electronic Patient Dossier" (EPD)
	• Mandatory participation for in-patient care providers
	• Voluntary participation for out-patient health care providers and citizens (Opt-In); patients themselves determine access rights
	• National subsidies to fund and build the necessary preconditions for the EPD
	• Defined monetary penalties in case of misuse
	• Defined standards, which are to be used to get certified (legal obligation)
GER	**E-Health-Gesetz** *(Act for Secure Digital Communication and Applications in the Healthcare Sector)*
	• Planned: Medication summary, telemedical applications, emergency data management, electronic patient records
	• Subsidies for sending and receiving medical eSummaries
	• Penalty for out-patient health care providers in case the insurance data is not up to date
	• Implementation of an interoperability register

Recent studies show that Germany is lagging behind Austria and Switzerland when it comes to diffusion and use of health IT applications in hospitals [4–7]. Spreading medical innovation in health care, hospitals are crucial hubs also for national eHealth infrastructures [8]. While there is information about the current state in terms of numbers, little is known about how the stakeholders perceive and evaluate this situation against the background of the national eHealth legislation and

the respective healthcare ecosystem. In order to find out how high-level survey data go along with the perceived reality, a combination of quantitative and qualitative methods is helpful to yield the full picture and cross-validate findings.

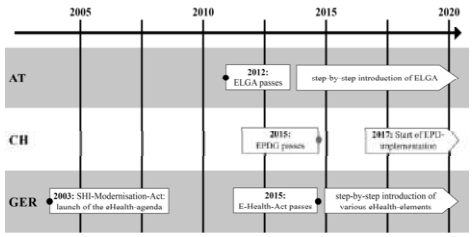

Figure 1 – Timeline of eHealth-laws

This study thus aims at investigating the current state of development and the combined views from a broad range of stakeholders in Austria, Germany, and Switzerland in the key areas: a) hospital internal electronic patient records (EPR)[1], b) health information exchange (HIE) across settings, and c) electronic communication with patients.

RQ1: Do quantitative data and qualitative findings provide a similar picture in the three key eHealth areas?

RQ2: Can qualitative findings explain potential quantitative differences between the three countries?

Methods

We used a parallel mixed method study design (Fig. 2) in which the data of both sets were collected simultaneously, hence providing a point in time observation [9]. Quantitative data were obtained from clinical directors (either nursing or medical directors) as hospital representatives using the standardised online survey *IT Report Healthcare 2017* [5] that measured various aspects of IT adoption [4]. Qualitative data were obtained from 59 health care experts representing a broad field of expertise (Fig. 2): health care delivery (hospitals, out-patient-care, nursing, telemedicine), industry (IT-provider, pharma industry), health care policy, and others (academia, data protection, patient organisations). Phone interviews were conducted using a guideline covering the national eHealth initiatives. Using the software *MAXQDA*®, interview data was screened systematically for statements regarding the three key eHealth areas in each country. Relevant quantitative data from the survey respondents (Fig. 2) was tested for country differences using logistic regression models in each area. In order to synthesise both data sets, the quantitative data was then complemented by selected quotes from the expert interviews. The screening of the qualitative interview material for hospital related statements lead to 547 initial hits of which we retained 97 statements for further analysis that were relevant to the research questions (AT=28, CH=29, GER=40,). The quantitative survey yielded a response rate (RR) of 17.8%. Out of 2,421 hospitals contacted (contact data were missing for some hospitals), we received 430 responses – 32 from Austria (RR = 12.3%), 43 from Switzerland (RR = 20.4%), and 355 from Germany (RR = 18.2%). Bigger and non-private hospitals were slightly overrepresented in our samples.

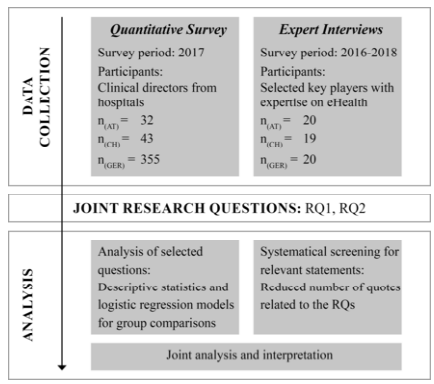

Figure 2 – Research process

Results

Research question 1:

Do quantitative data and qualitative findings provide a similar picture in the three key eHealth areas?

Key area a) Hospital internal electronic patient records

Adoption rates of EPR systems within hospitals showed to be similar in the German and Austrian sample while Swiss hospitals indicated a significantly higher EPR adoption rate (Tab. 3).

Table 3 – Adoption rates of electronic patient records with 95% confidence intervals (CI) and test for group differences

Question	Country	% of Hospitals with an EPR
Q1: Does your hospital have an Electronic Patient Record (EPR)?	AT (n=29)	52% (±18%)
	CH (n=41)	78%*(±13%)
	GER (n=338)	50% (±5%)

*significantly higher adoption rate (p<0.01), GER as reference category

As summarized in Table 4, experts in all three countries provided a mixed picture, with some recognizable trends: Austrian experts pointed to the progress in building the clinical IT-infrastructure but also showed to be aware of the still existing deficiencies. In Germany, experts mostly confirmed the deficiencies and only alluded to progress made in selected institutions. The Swiss experts clearly perceived some progress and an advanced state of developments without neglecting some deficiencies. The similarity in adoption rates between Austria and Germany were referred to by one Austrian expert as follows:

"In the hospital sector, I think we have approximately the same IT status as, for example, in Germany or other comparable EU-countries."

The German experts pointed at only modest maturity levels, stressing for instance that

"talking about EPRs, hospitals are already somewhat advanced, although there are still many blank spots".

Swiss hospitals appeared to be better off with EPR adoption rates close to 80% based on the quantitative survey. These results were supported to some extent by expert opinions in the interviews:

[1] We provided the following definition of an EPR for all respondents: "The EPR is an electronically generated and based institution-specific collection of patient information on current and previous stays in the institution. It is supported by clinical decision-making systems and replaces paper based medical documentation as the primary source of information."

"So many hospitals are now becoming much more active in this domain."

However, seen collectively, the interviewees also added more sceptical assessments and pointed to difficulties (Tab. 4):

"One would simply have to show much more the benefits, wouldn't one? If you are looking at the hospital processes and you are a clinical director and you know this system offers me benefits (presumably in monetary terms as well) and the processes are so much better and so on… then I consider using the system – but usually it´s not like that right now."

Table 4 – Expert statements on the electronic patient record and clinical IT-infrastructure within hospitals

Expert assessments	AT	CH	GER
Existing deficiencies	6	3	6
Selected progress among individual hospitals	2	2	4
Progress in the clinical IT-infrastructure is recognisable	1	5	2
Advanced status	6	2	1
Included interview statements in total*	15	12	13

*representing 40 out of 97 or 41.2% of all included expert statements

Key area b) Health information exchange

When extending the focus to information exchange with other health care institutions, the quantitative survey data indicated lower implementation rates in German and Swiss hospitals and somewhat higher implementation rates in Austrian hospitals (Q2). Austria is also using more sophisticated technology (Q3), i.e. portals, compared to Swiss hospitals, which were using primarily email to communicate (Tab. 5).

Table 5 – Health Information Exchange with 95% CI's and tests for group differences.

Question	Country	Respondents indicating "yes"		
Q2: Are external health data usually transferred using a portal?†	AT (n=12)	52%** (±28%)		
	CH (n=20)	14% (±15%)		
	GER (n=123)	17% (±5%)		
Q3: Is the medical discharge letter (doctor's letter) provided electronically for outside practitioners?		**No**	**Via email**	**Via Portal**
	AT (n=26)	31%** (±18%)	11% (±11%)	58%** (±19%)
	CH (n=39)	33%** (±15%)	54%** (±16%)	13% (±11%)
	GER (n=315)	87% (±5%)	5% (±2%)	8% (±3%)

*significantly higher adoption rates (p<0.05), GER as reference category
**significantly higher/lower adoption rates (p<0.01), GER as reference category
†This question was addressed only to those who indicated that they electronically integrate data from previous care stages into their systems. Almost all other respondents that didn't use a portal, answered that they scan in paper documents.

The experts pointed at comparably few deficits and more progress in Austria than in the other two countries, though structural barriers were reported in all three of them (Tab. 6).

"I think we're on the right track with this IT-infrastructure, which we're currently setting up in the course of introducing ELGA." one Austrian expert reported.

The modest adoption rates of HIE in Switzerland (see Tab. 5) were reflected by existing deficits and structural barriers as expressed by one Swiss expert:

"The possibilities for health information exchange across settings are still very limited and the patient record, i.e. the EPD, does not yet exist."

German hospitals were significantly poorer developed with regard to transferring discharge letters (Tab. 5) – a well-known drawback in Germany´s eHealth landscape which was reiterated by many of our interviewees (Tab. 6). One expert stated:

"Even across sector boundaries, from hospitals to out-patient care. We are still, I don't know, 20 years behind."

Table 6 – Expert statements on HIE

Expert assessments	AT	CH	GER
Existing deficits in HIE	1	4	9
Structural barriers for HIE	4	4	7
Progress in HIE recognisable	4	1	1
Structural facilitators for HIE	1	3	2
Included interview statements in total*	10	12	19

*representing 41 out of 97 or 42.3% of all included expert statements

Key area c) Electronic communication with patients

Looking at IT-functions that allow for direct communication between patients and providers, all countries still operated on a rather low level (Tab. 7). Swiss hospitals reported the lowest adoption rates while rates in Austria and Germany were slightly, but not significantly, higher. This pattern was mostly in line with the experts´ comments (Tab. 8). However, deficits were more often voiced by German experts. In total, this topic was not addressed all too often by the experts.

Table 7 – "Communication with patients" with 95% CI and test for group differences.

Item	Country	% of Hospitals indicating availability
Q4: Availability of IT function for communication with patients (e.g. via patient portals)*	AT (n=30)	17% (±13%)
	CH (n=40)	8% (±8%)
	GER (n=319)	19% (±4%)

*no significant group differences, GER as reference category

Table 8 – Expert statements on electronic communication with patients

Expert assessments	AT	CH	GER
Deficits present	1	3	5
Increasing expectations	1	1	2
Progress discernible	1	1	1
Included interview statements in total*	3	5	8

*representing 16 out of 97 or 16.5% of all included expert statements

Research question 2:

Can qualitative findings explain potential quantitative differences between the three countries?

Key area a) Hospital internal electronic patient records

The quantitative data pointed to a more advanced situation with regard to EPRs in Switzerland in comparison to the other countries. However, the Swiss experts did not offer a comprehensive explanation but rather pointed to the strengths of the Swiss hospitals, as one expert stated:

"And that is why in-patient structures, such as hospitals, are of course good carriers for ICT-innovations and for the promotion of the EPD, because with their central structures they have the necessary power (human and financial resources) to carry out such projects much better."

The qualitative interviews provided some background information on the mixed results among the Austrian hospitals. One participant indicated that ELGA initiated positive stimuli:

"I also think that such topics are very good drivers for innovation in a hospital. I see it this way: When you introduce a new system, when you deal with processes, then you always have the opportunity to clean up old things and think about how processes can be streamlined. From my point of view, the ELGA system has also brought us something positive."

However, criticism was also expressed particularly with regard to advanced functionalities:

"What is missing is a real innovation, like automatically creating summaries, displaying trends, abstracted from the concrete data. [...] What used to be known as a medical expert system or as clinical decision support is now completely lacking. We are currently at the level of medical raw data."

Reasons for the rather modest EPR adoption rates in Germany included the following explanation given by one expert:

"Of course, there are reasons for that, as I already mentioned, the financial situation: Half of the hospitals generate a deficit and they have to try to buy IT with the resources they have. There is only little support, financial funding in other words."

Key area b) Health information exchange

The Austrian hospitals showed the greatest progress in HIE in comparison to Switzerland and Germany based on the quantitative survey results. This progress was reflected in the interviews particularly in reference to ELGA:

"And ELGA has actually started to standardise all the documents in the hospital. This means that the doctor´s summary looks the same throughout Austria: it has the same structure, the same layout, it is generated in the same way. From my point of view, this is something that will help the health care system to move forward."

However, as one expert expressed, implementation was not yet completed among all stakeholders and some unsolved problems remain:

"But what's still a problem for us, is the representation and integration into local information systems."

The survey results indicated limited HIE capabilities of Swiss hospitals. This could be related to the ongoing introduction of the EPD as the following statement illustrates:

"Due to the obligation of hospitals and other in-patient providers, it will inevitably happen within a time horizon of three to five years, all in-patient providers will become part of this system."

Despite similar HIE adoption rates in Switzerland and Germany, the German experts described the situation differently and expanded on the missing incentives for collaboration across care settings:

"Our health care system has a silo mentality. […] One worries if something works in one´s own system. As soon as it comes to cross-sectorial issues, it doesn´t work because there is no incentive, no financial incentive, to do so."

They also criticized the *E-Health-Gesetz* for its one-sided focus on the out-patient sector and for its missing strategic approach.

Overall, experts from all three countries addressed similar barriers and facilitators for hospitals (Tab. 6):

- missing, insufficient, or inadequate funding,
- lack of interoperability,
- lack of willingness to cooperate across sectors,
- resistance of physicians,
- less technically advanced out-patient sector.

In total, more barriers than facilitators were mentioned in this context. Only Austrian and Swiss experts stated that the national eHealth laws serve as facilitators.

Key area c) Electronic communication with patients

The quantitative survey results suggested that the capabilities to communicate with patients were equally poor in all three countries. The interviews provided some background information on this issue. For instance, interviewees stressed that citizens did not yet make use of the power they possess – there was a clearly lacking demand on the patients´ end. One Austrian expert commented on the role of citizens within the ELGA initiatives as follows:

"I think it's true that many people may not even know that they have access to ELGA, they don't care about it."

Similarly, a Swiss hospital representative stated:

"On the other hand, we have not had a single request from a patient in recent years: Can I access my data? In this respect, interest in effective access to the data: zero. Really, zero. And that also tells me, how active are we there as a hospital at the moment? And the answer is: not at all. Because there would be no balance between effort and yield."

However, according to one German expert patients and health policy makers actually are desirable facilitators of electronic data exchange with patients:

"If you follow the treatment process and realise that hospitals send their documents via mail to the GP or that you yourself are walking around with a letter, then that is very absurd. In my opinion, the driver can only be the citizen or policy by changing certain laws."

The lacking demand and the resulting unwillingness to offer an electronic communication service was summarised by another German expert as follows:

"Well, I think there´s going to be a lot of adjustments. […] Because there are a lot of patients who are ignorant of this; or patients who don´t want it and don´t request it at all. Then, the hospitals notice: Oh, we don´t necessarily have to provide this service, people don´t want to have it anyway, and there is no one who keeps track if we are providing these things."

This statement highlighted the need of health policy to get involved and to set up mechanisms of informing the citizens.

Discussion

This study offered unique insights into key eHealth areas by combining cross-country surveys with qualitative expert interviews from the countries involved. To our knowledge, it is the first study of this kind. Many of the interview statements corroborated the survey findings and thus contributed to their validation. There is some support from other studies as well [4,7,10] that overlap in parts.

Overall, adoption rates were the highest for EPRs, followed by HIE, and electronic patient communication ranking lowest. This finding largely matched the patterns of statements on deficiencies, progress and advanced status provided by the experts. Background information provided by the experts shed light into the "whys". Among the most salient reasons given were increased expectations towards the rather new legislative frameworks in Austria as well as Switzerland that might have sparked some advances of hospital EPRs. Moreover, particularly Switzerland spends more on secondary care, thus allowing more operational flexibility. In contrast, missing incentives in Germany could have dulled the motivation of hospitals to invest in EPR systems. A clear story of the benefits can work as a strong motivator. ELGA is seen as an important lever for HIE in Austria. Due to the fact that the Swiss eHealth act, the EPDG, is a rather young law, the technical developments for HIE are still in their infancy and effects do not materialise yet. In Germany, where HIE exists only in few places, lack of real incentives and a preponderance of the out-

patient sector in the eHealth law seem to function as strong barriers. In general, wherever funding, willingness to cooperate and interoperability are missing, the odds are rather low to have HIE in place. Electronic communication with patients is not well developed in all three countries. Experts spoke about the chicken or egg problem in this context: Because patients do not voice a strong demand hospitals do not offer it. Because there are no offers from providers, patients do not know about them and do not ask for it.

Policy recommendations

Based on results of this study, some massages might be of interest for health policy considerations: All three countries are facing similar structural barriers for HIE when it comes to funding, interoperability, and willingness for collaboration across settings. Despite these communalities eHealth took a different path in Austria and Switzerland than in Germany that could be due to the design of eHealth legislation that better integrates hospitals in Austria and Switzerland. Large healthcare organisations are well known for being able to drive and spread IT innovation [4,8]. Although patient centred approaches are claimed to be pursued in all three, the citizen is not really part of the digital agenda yet, raising efforts by health policy. Effects of pertinent new laws that are under way, e.g. in Germany, need to be observed.

Findings from other countries

Especially many Nordic countries such as Finland, Norway and Denmark, that compare to Austria and Switzerland at least in terms of population, have made noticeably greater progress towards national eHealth infrastructures. Following early political commitment, all three countries approached market saturation of hospital EPR's about 5-10 years ago [11–13] and policy makers have since moved on to establish HIE capabilities across sectors and connect all citizens. Other, larger OECD countries, like the United Kingdom made some more troublesome experiences. Despite early advances through the "National Programme for Information Technology" (NPfIT) in 2004, aiming (amongst others) at digitizing secondary care, the program was terminated unsuccessfully in 2011 – essentially due to inadequate management [14]. However, in contrast to Germany, the UK has and still does acknowledge secondary care to be a crucial determinant for fostering eHealth and is thus launching new funding initiatives [15]. In essence, the different approaches seen internationally show that it is not only about doing it but also about doing it right.

Limitations

Due to the study design, some limitations need to be considered: Selection bias might occur in the survey data in light of the modest response rates (volunteer bias) and in the qualitative data (purposive sampling). Furthermore, this study provided a point in time analysis only. Follow-ups are planned and an in-depth analysis of the qualitative data is currently in progress. However, we tried to mitigate these limitations by pooling the two data sets, thereby mutually validating the findings and by blending a broad scope with contextual information.

Conclusions

The mixed methods study offered a new approach, contributed to a validation of the findings per country and provided a better insight into the overall context than with a single method alone. Hospitals and large care providing organisations must be well integrated into a national eHealth strategy before all sectors can benefit. The patients' awareness of the potential of eHealth still needs to be developed by health policy in conjunction with providers offering tangible solutions. Cross-national studies yield a good and rich basis to leverage the science-politics dialogue.

Abstract

Recently the two most influential clinical guideline were published for diagnosing and treating hypertension in US and Europe: 2017 American College of Cardiology/American Heart Association (ACC/AHA) and 2018 European Society of Cardiology/European Society of Hypertension (ESC/ESH) Guideline. Though both of them have most in common, the differences in details between guidelines have confused many clinicians in the world. Because guidelines were evidence-based literature, through the analysis of articles cited in guidelines, these similarities and differences could be explained. Bibliometric analysis is a method of quantifying the contents of literature to analyze literature. So using the bibliometric analysis including co-citation network analysis, articles cited in guideline were analyzed. As a result, we figured out that bibliometrics can analyze the influence of the countries, authors and studies on the guidelines, which might affect on the similarities and the differences between both guidelines.

Keywords:

Hypertension; Bibliometrics; Guideline

Introduction

In clinical areas, guidelines serve as standards to diagnose diseases and to give proper treatment to patients. Guidelines rely on evidence-based literature [1], citing articles about relevant diseases and treatments, and they are continually updated based on newly identified clinical research [2]. Therefore, guidelines can be used to identify key literature that contains the most important and essential information in the clinical domain from past to present.

Recently, two most influential guidelines for hypertension, the 2018 European Society of Cardiology/European Society of Hypertension (ESC/ESH) Guideline and the 2017 American College of Cardiology/American Heart Association (ACC/AHA) guideline have resulted in vigorus debate because of common ground in a broad view and differences in details [3]. Since both guidelines have been established on thorough review of hugh amount of high-quality evidences, the complex network of cited articles might reflect and help to understand the inherent intention of the guidelines.

Bibliometric analysis is a method of quantifying the contents of literature through statistical methods to analyze literature [4]. Co-citation analysis is one of the bibliometric analysis, which focuses on the documents cited, by calculating the frequency of two documents that are co-cited by specific documents [5]. We conducted bibliometric analysis using articles which were cited in guidelines to identify the contributions according to the countries, authors, cited articles [6]. We can present the network between articles' references, co-citation network [7,8].

To our knowledge, there has been no previous evidence of a comparative bibliometric analysis of articles cited between two clinical guideline for the same theme. We explored the impact of the articles that make up the guideline and how these influences explain the similarities and differences between two guidelines.

Methods

Extracting data

Data was gathered by using the Web of Science (WoS) database. The references cited in the 2018 ESC/ESH hypertension guideline and the 2017 ACC/AHA hypertension guideline were searched. Published years, author(s), countries, and cited references were obtained. 629 articles for 2018 European guideline and 991 for 2017 US guideline were included.

Bibliometric analysis

The countributions of countries and author participation in guideline production were obtained with the open-source Bibliometrix R-package (http://www.bibliometrix.org/) [9]. We conducted the co-citation analysis to identify highly cited references and productive authors. The results of co-citation analysis was presented as network visualization maps using the VOSviewer version 1.6.9 (Leiden University, Leiden, Netherlands) techniques [10].

Results

Through the WoS, total 609 references for the European guideline and 860 for the US guideline were extracted out of the total cited papers 629, and 991, respectively. Articles cited in the 2018 European guideline were published from 1950 to 2018, and articles cited in the 2017 US guidelin were from 1967 to 2018. Guidelines tended to cite more recent referneces (Figure 1a,b).

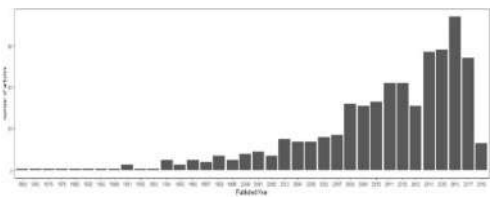

Figure 1a – Annual articles cited in the 2018 European guideline

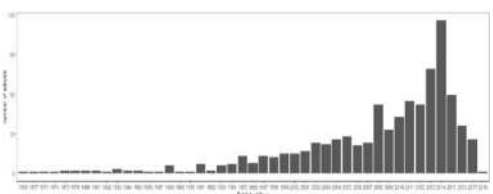

Figure 1b – Annual articles cited in the 2017 US guideline

Table 1 lists the top ten countries that contributed to each guideline using citation analysis. The US was the country with the highest production in both guidelines. In the European guideline, the articles published by the US was total 133, 22.2 %, followed by the UK 102 articles, 16.9 % and the Italy 99, 16.4 %. In the US guideline, the articles published by the US was 395, 47.0 %, followed by the UK (68, 8.1 %), Australia (48, 5.7 %), Italy (37, 4.4 %).

Table 1 – The contribution of countries

Europe guideline		US guideline	
Country	Publication, n (%)	Country	Publication, n
USA	133 (22.1)	USA	395 (47.0)
UK	102 (16.9)	UK	68 (8.1)
Italy	99 (16.4)	Australia	48 (5.7)
Canada	29 (4.8)	Italy	37 (4.4)
France	24 (4.0)	Canada	28 (3.3)
Germany	22 (3.6)	China	24 (2.9)
Australia	20 (3.3)	Netherlands	24 (2.9)
Spain	20 (3.3)	Belgium	18 (2.1)
Belgium	19 (3.2)	Japan	17 (2.0)
Netherlands	19 (3.2)	Spain	17 (2.0)

The contributions of authors published articles cited in each guideline were analyzed, and the top 10 most cited author were listed in the table 2. In the European guideline, G. Mancia published 83 articles and it took 13.6 % in total articles cited in the European guideline. A. Zanchetti and B. Williams followed next published 44 (7.2 %), 36 (5.9 %). In the US guideline, P.K. Whelton contributed most, 40 articles 4.7 %. B. Neal, M. Woodward were 2nd and 3rd most contributed author, 23 (2.7 %), 23 (2.7 %). In case of G. Mancia, ranked 10th in the US guideline, published 19 articles (2.2 %).

Table 2 – The contribution of authors

Europe guideline		US guideline	
Author	Publication, n (%)	Author	Publication, n (%)
G. Mancia	83 (13.8)	P.K. Whelton	40 (4.8)
A. Zanchetti	44 (7.3)	B. Neal	23 (2.7)
B. Williams	36 (6.0)	M. Woodward	23 (2.7)
G. Parati	35 (5.8)	J. He	22 (2.6)
J. Redon	26 (4.3)	S. Oparils	22 (2.6)
S.E. Kjeldsen	23 (3.8)	J. Chalmers	21 (2.5)
S. Yusuf	22 (3.6)	L.J. Appel	20 (2.4)
J.A. Staessen	21 (3.5)	J.A. Cutler	20 (2.4)
G. Grassi	20 (3.3)	J.T. Wright	20 (2.4)
B. Dahlof	19 (3.2)	G. Mancia	19 (2.3)

In co-citation network analysis, the most frequent appeared author in articles cited in the European guideline's references was G. Mancia. His citation count was nearly 3 times more than the second highest citation count, P. Verdecchia. The thrid was S. Yusuf, similar with P. Verdecchia (Figure 2a). In the US guideline, the first most frequently cited author, G. Mancia, and the second most, A.V. Chobanian. G. Mancia and A.V. Chobanian had almost similar citation counts. The third most frequently cited author was S. Yusuf (Figure 2b).

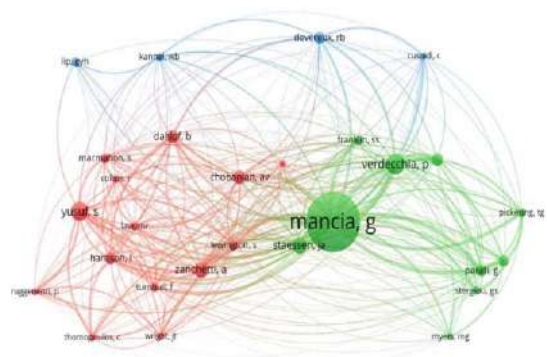

Figure 2a – co-citation network map presenting cited authors in references of the 2018 European guideline's references

The size of each circle reflects the number of citations an article has received. So citation count could be estimated and compared by circles' size. And circles that are located close to each other in the visualization tend to be more strongly related

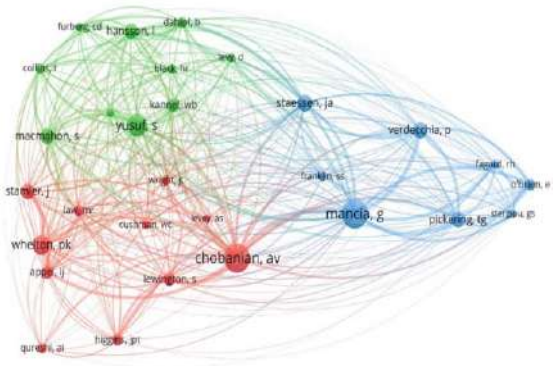

Figure 2b – co-citation network map presenting cited authors in references of the 2017 US guideline's references

Except for the previous versions of hypertension guidelines, the most frequently cited study in the European guideline's references was *S. Lewington, 2002, LANCET* which was meta-analysis. The next most frequently cited study was Syst-Eur trial which targeted people aged more than 60, followed by *F. Turnbull, 2003, LANCET* (meta-analysis), HOT trial, HOPE trial, ACCORD-BP trial, *M.R. Law, 2009, BMJ* (meta-analysis), SHEP trial, HYVET trial, SPRINT trial. In the US guideline, except for previous version of guidelines, *S. Lewington, 2002, LANCET* was the most frequently cited study same as the European guideline. The next was the HOPE trial, followed by *S. MacMahon, 1990, LANCET* (meta-analysis), ALLHAT trial, *M.R. Law, 2009, BMJ* (meta-analysis), *F. Turnbull, 2003, LANCET* (meta-analysis), SEHP trial, Syst-Eur trial, HOT trial, PROGRESS trial, ACCORD-BP trial. The list of top 15 studies most higly cited were almost same between two guidelines except for 4 studies.

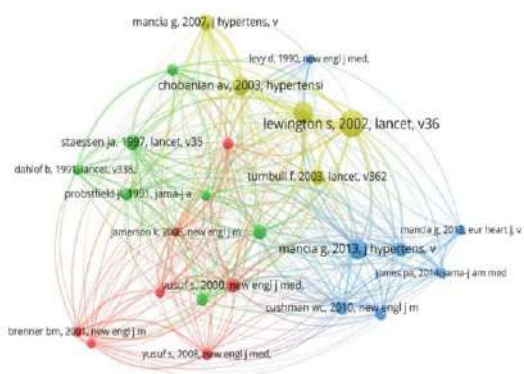

Figure 3a – co-citation network map present cited articles in references of the 2018 European guideline's references

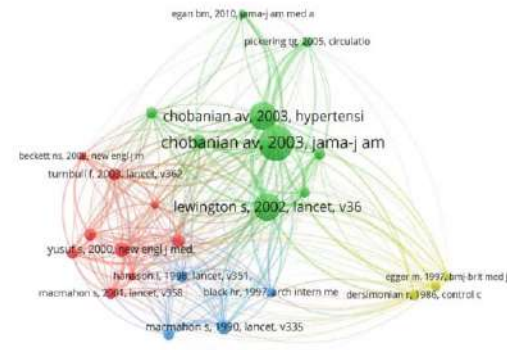

Figure 3b – co-citation network map present cited articles in references of the 2017 US guideline's references

Discussions

Our study figured out that the results of the bibliometric analysis using articles cited in the guideline had similarities and differences between two clinical guidelines. The result of measuring published countries of articles citied in the two guidelines was that the US guideline chose the articles published in the US, and the european guideline chose the articles published in the US, UK, Italy evenly. Because Europe consists of various countries, the European guideline had tendency to choose multi-country published articles.

The list of top 10 most contributed author, there were no authors that ranked at the same time except for G. Mancia. In the terms of the contributed authors, the composition of the two guidelines looked different. However, there were more similarities between two guidelines in the influence of the author obtained by author co-citation analysis. It had something in common with the results of reference co-citation analysis. Studies most cited in the articles used in the guideline were almost same in the Europe and the US guideline. Compared with the 15 highest cited articles in both the European and the US guideline, the list of studies were same except 4 articles. The bases of the two guidelines's evidences were similar. It could explain the European guideline and the US guideline were similar in general. And these similarities showed that the contents of the actual guidelines are similar to each other. For example, *S. Lewington, 2002, LANCET* was the most cited study in both guidelines except for previous guidelines. It is meta-analysis which said even in the normotensive people lowering systolic and diastolic blood pressure lowers the risk of vascular death. It could reflect the tendency of the two guidelines treats hypertension more tightly. The SHEP trial and the Syst-Eur trial which had high citation count in both guidelines could explain to set more strict target blood pressure for elder people who aged and over 65 years in the 2018 European guideline and the 2017 US guideline. Also, the HOPE trial ranked high in both guidelines, and it could explain the reason why angiotensin converting enzyme inhibitors (ACE inhs) remain first line drug in both guidelines. There were also differences between the results of reference co-citation analysis. The ALLHAT trial was ranked high in the US guideline, but not in the European guideline. It could make differences between two guidelines' drug choice. While the European guideline recommended single pill combination consisting of ACE inhs or angiotensin receptor blockers (ARB) plus Calcium channel blockers (CCB) or thiazide-like diuretics to start anti-hypertensive medication, the US guideline recommended to start with thiazide-like diuretics ahead of other

classes. In this way, analyses of articles cited in guideline could explain the similarity and differences between the European guideline and the US guideline.

But the influence of previous guidelines could not be excluded. JNC 7, 2013 European guideline, 2007 European guideline ranked high in the results of reference co-citation analyses. Actually studies of hypertension are inevitably affected by the previous guidelines, because their settion followed previous guidelines. It could cause overestimation of the power of some articles or authors. The result of author co-citation analysis was that G. Mancia had the most frequently cited count in both guidelines. Espetially in the Europe guideline, his cited count was almost three times more than P. Verdecchia. This overwhelming number of citation count was seen because G. Mancia was overestimated by previous guidelines.

Conclusions

In the bibliometric analysis, the contributions of countries in the European guideline and the US guideline were found. There were differences the list of most highly contributed author between two guidelines, but almost same in the list of the most highly cited in the guideline's references. Also, the studies highly cited in the guideline's references were almost similar in both but slightly different. In these results, we could find two guidelines looked different but its bases were most in common. Through the co-citation analysis, we figured out how much the whose or which articles contributed to the references used in guidelines. These contributions affected guideline's direction. As a result, analysis of references used in guideline could explain the similarity and differences between two guidelines.

Using Simulation Modeling to Inform Policy Makers for Planning Physician Workforce in Healthcare System in Croatia

Danko Relić[a], Kristina Fišter[a], Jadranka Božikov[a]

[a] *Andrija Štampar School of Public Health, University of Zagreb School of Medicine, Zagreb, Croatia*

Abstract

The objective of this paper is to show how a simple but powerful simulation model can be build up using standard spreadsheet program and used to simulate future, needs and supply of physicians in order to inform policy makers at national level when deciding on enrollment to medical schools and immigration quotas for physicians. The Republic of Croatia is facing a serious shortage of physicians in the healthcare system and simulation results have shown that the gap between needs and supply will even increase if current enrollment qoutas to medical schools would persist. Increasing enrollment quotas, adjusting immigration policy, re-directing physicians from other professions to the healthcare system, task shift and skill mix options are just some of the measures needed to be taken promptly in order to prevent a huge deficit of physicians in the future. Simulation modeling is certainly a method for predicting changes within healthcare systems with a possibility to examine multiple different scenarios and suggest interventions.

Keywords:

Physicians; Decision Support Techniques; System Analysis

Introduction

Imbalance in the health workforce is a major concern in both developed and developing countries [1]. Shortage of proper policy planning and human resources management in many countries has resulted in an imbalance of needs and supply with multiple effects on employees in health care as well as on population health. Although the determination of the ratio between number of health workers and population size including age structure has become an aim of national policy on the human resources development in health care, in most cases remains a gap between plans and their realization [2]. The number of physicians is continuously changing because new physicians enter the system almost daily, and many in different ways come out of it. During 10-year period starting by 1 January 2007 the number of physicians in Croatia increased from 12,065 to 14,394 (i.e. by 19% or from 2.8 to 3.5 per 1,000 inhabitants) while in the same period number of inhabitants decreased by 4%. In the same time population ageing continued and a shift of age distribution towards older ages resulted in the increased needs for health care services and surge of their use [3].

The increase of the number of elderly people in Croatia in the upcoming period could become one of the major generators of increasing need for physicians, despite the expected stagnation or even decline in the total population. Folowing the country's accession to the European Union (EU) in 2013, the outward migration of health workers to other Member States has increased and contributed to the workforce shortage in the Croatian health care system. The majority of physicians are concentrated in major cities and their density varies regionally within country which is administratively organized in 21 counties. Some counties do not have enough physicians in primary health care, particularly in remote poorly populated areas and islands. In some counties, more than 35% of physicians are aged 55 and over, what raises concerns about their number in the near future when they will be retired, especially having in mind that those counties are less developed [3].

With around 3.3 full-time physicians per 1,000 inhabitants including those without specialization and interns, Croatia was at the end of 2016 below the EU average being 3.6 physicians per 1,000 inhabitants, despite the fact that the number of physicians in the last three decades has increased by about 57%. A large increase in number of physicians was recorded by mostly developed EU member states, while among Central and Eastern European countries an increase in number of physicians was less pronounced, especially after their accession to the EU (e.g. Estonia and Romania) [3].

Croatia has kept publicly funded health care services accessible to its population. Besides concerns about financial sustainability of health care system due to large share of expenditures spend on pharmaceuticals and low efficiency of hospital sector accumulating debts, shortage of health care personel is seen as a main threat to the sustainability of health care system, particularly after EU accession. Number of physicians, and particularly nurses, is below the EU average and thus the strategic planning of human resources for health is urgently needed [4].

Simulation modeling has been used for a long time primarily for understanding of complex phenomena but it is also a suitable tool to present a problem and enhance a systematic debate between the stakeholders in many areas of human activity including healthcare. It allows to imitate a complex system behaviour in situations wich are unfit for experiment and prediction of future events under assumed circumstances. Generally, simulation models have been successfully used in research, instruction and training as well as an aid to decision making why they have been long ago named also policy simulations. The main advantage of policy simulations is their capacity to deal with considerable complexity of the system and the ability to explore "What if …?" type of questions [5].

There are comercialy available application-oriented simulation packages but a special program can also be developed in any programing language including standard spreadsheet as a platform for representing model structure with a set of formuals, performing simulation experiments and charting results [6].

The objective of this paper is to show how a simple but powerful simulation model can be build up using standard spreadsheet program and used to simulate future needs and supply of physicians in order to inform policy makers at national level when deciding on enrollment to medical schools

and immigration quotas for physicians entering the public healthcare system.

Methods

Two main types of simulation models are discrete events simulation and continuous simulation also known as system dynamics which proved to be powerful method not only when used in research but also as a tool in decision making providing necessary information to policy makers [6].

Already in late 1980s, an original method based on the use of standard spreadsheet program was developed in authors' Department at the Andrija Štampar School of Public Health and used to simulate population dynamics of infectious diseases. The approach was general and method enables simple and intuitive use of simulation models including model implementation, changes of parameters and initial values in an easy manner, performing simulation experiments and display of results in tabular and graphical form [7]. At that time the most used spreadsheet program was Lotus 1-2-3 like nowadays is Microsoft EXCEL. It proved to be powerful tool for development of system dynamics models and running of simulations. Same approach was employed in simulation modeling of health personnel dynamics aimed for decision making on enrollment policy to medical schools and higher education programs in health sciences in Croatia [6].

The working group established in 1989 by the Association of higher education schools in medicine and health sciences as a consultative body at national level (at that time of the Federal Republic of Croatia), whose founding was initiated by discussions on enrollment quotas at schools of medicine and proposals for their reduction, accepted the proposal to use the simulation modeling as an aid for decision making. A simulation model was developed with the aim to simulate needs and supply of physicians as well as other health professionals (nurses, laboratory technicians, radiology technicians and other). A series of simulation experiments has been performed with different assumptions about the number of enrolled students and other relevant aspects (e.g. introduction of private practice, employment outside health care and differences in the presumed number of health care users), and the results served as a basis for decisions on enrollment policy [8,9]. Based on that results authorities adopted a decision to decrease the enrollment quotas starting from the year 1993 because at the time there were a surplus of physicians resulting in rise of their unemployment rates.

Adaptation of the previously developed model structure and parameters has been made in order to use the simulation again as a tool to inform decision makers in current situation when the Republic of Croatia is faced with an opposite situation, a huge lack of physicians.

Simulation model is structured as multicompartmental (or multistate) model in which variable values are numbers of physicians in one-year age groups and simulation is run by calculating changes in one-year steps (calculated values for successive years are stored in rows). We can consider data as a table (or matrix) with rows being consecutive years (here 2016-2040) and columns are containing number of persons of the same age (25-65). We can denote these values with $X_{i,j}$, i=2016, …,2040; j=25, …, 65 having in mind that the youngest age at which one can graduate in medicine is 25 years and 65 is age for retirement. Thus model simulation correspond to calculation of state variables (or compartments) and intuitively results in a move of one compartment in diagonal direction (from left to right means ageing for one year, from one row to the next one is move to the next year value). Of course, it is not only about moving because of ageing, but other different calculations are taking place (mortality, disability, emigration and immigration as well as flows reproducing graduation and retirement). Model parameters (mortality and disability rates, immigration and emigration and other parameters and input values) are entered in different areas of spreadsheet and used in calculations.

Parameters' estimation

Population projections by 2040 were taken from the publication of the Croatian Bureau of Statistics [10]. Currently there are 3.3 full-time physicians employed in health care system per 1,000 population while in the more developed EU Members States there are 3.6 physicians per 1,000 inhabitants [4]. It can be noticed that Croatia lags behind the European average that we strive for. The target value is defined as the EU average (3.6 practicing physicians per 1,000 population).

In developing this model and assessing the needs for physicians in Croatia, it is important to consider the following factors: the number of physicians working in the healthcare system and their age distribution, the number of inhabitants, the number of enrolled students at the medical schools and their years of studying span, as well as the mortality, disability and emigration rates of physicians. The rate of emigration is particularly significant after Croatia joined the EU, but one has to take in account also the employment opportunities for physicians within the country but outside the healthcare system (for example in pharmaceutical industry, insurance companies or even outside the biomedical profession). We estimated that about 11% of physicians are currently employed outside the healthcare system and it is expected that this percentage will rise up to 15% by 2040. According to available data there are 14,394 practicing physicians and it is estimated that another 1,600 are out of the health system [3].

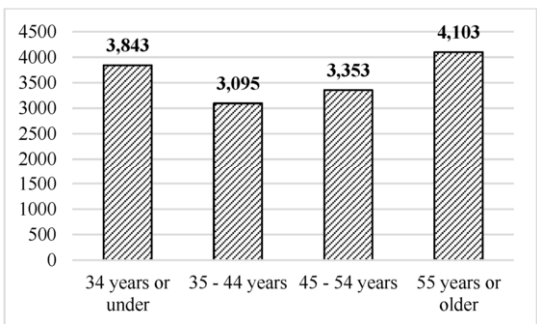

Figure 1 Age distribution of Croatian physicians

Age distribution of physicians employed in Croatian healthcare system is shown in Figure 1. Data are for the year 2016 and it is obvious that the age group 55 years and older is the largest one and having in mind that according to present regulations retirement age is 65 years, it means that in the next 10 years 28.5% of working force is going to be out of employment.

There are four medical schools in Croatia and medical study lasts 6 years. We estimated that about 5% of enrolled students never complete their studies while 80% of students graduate six years since enrollment, 10% after seven years, 3% after eight years, while approximately 2% of students complete their studies at the age of 28 years i.e. after nine years of study.

Estimated rates of mortality and disability are spanning from 0.12% for physicians at 25 years of age up to 2.39% for those aged 61 to 65. Apart from mortality and disability, which affect drain outside profession, migration outside Croatia is also supposed to be significant. It is estimated that the number of

those who will leave the country will increase. Simulations were made with the assumption that 3% of those aged 25 to 27 years will leave the country every year, 2% of those aged 28 to 29 years, and 1% of physicians aged 30 to 45 years. No outflow is expected for those over 45 years of age who are already acknowledged in their profession and have established their social and family surrounding.

Simulation was made for three potentially achievable scenarios: (1) increase of the total enrollment quota at the existing four medical schools by 50 students per year starting from 2020; (2) introduction of immigration quota for of 50 physicians per year and (3) combination of previous two scenarios - increase of the enrollment quota by 50 students per year and immigration of 50 physicians per year. Year 2020 has been taken as the earliest year when potential changes could be implemented with respect to all political and administrative procedures.

Results

In the case of an increased enrollment quota by 50 medical students starting from the year 2020 (a total of 650 instead of current 600 freshmen per year at the national level) there will be a huge lack of 3,511 physicians in the health care system in 2025 if we want to reach most developed EU countries which have 3.6 physicians per 1,000 population; in 2040 there will be shortage of 1,769 physicians. Second scenario with introduction of immigration quota of 50 physicians per year would give a little bit faster raise of supply with a shortage of 3,467 physicians in 2020 and 1,542 in 2040. Third (combined) scenario would result in the growing number of physicians from the year 2020 and the lack of 1,029 physicians in 2040. Not only with current enrollment quota, but even with higher quota of 650 freshmen per year it is obviously not possible to meet the needs for physicians in the Republic of Croatia by the year 2040.The results of all three scenarios are presented in one chart (Figure 2).

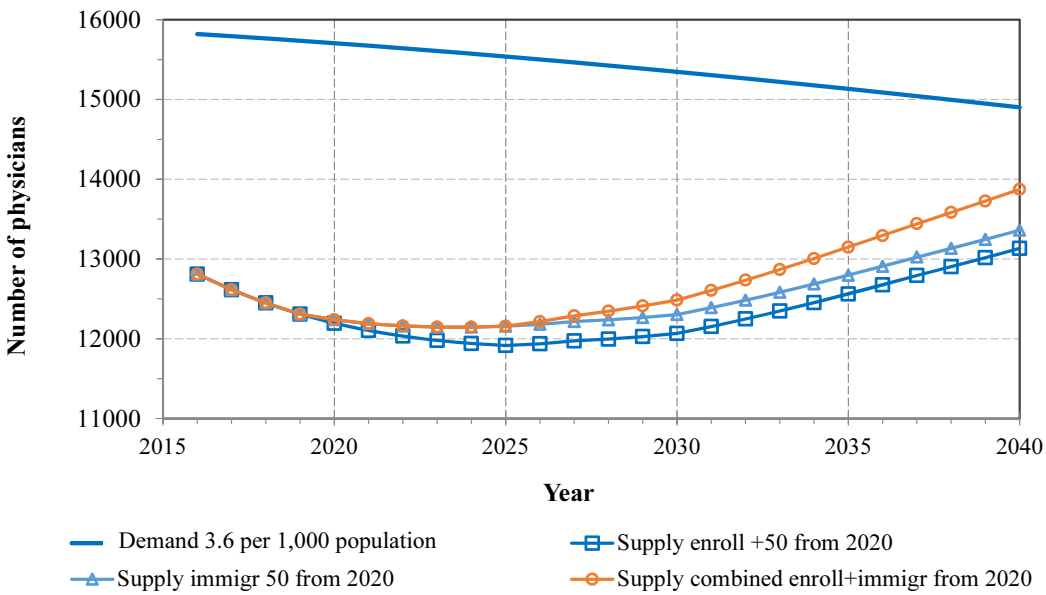

Figure 2 Results of simulation experiment

Table 1 Predicted number of physicians in the Republic of Croatia – results of simulation with 650 freshmen medical students and immigration quota of 50 physicians per year

Year	Enrolled	Graduated	Health care	Total	Drain				
					Total	%	Retirement	Emigration	Death+Disability + Emigration
2020	650	570	12,239	13,930	633	4.53	313	109	320
2025	650	570	12,157	14,066	547	3.90	236	124	311
2030	650	618	12,485	14,688	524	3.60	212	138	312
2035	650	618	13,148	15,468	494	3.23	176	149	318
2040	650	618	13,873	16,321	492	3.04	164	154	328

Discussion

Use of spreadsheet program for simulation modeling

Although the application-oriented programing languages and packages for simulation modelling appeared very early and became commercially available already during 1980s and 1990s, different software tools can be used to represent structure of simulation model and perform simulation experiments. Many applications were developed and used within certain academic or other institutions, among them widely used standard spreadsheet programs like Microsoft EXCEL proved to be a suitable platform for development and use of simulation models of both type's system dynamics and discrete events simulation [6, 11].

"Spreadsheet simulation" refers to the use of a spreadsheet as a platform for representing simulation models and performing simulation experiments. Despite nowadays advanced commercial program packages for modeling and simulation would be a method to choose, standard spreadsheet programs as a tool for model implementation and simulation run is worthy to use due to many reasons. Spreadsheets are widely used by many people for different tasks on everyday basis and the spreadsheet's table structure allows the developer to organize the computations and outputs in a natural and intuitive manner. A large number of functions to do mathematical, statistical, database, date/time, financial and other calculations are available and, very important, it is easy to make charts and present simulation results either in table or graphical form. It is very important that end users are either able to develop simulation models by themselves or understand and use models developed by others, control parameters and perform simulation experiments [11].

Informativeness of simulation results for policy makers and applicability to other circumstances and countries

Although the enrollment quotas have been increased at Croatian medical schools since the year 2009, this increase is not sufficient to meet the current needs for physicians. Unfortunately, this increase in quotas was not followed by the adequate staff and financial needs of medical schools. As we see in the projections made in this research - if the enrollment quotas were increased by 50 students per year, what is challenging in an organizational and financial way; it would be insufficient if Croatia were to reach the current EU average of 3.6 physicians per 1,000 inhabitants.

In recent years the interest of students in studying medicine is decreasing, there are less and less applicants competing for one enrollment place [3]. Reasons may be different, from the quite a long lasting and demanding study program, difficulties in getting the desired specialization at the desired place upon graduation to the better opportunities in other professions. The diploma of physician still does not provide income and the position adequate to the invested efforts and time. The fact is that most physicians are still at the beginning of their careers in their middle age, while other professions are at the peak of their careers.

Since increasing quotas is not an only option that can contribute good results, a potential option is a better organized and coordinated immigration policy - recruitment of physicians trained in other countries to whom work environment and life in Croatia are acceptable. Since Croatia joined the EU (1st July 2013) till the end of 2016 only 30 foreign-trained physicians have been employed in Croatia. The largest number came from Macedonia (32.3%), Bosnia and Herzegovina (19.4%), Serbia (16.1%), Syria (9.7%) and the rest of physicians migrated from Slovakia, Montenegro, Lithuania, Russia, Slovenia and Kosovo [3]. Current quotas for physician's immigration in Croatia are negligible. A significant number of domestically trained physicians work outside of their profession (around 1,600) so another possibility might be to return some of them to the healthcare system. A harmonized combination of increasing enrollment quotas for medical students and increasing immigration of physicians will lead to an EU average of over the next 20 years.

There is a problem of organization and insufficient planning of healthcare staff in Croatia visible in the fact that there are 116 physicians per 100,000 inhabitants at the tertiary level of health care, 107 at the secondary level and 92 physicians in primary health care. This is also manifested by a huge number of overtime working hours and imbalanced geographical distribution of physicians [3].

It is necessary to take into account all that provide skill mix – the mix that produces the maximum number of health care services at a given quality and cost – more health care services are going to be accessible and affordable to populations seeking care and task shifting - a policy option that should be considered to help achieve productive efficiency and provide access to services that otherwise might not be available. A more productively efficient skill mix will partially dampen the effect of health workforce needs-based shortages [12].

According to estimates of population trends in Croatia, reduction in the number of inhabitants is forecasted along with population aging, what means that the number of patients and those who need health care will increase.

Other groups of researchers also used system dynamics modeling for the forecasting of needs/demand and supply of physicians at national or regional level. Similarly to Croatian situation in the late 1980s, Japan had also reduced enrollment quotas to medical schools due to surplus in number of physicians and has faced absolute and relative shortage of physicians twenty years later. Of course, Japanese absolute numbers are more than tenfold higher than Croatian ones, but the problem and approach employed in order to inform policy makers are the same [13]. Majority of other problems inherent to healthcare system are similar: maldistribution of physicians at both the regional and departmental level and others. Regarding calculation of needs/demand similar approach was taken: the number has been evaluated by a comparison with OECD average. Spain has also gone from a surplus to a shortage of physicians in a very few years what initialed a development of a system dynamics model for simulation of supply and demand/need of specialist of 43 medical specialties [14]. Problems and debates within the medical profession and in public at general are very similar in many countries. Besides planning of enrollment quotas to medical schools and immigration quotas for foreign trained physicians, an important question that needs to be tackled is how to plan specialist education [2, 14]. Another example is simulation model of the allocation of residency grants for medical specializations given from regional and national level [15]. System dynamics model was developed with the aim to project and optimize supply of medical specialist under three different supply scenarios in Emilia-Romagna Region in Italy. Demography, service utilization rates and hospital beds were taken into account as demand drivers while a potentially effective assignment of medical specialization grants for each year in 20-year period was targeted.

System dynamics modeling is an excellent method for simulation of health workforce supply and demand. A proactive approach to the planning and management of health workforce, involving continued monitoring, might facilitate more frequent and less dramatic adjustments to needed supply. Many issues

and challenges of public health can also be presented and analyzed using simulation modeling [16].

Limitations

This study did not take into account the number of medical students in English study programs (Medical Studies in English) that are running by the Croatian medical schools. Students enrolling in English programs are largely foreigners who plan their employment after graduation in their homelands.

Furthermore, the study did not take the geographical distribution of physicians and it has not targeted adequate distribution according to the levels of health care – these are very important determinants of quality planning of a public healthcare system.

Although official data and projections of the Croatian Bureau of Statistics on the population trends have been used, we are already witnessing of a decline in the total population that happened by the year 2018 which is far greater than it was forecasted in 2015. Population aging has not been taken into account, but only projected total number of inhabitants.

Conclusions

The Republic of Croatia is facing a serious shortage of more than 3,000 physicians in the healthcare system.

Increasing enrollment quotas, defined and agreed immigration policy, re-directing physicians from other occupations to the healthcare system, task shift and skill mix options are just some of the measures that need to be taken now in order to improve the situation in the near future.

Simulation modeling is certainly a method for predicting flow of physicians and other health professionals within healthcare system capable to simulate different scenarios that can potentially take place in future. Standard spreadsheet program proved to be powerful platform for model implementation, simulation experiments and presentation of results.

Abstract

Patient safety is an important topic but non-trivial to measure, as it comprises very different phenomena. One important example of patient safety issues is delirium. Many approaches for the detection and prediction of delirium are described in the literature. However, additional effort is often needed for a comprehensive data collection and for the avoidance of potential biases. To systematize a process for the detection and prediction of delirium reusing available clinical routine data, we aim to develop a minimum data set (MDS) for delirium. By combining a top-down and bottom-up approach, we compiled a comprehensive delirium map containing potential delirium elements based on evidence. The alignment with clinical routine data led to a specific version of an MDS for delirium and revealed that most of the delirium elements could be identified within available nursing routine data.

Keywords:
Delirium, Data Collection, Patient Safety

Introduction

Patient safety is an important topic receiving increasing attention [1,2]. The World Health Organization defines patient safety as the reduction of risk of unnecessary, preventable harm to an acceptable minimum [3]. Issues of patient safety and patient safety research have a big impact on the health care sector. However, patient safety features a high complexity characterized by a whole series of interacting factors and dimensions [1,4].

Hence, measuring patient safety is not a trivial task. Several methods for the detection of patient safety incidents are already described in the literature, e.g., patient safety indicators for the detection of adverse events, chart reviews, incident reporting systems, or trigger tools [2,4,5].

However, various weaknesses of those methods and instruments are evident [2,4–7]: Incident reporting systems tend to have a lack of sensitivity and an increased risk of (reporting) bias; manual review of patient records (as necessary for global trigger tools) requires a vast amount of resources; patient safety indicators based on administrative data are often biased, as documentation follows accounting and billing instead of clinical purposes.

In order to overcome some of those disadvantages, especially to reduce the resources needed to measure patient safety accurately, the secondary use of available clinical routine data within an institution seems to be a helpful approach [2,8].

Secondary use of clinical routine data is defined as usage of available clinical routine data for other purposes than patient care, e.g., for health care research or quality management [9,10].

Examples of secondary use of clinical routine data can be found in the literature [9,11]. However, secondary use projects exhibit a high level of complexity and issues to be resolved, such as inadequate standardization and poor data quality. This demands the structured and goal-oriented planning of such projects. The SPIRIT framework (Systematic Planning of Intelligent Reuse of Integrated Clinical Routine Data), which is designed for systematic planning of secondary use of clinical routine data, can help [9].

Every incident and measuring method requires a clearly defined set of well-described specific data, and available clinical routine data often diverge from one institution to another. Thus, it seems necessary to individually align patient safety issues of interest with the available clinical routine data. For such an alignment, the issues of interest must first be selected. Then a priori knowledge and expert knowledge on all dimensions of these issues must be assessed to define all relevant data elements for the respective issues. These elements would constitute the theoretic “maximum data set”.

In a following step, the clinical routine data set has to be screened for these elements. If available, the routine data elements are included in a special data set which can be understood as the “greatest common divisor” between all available routine data and the maximum data set. It thus represents the “minimum data set” for the patient safety incident of interest. Implicit is that minimum data sets can vary between institutions.

In this study, we want to demonstrate how this approach is applied to a very important patient safety issue: delirium. Delirium is an acute disturbance of mental functioning which occurs quite often within the population of older hospitalized persons. It is associated with an enormous burden to the affected people and to the health care systems. It is regarded as preventable in up to 40% of the delirium events and is considered to be an important patient safety indicator [12,13].

Delirium features a high complexity and is often overlooked by clinical staff. It is estimated that up to two out of three of all delirium cases are overlooked in hospitals despite available assessment and screening instruments [12–14].

Several predictive models for the detection of delirium are proposed in the previous studies [15], some of which are based on routine data [16,17]. However, the available clinical routine data often diverge from one institution to another,

which makes the generalizability and usability of these predictive models challenging. Thus, it is necessary to specify the data types necessary for detection of delirium as well as data availability.

Our objective is to systematically compile a Minimum Data Set for the Detection of Delirium (MDS-DD). We will achieve this aim through the systematic development of a generally applicable and comprehensive view of relevant delirium elements (maximum data set) as a basis for the alignment with already available clinical routine data in hospitals with divergent hospital information systems.

Methods

Based on the SPIRIT framework as a systematic approach for the secondary use of clinical routine data [9], we combined a top-down with a bottom-up approach to construct the MDS-DD. Figure 1 depicts in a summarizing manner the undertaken actions (grey boxes) and the expected results (white boxes).

Top-Down Approach: Literature Work and Expert Review

A literature and guideline review was conducted to obtain a thorough overview of relevant elements of delirium as an important patient safety incident in order to generate the maximum data set for delirium. The maximum data set thus comprises all those elements associated with delirium. Thus, it is necessary to incorporate and collect all elements related to risk factors , diagnosis, and treatment for delirium measurement tools. In order to systematize our findings and to gain a classification of delirium, the identified elements were assigned to different classes based on common features. A classification is the compilation of classes (e.g., risk factors) with their semantic relationships [3]. The classes for outlining delirium were developed inductively and deductively out of the body of literature.

Furthermore, previously developed relevant classification systems were screened systematically to collect information on delirium, including the International Statistical Classification of Diseases and Related Health Problems (ICD), the Diagnostic and Statistical Manual of Mental Disorders (DSM), the nursing diagnosis classification of the North American Nursing Diagnosis Association International (NANDA-I), and the Nursing Outcome Classification (NOC).

To validate the usability of the comprehensive maximum data set, the first draft was reviewed by clinical and IT experts and within our working groups in addition to literature.

During the iterative developing process, we found that the alignment of the classes of the maximum data set with the International Classification for Patient Safety (ICPS) key concepts in PS-CAST (Patient Safety – Categorical Structure) [3,18] expedient as a first step for knowledge management and representation.

In order to obtain a visual representation of the maximum data set, PS-CAST was used to structure a "delirium map", including the identified classes and particular elements of delirium.

Bottom-Up Approach: Case Study

The maximum data set, a comprehensive collection of relevant elements for delirium, was then used as a "dragnet" to screen in a clinical information system of Tirol Kliniken, a health care institute in western Austria, for available delirium-specific routine data elements.

In cooperation with an IT expert from Tirol Kliniken, first all (nursing) data elements were screened, as they were easily accessible in a comprehensive nursing data mart [19]. In the next step, the clinical and medical data elements were screened together with a chief physician from a psychiatric clinic within Tirol Kliniken.

The Minimum Data Set for the Detection of Delirium (MDS-DD) was then described as a simple spreadsheet which contains the linkage between the elements of the maximum data set and the available clinical routine in the clinical information system of Tirol Kliniken. This MDS-DD can now be used as a basis for all following data extraction processes.

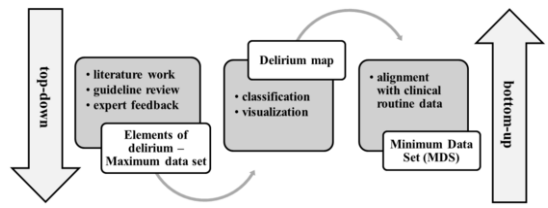

Figure 1 – Systematic approach for the development of a Minimum Data Set

Results

With this approach, we were able to collect, classify, and visualize relevant elements associated with delirium. The alignment of the maximum data set with the available clinical routine data revealed that several elements could be identified within various data sources. That means, indications for the risk factor such as *infection* could be identified within the laboratory information system, administrative data, nursing assessment, etc., although other elements, e.g., the training of the staff, were not identifiable within the routine data. Most of the elements could be identified in available nursing data. The medical data often remained on a less structured data quality level.

Elements of Delirium - Maximum Data Set

We identified eight classes: *circumstance, action, outcome, detection, care setting, agent, data,* and *classification.*

The class *circumstance* has two subclasses: *risk factors* and *organizational factors*. *Risk factors* are divided into *contributing factors (pathophysiological factors), predisposing factors* and *precipitating factors*. The *predisposing factors* can be further divided into *demographic characteristics* (with 14 concrete elements, e.g., age, sex, language), *cognitive status* (four elements, e.g., dementia, cognitive impairment), *functional status* (eight elements, e.g., functional dependence, pain), *sensory impairment* (two elements, e.g., visual impairment) and *coexisting medical conditions* (ten elements, e.g., comorbidity). The *precipitating factors* are constituted of *primary neurologic diseases* (six elements, e.g., stroke, head trauma), *intercurrent illnesses* (14 elements, e.g., infection, hypoxia), *surgery* (nine elements, e.g., orthopedic surgery), *environmental factors* (17 elements, e.g., setting, social isolation) and *physiological factors* (five elements, e.g., electrolyte disturbance). Additionally, *drugs* are related to the class *risk factors* (28 elements, e.g., drug abuse, analgesic agents). We also found 34 *pathophysiological factors* (e.g., proinflammatory markers) and genetic factors (e.g., Apolipoprotein E). Altogether, 151 risk factors were identified. The distinction of the elements was not always clear; for the purpose of integrity,

therefore, if it was possible to assign the same risk factors to two or more classes within the literature. Those factors were also represented as many times in the maximum data set. The *organizational factors* comprise five elements, including occupancy rate and technical resources; they were mainly mentioned in the expert review.

We screened four classification systems thoroughly: ICD, DSM, NANDA-I, and NOC. We identified 237 delirium-related nursing outcomes according to the Nursing Outcome Classification (NOC), e.g., 0905-Concentration (the ability to focus on a specific stimulus). These can be linked to the NANDA-I diagnoses "acute confusion" (00128) and "risk for acute confusion" (00173).

Furthermore, features and symptoms constitute additional delirium elements. They were assigned to the class detection. According to the literature, relevant criteria of delirium in ICD-10 and DSM-5 are: consciousness disturbance, inattention/ disturbance in attention, perceptual disturbance, disturbance in day-night rhythm, increased or decreased activity/agitation; disturbance in psychomotor activity, disorientation, memory disorder, cognitive disturbance, thought disorder, communication disorder, disturbance in visual-spatial capabilities, and/or disturbance in emotion/affect, characterized by an acute outbreak, a remarkable trigger, and changes during the course of the day and in the degree of severity.

Additionally, 51 assessment and screening instruments as relevant elements for delirium were identified for differential diagnostics and the *detection* of delirium, respectively. Examples are the Confusion Assessment Method (CAM) and the Delirium Observation Screening Scale (DOSS). Several tools for the measurement of delirium (patient safety indicators, trigger tools) were added to the maximum data set.

Concrete elements concerning the *outcome* class were identified which could be divided into *patient outcome* and *organizational outcome*. Relevant elements are the consequences for hospitalized patients with delirium, e.g., higher mortality during hospitalization, an increased length of stay, and higher expenditure.

Delirium management (6 elements, e.g., drug adjustments), therapy/treatment (pharmacological vs. non-pharmacological therapy), prevention (12 elements, e.g., prevention of cognitive impairment/disorientation), and diagnostics constitute the class *action*, i.e. interventions and actions to handle the topic were subsumed under this class.

Moreover, we identified the class *data*. Here, we screened the literature in order to find the first data group where the relevant data elements of delirium could be stored in general. The data are categorized as: demographic data, administrative data, nursing assessment, laboratory data, diagnosis, and procedures (health interventions).

The classes *care setting* and *agent* are not addressed at this point since they have been already discussed above.

Delirium Map

Figure 2 shows the structure of these classes and their subclasses without the concrete elements. Furthermore, the first-level relationships between delirium and the eight main classes are shown. This visualization can be regarded as the first step for knowledge management and representation for delirium.

Minimum Data Set for the Detection of Delirium (MDS-DD)

The bottom-up approach led to a specialized version of a minimum data set for delirium and revealed that most of the delirium elements could be identified within the available nursing data.

Based on the comprehensive maximum data set, we were enabled to screen the available clinical routine data in a goal-oriented manner. Every single element was considered. Within this screening process, we were able to compile a special data set, the "greatest common divisor" between all available routine data and the maximum data set: the Minimum Data Set for the Detection of Delirium (MDS-DD).

As it turned out within the case study, the minimum requirement for future data extraction and analyses is the access to the following data groups: nursing assessment data, care planning data (including nursing diagnoses, nursing goals, nursing interventions), administrative data, laboratory data, surgery data, medication data, medical data, several

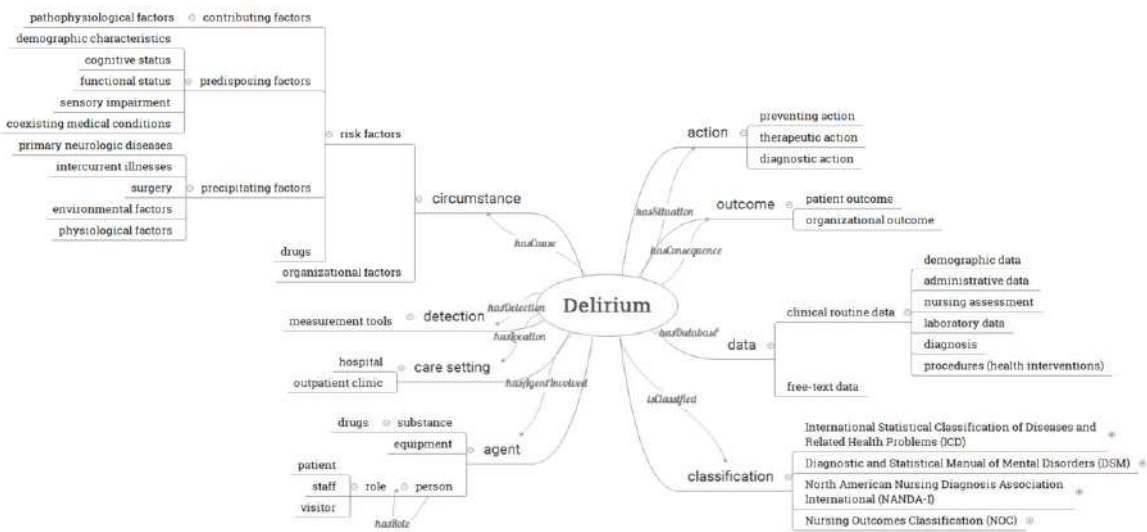

Figure 1– Delirium map following the PS-CAST with classes, subclasses and relationships (arrows)

additional forms (vital signs, pain, stool excretion, physical restraints, falls, decubital ulcers).

Within the class of risk factors, we ascertained that approximately 50% (75 elements) of the risk factors could be identified within the nursing routine data.

In table 1, we present a short extract of the MDS-DD.

Table 1 – Extract from MDS-DD with elements, classes, and the data source where it is stored; "n.a." denotes "not available in clinical routine data".

Element	Class	Data source
Age	Risk factors	Nursing assessment/ administrative data
Cognitive impairment	Risk factors	Nursing assessment/care planning data/medical data/administrative data
Electrolyte disturbance	Risk factors	Laboratory data
Pain	Risk factors	Nursing assessment/care planning data/forms
Technical resources	Organizational factors	n.a.
Apolipoprotein E	Pathophysiological factors	n.a.
Inattention/ disturbance in attention	Detection	Nursing assessment/care planning data
Normalize sleep-wake cycle	Action	Care planning data (nursing interventions)
Acute confusion (00128)	Classification	Care planning data (nursing diagnoses)

Discussion

The first version of a Minimum Data Set for the Detection of Delirium (MDS-DD) was developed at Tirol Kliniken. The MDS-DD consists of eight main classes which were further divided into subclasses. The content of the classes constitutes the relevant elements associated with delirium.

The compiled data set has not yet been validated. This circumstance must be regarded as a limitation for now.

One strength of our approach is the reproducibility with regard to further patient safety phenomena and especially to various hospital information systems that are designed in different ways. Evidence within our development procedure are several similarities to the existing indicator development approaches [20, 21], such as the combination of literature work, guideline reviews, and expert feedbacks with regard to available clinical routine data.

Relevant measuring methods for delirium, such as delirium indicators and assessment methods, were also incorporated into the delirium map. This comprehensive compilation of the different delirium classes offers the possibility to link several approaches in order to detect delirium events with one automated tool. This the secondary use of clinical routine data to avoid the disadvantages of the particular existing methods and instruments within future stages of the project.

The delirium map can be used as the foundation for a concept map to represent concepts and relationships and describe the safety-related phenomenon of delirium. Furthermore, the map's elements and classes could be aligned in further steps in directed acyclic graphs to attempt to find causal effects and identify confounders. The cross mapping between delirium map and the International Classification for Patient Safety (ICPS) key concepts in PS-CAST provides the advantage of incorporating the ontology with the indicator measurement [22]. One of the next steps in the patient safety project could therefore be the formalization of the delirium map into a context-embedded and secondary data-based ontology to automatically detect and compute delirium indicators both retrospectively and prospectively.

There might be potential elements missed in our method. It is conspicuous, however, that social factors such as *family absent* or *social isolation* are named as risk factors in the literature but concrete mention of risk factors such as *language, religion* or *socioeconomic status* could be hardly identified, likewise *organizational aspects*, e.g., light conditions, the organizational occupancy rate or available technical resources. Such potentially relevant delirium elements were added after expert feedback with regard to the meaningfulness of the comprehensive delirium element set.

Another possibility for the execution of the bottom-up approach would be a comprehensive analysis of the existing information systems and available data within an organization, i.e. a thorough description of the whole system, for example, with a so-called three-layer graph-based meta model [9]. This will make it possible to identify unknown risk factors and enable in-depth exploratory analyses.

According to our results, the maximum data set seems to be a generally applicable and comprehensive overview of relevant delirium elements as a basis for the alignment with already available clinical routine data in hospitals with divergent hospital information systems. It must be clarified, however, which data elements can be used for which analyses and whether this makes sense. This means, for example, that a symptom as an element of delirium cannot be used as a predictor variable.

Up to this point, it was clarified which data groups are relevant for subsequent analyses. The next steps on the way to these analyses are the development of data extraction and transformation routines.

Conclusions

In this study, a comprehensive maximum data set for relevant delirium elements was developed systematically. This maximum data set shows its applicability for the alignment with publically available data and the construction of MDS for delirium in various organizations. We tried to confirm the issue in a first case study. As a next step, we will use the MDS-DD as the basis to develop a model for automated delirium detection and prediction and validate our data model.

Overall, the approach we applied for the systematic construction of concrete MDSs seems to be usable for the development of other patient safety phenomenon element and data sets. This circumstance should be considered for further studies.

Acknowledgements

We would like to thank Tirol Kliniken GmbH for the possibility to cooperate and especially Stefanos Rauchegger and Prof. Josef Marksteiner for their support. The authors did not report any conflicts of interest. This work forms part of the PATIS Project (A PATient Safety Intelligence System and framework

for the secondary use of multimodal clinical data to assess and improve patient safety) funded by the Austrian Science Fund (FWF – P 29076).

Abstract

This study selects the users generated content in diabetes groups of ManYouBang and DailyStrength which are two representative HCQA (Health Communities of Questions and Answers). Theme coding was applied to identify information needs while social network analysis was used to compare Chinese and American HCQA. In theory, we combine Social Network Analysis and content analysis to capture and contrast the pattern of Q&A in HCQA. On the one hand, the core needs of HCQA are "how to treat the disease" and the "diet" theme is closely related to other themes. On the other hand, the Chinese diabetes communities have "question and answer attributes" while the American diabetes communities have both "question and answer attributes" and "social support attributes." In practice, the founding provides enlightenment for the development of HCQA including improving content quality and strengthen emotional connection and disease treatment infrastructure.

Keywords:

Diabetes Mellitus; Diet; Social Support

Introduction

Health information refers to information related to people's physical and mental diseases, nutrition, health care, etc. [1] Health Information Seeking Behavior (HISB) is described as "verbal or nonverbal behavior used to obtain, clarify or confirm knowledge or information about a specific event or situation" [2]. Recently, most HISB researches have adopted questionnaire and structured interview methods to conduct quantitative analysis[3]. Themes cover searching behaviors, motivations, purposes, influence factors, information quality assessment, impact on health practice, and so on [5]. Many people, either adolescents or older adults, reported that the Internet was an important channel to reach health information source available [4]. HISB can be affected by external and internal factors, such as uses and gratifications (U&G), Media System Dependency (MSD) [6], user's goals, motivations, emotions and so on [7]. Betsch [8] studied online vaccine information's impact on patient's vaccine receiving behaviors based on TPB theory. It appears information plays an important role in patient's vaccine receiving behaviors, especially for lack-of-knowledge individuals.

HCQA is different from users' online health information browsing. It is characterized by two main functions: informational support and social support. With the number of people with chronic diseases skyrocketing, more and more users joined HCQA to seek and share treatment experience and health knowledge. They offer views, conduct emotional communication, and seek emotional support from others in the community. It is considered to be critical in patient's recovery [9]. Researches analyze more based on encoding topics including content analysis and quality evaluation [10,11]; user behaviors and psychological analysis [12, 13]; topic identification [14-16].

Kim et al. [10] and Oh et al. [11] studied the content of forums in Yahoo！Answers. The former analyzes linguistic properties of different types of questions about eating disorders while the latter investigates evaluation criteria people use about the online health information. Factor and regression analyses conducted among 231 breast cancer patients were used to examine the role of social support perception and emotional wellbeing on online information seeking within the context of CHESS [12]. Ahadzadeh [13] used PLS-SEM to test the moderating effect of health consciousness on attitude towards internet usage in HISB. Coulson [14] and Arden [15] captured three main themes of alcohol discussion forums and guidance on public forums respectively by qualitatively thematic analysis. The current body of research has shed light on the HCQA related landscape. Notwithstanding, researches using hybrid methods on user online health information need are limited. Only a few studies focused on understanding information needs. Min [16] used both content and semantic network to analyze forums which revealed two dominant topics: breast cancer tests and treatment.

Few researchers have applied Social Network Analysis combined with content analysis to capture and contrast the pattern of Q&A in HCQA. To fill the gap, this study focuses on understanding the patterns and users' needs of HISB in Chinese and American communities, taking diabetes for example.

Methods

Data were obtained from diabetes-patient-group in DailyStrength (https://www.dailystrength.org/) and Man Youbang (http://www.manyoubang.com/), one of the largest online communities in the USA and China. DailyStrength was established in 2006 comprised of 421 patients-groups and 1096 members in diabetes-group; while Man Youbang was established in 2013 comprised of 84 patients-groups and 7,995 members in diabetes-group. Although Man Youbang also raises money for patients, we only focus on its Q&A which is a relatively separate and important section in fact.

Users post messages and replies on a variety of topics referring to diabetes. A total of 3,553 replies associated with 777 questions from Man Youbang and 11,754 replies associated with 2,115 questions from DailyStrength related to diabetes posted in Jan. 1st, 2013 to Dec. 3st, 2017 were collected. Through manual review, meaningless entries are deleted. Then, we get 2,556 replies associated with 777 English questions fr

Table 1 – Topic Coding Scheme of Dataset

Level 3	Level 2	Level 1	Connotation
Disease specific information	Prevention	How to prevent diabetes	How to prevent diabetes from genetic, environmental, diet, exercise, and other factors.
	Diagnose	Symptom	Anything that accompanies diabetes and is regarded as an indication of diabetes.
		Cause	Events that lead to diabetes.
		Typing	Diabetes is divided into type 1 and type 2
	State of an illness	Describe the state of an illness.	Description of the patient's condition.
	Treatment	insulin therapy	Treatment with insulin injection.
		Other treatments	Other treatments, such as oral medication.
	Complication	Diabetic foot	A diabetic foot is a foot that exhibits any pathology that results directly from diabetes.
		Ketoacidosis	Acidosis with an accumulation of ketone bodies; occurs primarily in diabetes mellitus.
		Retinopathy	The most important manifestation of diabetic microangiopathy is specific changes in the fundus.
	Blood glucose monitoring	Self-monitoring of blood glucose	Patients observe and record their blood glucose by instruments, test paper, etc.
	Special cases	Gestational diabetes	Pregnant women develop diabetes before or during pregnancy.
		Juvenile diabetes	Patients are diagnosed with diabetes between the ages of 13-25.
		Senile diabetes	Patients are diagnosed with diabetes after age 60.
		Others	Patients have other diseases besides diabetes.
	Drug's side effects	Side effects caused by drugs	Symptoms, such as nausea, vomiting, hair loss and fatigue, caused by drugs.
Non-disease specific information	Diet	Dietary precautions	Food that helps or deteriorates with treatment.
	Exercise	Exercise to lose weight	Exercise during illness to lose weight.
	Insurance	Medical insurance	Obtain compensation or security for treatment.
		Other insurance	Other insurance.
	Finance	Financial concerns	Financial pressure during treatment.
	Emotional support	Spiritual support	Seek comfort and encouragement during treatment.
	Social support	Charity relief	Property and other charitable assistance during treatment.

Man Youbang and 9,179 replies associated with1,640 questions from DailyStrength. In this study, we explore hot topics and the evolution in different periods by coding content to reflect users' information need.

Manual annotation and word frequency statistics are often used to summarize the characteristics of information needs. Topics are identified manually by two coders considering the coding scheme adapted by Oh, Zhang, and Park [17]. Table 1 shows the coding results. 50 English and 50 Chinese questions and associated replies were selected randomly to test inter-rater reliability. For the level 2 categories, Cohen's kappa scores were 0.892 and 0.913 for the English questions and Chinese questions respectively. For the level 1 categories, Cohen's kappa score were 0.812 and 0.791 for them. It indicated that the two coders achieved good agreement on categories.

Results

Hot Topics Comparison of Chinese and American HCQA

Topics in domestic and foreign have similar performance. The most popular topics are treatment, diet, and state of illness. It is surprising that "community health service" is mentioned merely as an important auxiliary treatment for chronic diseases. It reflects that patients still pay more attention to disease-specific information. Most of them expect to obtain practical and reliable treatment and health management information, which can guide medical treatment and drug selection.

We also found some differences. To make numbers comparable, we calculate the proportion of each topic instead of absolute value. In Man Youbang, participants sought information about treatment most frequently, followed by diet, state of illness, complication, and diagnose, which reflects obvious practicability. Especially, "treatment" accounted for more than a quarter of all topics, which was the top priority for patients in Chinese communities. The least were prevention, insurance and, social support. Regarding DailyStrength, information need focuses on treatment, state of illness, and diet. Beyond the disease-specific information, an important non-disease specific term, emotional support, accounts for 15% in DailyStrength. It appears that American users pay great attention to the impact of emotion and gain comfort and encouragement from others in the community. Figure 1 present the top 5 hot topics.

Comparing the two communities, it becomes apparent that the proportion of "emotional support" in DailyStrength is about twice that of Man Youbang. Considering the content of relevant posts, American users intend to use emotional words more frequently out of religious belief, humanistic concern, and so on. Most questioners not only describe conditions but show their moods. At the same time, answers deliver their concern, sympathy, and support. It reflects the fact that DailyStrength not only possesses the attribute of "Q&A" but the attribute of "social contact." Patients express emotions and seek support frequently because they trust and depend on other members. It becomes apparent that western countries pay attention to emotional support in addition to drugs and physical ways.

Figure 1– Comparison of the top 5 hot topics in HCQA

Evolution of Hot Topics

Combined with the time label, Figure 2 and Figure 3 show the topics' composition of diabetes forums' in 2013-2017.

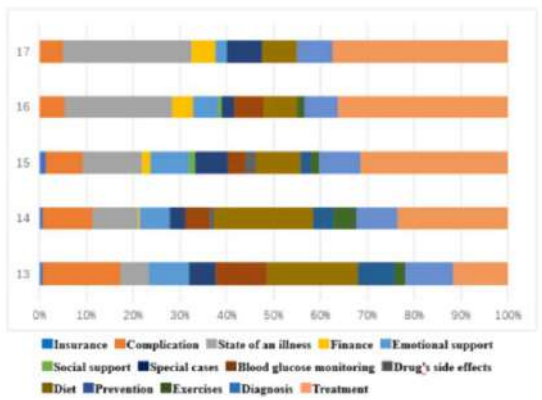

Figure 2– Theme Tags of Man Youbang

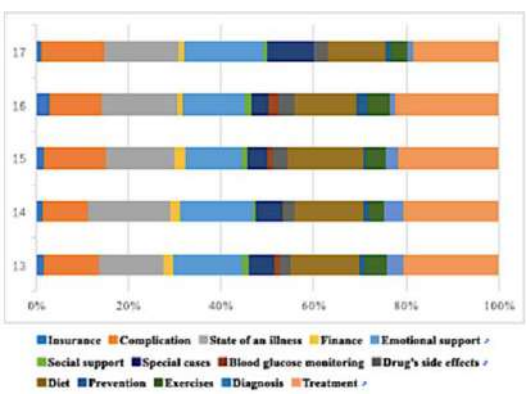

Figure 3– Theme Tags of DailyStrength

First, the overall trend of topics evolution is different. Annual topics' composition changes obviously in Man Youbang while not in DailyStrength. It is related to the development of HCQA in Chinese and American. Founded in 2006, DailyStrength is at a stable stage now. Users of various conditions and courses are balanced. By contrast, the heats have a larger fluctuation with members in different stages altering in Man Youbang.

Second, specific topics have different trends. In Man Youbang, the proportion of "treatment," "state of illness," and "finance" increase while "complication" and "diet" decrease. "Emotional support" and "diagnosis" are stable. By contrast, topics proportion is more balanced in DailyStrength. "Complication" usually posted by severe patients while "treatment" and "state of illness" may be issued by newcomers. In China, changing topics' proportion reflects Diabetes incidence and treatment burden are growing.

Comparison of Co-occurrence Network of Topics

Figure 4 shows the co-occurrence networks of Man Youbang and DailyStrength, which demonstrates the overall patterns and holistic properties. The larger the node, the higher the betweenness centrality. It shows that these topics are more likely to co-occurrence with others. The thicker the line, the higher the co-occurrence frequency between two topics.

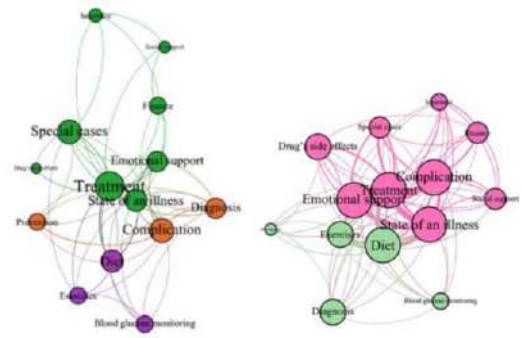

Figure 4– Co-occurrence Network of Topics in Man Youbang(left) and DailyStrength(right)

Figure 4 indicates the heats distribution is similar. We also focus on detailed information on different topics.

First, the top degree centrality topics are "treatment," "special cases," "state of illness," and "diet" in both Man Youbang and DailyStrength. All of them appear alongside more than 10 themes. "Treatment" is the most critical theme. Even if the main purpose of the question is not "treatment," the related narrative emerge. Second, we found that although "diet" does not co-occur with many topics, its average co-occurrence rate is high. It indicates "diet" has a closer correlation with its co-occurrence.

Diabetes is closely related to dietary habits for improper diet leading to the fluctuation of blood sugar. Therefore, patients discuss whether certain food can be eaten and how to control blood sugar. Food therapy is also used in the treatment of diabetes, which explains why "diet" is frequently associated with "treatment" and "state of illness." Also, obesity is one of the causes, and losing weight is a hot topic for diabetic patients. As two major ways to lose weight, "exercise" and "diet" are connected closely.

On the other hand, there are also significant differences. First, the overall network attributes are different. Topics in DailyStrength are connected more closely than Man Youbang. The co-occurrence network of Man Youbang includes 14 nodes and 50 lines. Average degree is 7.143, that is each topic co-occurs with other 7 topics on average. The density is 0.549, and average weighting degree is 48.571. Overall, the topic themes are not closely connected. The co-occurrence network of DailyStrength includes 14 nodes and 77 lines. Average degree is 11. The density is 0.846, and average weighting degree is 208.571. Overall, these themes are closely connected.

Second, topics play different roles. The high-degree nodes in DailyStrength are more than that in Man Youbang. In DailyStrength, nodes with a degree centrality above 10 accounts for 79% where "complication," "state of illness,"

"emotional support," "diet," and "treatment" co-occur with all other topics. We found that DailyStrength has a distinct role in "sharing." Patients ask and answer questions, also share their conditions, moods, and even matters in life. This increases the number of words and the probability of topics occurrence. While obvious attribute of "practice" in Man Youbang, patients ask and answer with short words involving fewer topics.

In addition, members have different emotional needs. As shown in Figure 4, "emotional support" not only co-occurs with all topics but appear a higher average co-occurrence rate In DailyStrength. Diabetes has a long treatment period accompanied by serious complications, which may cause fatigue and negative emotions. Diabetes is closely related to living habits, especially diet and exercise. Most patients have to reduce living quality and take on a greater economic burden.

At last, Topic clustering of Man Youbang is relatively scattered but more concentrated in DailyStrength. Table 2 presents the clusters. Cluster 1 refers to the main direct-related topics. Other topics are divided into 2 categories in Man Youbang. Cluster 2 refers to few disease-specific topics about diabetes or complications, while cluster 3 refers to non-disease specific topics about living habits. In DailyStrength, the remaining topics do not be divided. Therefore, we can infer American HCQA users pay more attention to the impact of diet and exercise on prevention. Improper living habits is an important cause of diabetes, such as high-calorie eating habits.

Table 2–Topics clusters results

Man Youbang		**DailyStrength**	
Clusters	**Topics**	**Clusters**	**Topics**
Treatment and protection of disease	Treatment, Special cases, State of an illness, Emotional support, Finance, Drug's side effects, Insurance	Treatment and protection of disease	Emotional support, Treatment, State of an illness, Complication, Drug's side effects, Special cases, Social support, Insurance, Finance
Prevention and complications	Prevention, Complication, Diagnosis	Diagnosis and management of disease	Diet, Exercises, Diagnosis, Blood glucose monitoring, Prevention
Daily management of disease	Diet, Exercises, Blood glucose monitoring		

Discussion

Using topic analysis and social network analysis, we examine hot topics evolution, related terms, and co-occurrence of HCQA in China and the USA. Then we will summarize the main similarities and differences of user information needs.

Common characteristics

First, the information needs of users in HCQA are similar. The main purpose is to provide patients with sharing disease and treatment experience. The core need is "how to treat diseases," which involves such topics as "state of illness," "treatment," "complication," and so on. It mainly depends on the function of HCQA. HCQA are working to provide information exchange channel for participants. Even if users do not intend to ask questions about treatment, most of the narratives relate to the core. Second, "diet" and "finance" are the most popular non-disease related topics. This is related to characteristics of chronic diseases, such as long treatment period, the healing process, multiple complications, high cost, etc. which brings greater financial burden to patients. Most patients expect to get practical and reliable information about treatment and health management in the community.

Different Characteristics

First, communities stand at different stages. American communities started early and develop stable now. The composition of members and demands are relatively stable, obvious, and connected more closely. Chinese communities started late and possess development period. Users' composition and demands fluctuate widely and are not closely related to each other. Second, there are different attributes. The attribute of "Q&A" is remarkable in Chinese communities. Patients prefer direct and short narrative for paying more attention to practicality. But they seldom seek mood expression and emotional support. However, American communities also show the attribute of "social connect" in addition to "Q&A." The former is even more significant. According to the content of related posts, it is related to differences in the social environment and living habits between Chinese and American communities. Due to religious beliefs and humanistic care, American HCQA users are better at expressing emotions and communicating with people. They intend to use more emotional words in expressions and eager to be comforted by others. Chinese users implicitly express their emotions and do not express their emotions to strangers or seek encouragement. It also reflects low trust and dependence in community members.

Although interesting findings were made, this study has its limitations. First, correlation degree and the quality of Q&A have not been considered. It remains to be studied to take correlation degree into the multi-dimensional analysis framework. Second, researches on topic and content evolution are not enough. We should consider time slice analysis by season, quarter, etc.

Conclusions

In this study, we analyze hot topics evolution and co-occurrence on the topic of diabetes. On the one hand, the information needs of HCQA in Chinese and American are similar focusing on "how to treat diseases." Other living-habits-specific needs, such as "diet," are clearly expressed in chronic disease groups. On the other hand, Chinese communities appear the attribute of "Q&A," and members pursue practicality. By contrast, American communities have both the attribute of "Q&A" and "social connect." Furthermore, topics fluctuate frequently in Chinese communities while stable in American communities.

In theory, we combine Social Network Analysis and content analysis to capture and contrast the pattern of Q&A in HCQA. Some clear conclusions are obtained referring to the similarities and differences of users' information needs of HCQA in China and the USA, which has certain theoretical significance for following researches. In practice, the founding provides enlightenment for the development of HCQA. Chinese communities should focus on improving the content quality and strengthen emotional connection among users to retain them. In addition, the rising incidence of diabetes must be taken seriously by government departments, which can take certain measures to further improve disease treatment infrastructure. For example, they can promote the role of community service and strengthen medical security to reduce the financial burden of patients.

Abstract

Health information exchange (HIE) is implemented in Quebec, Canada to improve the exchange and use of clinical information for decision making in the province's health care system. The objective of this mixed-method approach study was to evaluate the usage, usability, and usefulness of an electronic health record (EHR) to access and import clinical information from a centralized HIE. First, a heuristic analysis was performed of three different commercial EHRs, using end users to analyze the integration feature through think aloud protocols. Second, interviews were conducted with advanced users to describe the usefulness. Third, usage data were analyzed to describe the level of use of each data domain, per EHR and user. The results show that usefulness is high for medication data; leading to greater use of this domain, its relation to integration, and meets the needs of general practitioners. Difficulties in the implementation processes reduced the potential of this system.

Keywords:

Health Information Exchange, Electronic Health Records, Systems Integration

Introduction

Health Information Exchange (HIE) has been defined as the "electronic sharing of clinical information among users to facilitate care coordination and transitions between different settings of care" [1]. The use of HIE has the potential to generate significant improvements in patient safety, efficiency, and productivity of healthcare organizations [2]. In emergency departments (ED), the HIE can improve the quality of health care [3]. For example, sharing clinical information with a HIE has reduced the number of patient readmissions in seven hospitals in Israel [4]. In primary care, the use of HIE has led to improvements in efficiency: better access to test results, as well as reduced staff time for managing referrals and processing complaints [5]. Despite the achievements, several barriers to the exchange of health information have been recognized [1-2]: not enough information in the HIE to justify its use, differences in the way HIE is integrated into the clinical workflow and a poorly designed interface.

HIE usage has become an important issue in achieving the desired effects. Several studies have indicated that usefulness and usability are the most important variables for ensuring use of information technology[6-8]. The perceived usefulness of a health information technology depends on two types of impact: perceived improvement in work efficiency and perceived improvement in quality of care [6], two variables that have been evaluated by either quantitative or qualitative approaches [7].

Usability is the degree to which a system can be successfully integrated to perform tasks in a planned work environment [9]. As a result, usability is evaluated by user, system, and task interaction in a specified context. A review of usability assessments of electronic health records (EHR) revealed that the most common methods were surveys, think-aloud protocols and heuristic methods [10]. Heuristic methods involve the examination of an interface by a human evaluator looking for usability problems [11]. Such problems represent violations of the usability principles developed by Molich and Nielsen [12]. Scapin and Bastien developed ergonomic criteria as dimensions in order to synthesize best practices in the field of the person-machine interface[11].

In Canada, HIE initiatives have been developed in different provinces, resulting in a significant increase in the number of active monthly users of HIE from 2006 to 2017[13]. However, the same report indicates that adoption and utilization rates fluctuated between 22% and 42% of the total number of potential users, which is still far from optimal. The main barriers identified were at the level of system usability, project management, and how to integrate the HIE into clinical practice.

In Quebec, a HIE, the "Dossier Santé Québec" (DSQ), has been proposed as "a highly secure technological environment that allows the collection, storage, and consultation of certain health information" [14]. The law governing the exchange of health information stipulates that the HIE collects, stores and allows the consultation of health information in six domains: medication, laboratory tests, medical imaging, immunization, the hospitalization summary, and allergy and intolerance. In 2018, the information domains available are prescribed medications dispensed by community pharmacies, results of laboratory tests carried out in public and private labs, and reports and images from medical imaging examinations (radiography, computed tomography [scans], MRIs, etc.) carried out in public and private organizations.

The aim of our study was to assess the usage, perceived usefulness, and usability of the Quebec HIE in order to identify factors that may enhance or reduce its potential in clinical practice in primary care.

Methods

This mixed method study was conducted to evaluate three EHR systems integrated through HIE. The three chosen EHRs represented more than two thirds of all EHR users in the province of Quebec. The HIE integration features evaluated are

vendor-mediated HIE, with a pull-type mechanism to access information (clinicians needed to actively request or "pull" from their EHR the patient information from the HIE). The Quebec HIE applies an “opt-out” patient consent model, in which patients need to opt out if they want to make their information inaccessible to clinicians.

This study was conducted in three parallel parts. First, a descriptive analysis of HIE usage was conducted using audit trails of HIE accesses provided by the Ministry of Health from January 1 to December 31, 2017. The data provided included the user’s role, the data accessed, and the commercial EHR used to access the HIE. The median number of accesses per general physician (GP) was calculated per week, for each EHR-HIE interface (EHR 1, EHR 2, and EHR 3) and for each clinical data domain (Drugs, Laboratory, and Images).

Second, a modified heuristic analysis was performed using observation sessions with end-users, because in Quebec HIE access is not allowed if you are not a clinician. Experts had no access to the EMHR/HIE integrated interface without a clinician actually accessing it for a given patient. Usability problems were identified using the ergonomic criteria developed by Scapin and Bastien for assessing the usability of interfaces [11] (Table 1).

Table 1 Ergonomic criteria developed by Scaping and Bastien [7]

Criteria	Description
Guidance	Available to advise, orient, inform, instruct, and guide the user throughout their interactions, including from a lexical point of view.
Workload	Concerns all interface elements that play a role in reducing the user’s perceptual or cognitive load.
Explicit control	Concerns both the system processing of explicit user actions and the control that users have over the processing of their actions.
Adaptability	Refers to the system’s capacity to behave contextually and according to the users’ needs and preferences.
Error management	Refers to the means available to prevent or reduce errors and to recover from them when they occur. Errors are defined in this context as invalid data entry, an invalid format for data entry, incorrect command syntax, etc.
Consistency	The way interface design choices (codes, naming, formats, procedures, etc.) are maintained in similar contexts and are different when applied to different settings.
The significance of codes	Between a term and/or a sign and its reference. Codes and names are significant to the users when there is a strong semantic relationship.
Compatibility	Refers to the match between the real task and system inputs or outputs.

Think-aloud observation sessions were organized for each EHR. Clinicians had to perform specific tasks. The screen and the voice of the user were captured during the sessions. For each EHR, three physician sessions were recorded around the following subtasks:

1. Accessing the HIE for a given patient
2. Visualizing and importing drug-related information
3. Visualizing and importing laboratory-related information
4. Visualizing and importing clinical imaging-related information

Finally, a qualitative analysis was conducted of user perceptions of usefulness, benefits, and barriers. Twelve semi-structured individual interviews were conducted with the aim of identifying perceptions of usefulness as well as barriers and facilitators to the use of the HIE system. The participants were general practitioners (GP) and family medicine residents (FMR).

The distribution of the participants in the different HIE systems was as follows:

- EHR 1: 6 participants (4 GPs and 2 FMRs)
- EHR 2: 3 participants (3 GPs)
- EHR 3: 3 participants (2 GPs and 1 FMR)

An analysis was performed of the content of the interviews using a qualitative analysis software program (ATLAS TI) based on the following dimensions:

1. Completeness of clinical data: the underlying reasons for incomplete information can include that HIE systems do not integrate all essential sources of data, perhaps over a concern for losing referrals to competitors[1],
2. Organization and workflow: the perception of changes in work efficiency and quality of care,
3. Technology and user needs: forms of HIE technology (direct exchange or push vs. query-based exchange) and information needs (more information vs. meaningful information),
4. Perceived usefulness.

Results

HIE use

Medication-related information was the most used clinical data domain. EHR1 presented the highest level of HIE usage, followed by EHR 2, while EHR 3 showed the lowest level of use (Figure 1). In the laboratory test domain, EHR 1 and EHR 2 showed the highest level of HIE usage, while EHR 3 showed the lowest level of use. In the imaging test, the level of usage was similar among the three EHRs.

Figure 1 presents the differences in HIE usage among the EHRs by clinical data domain.

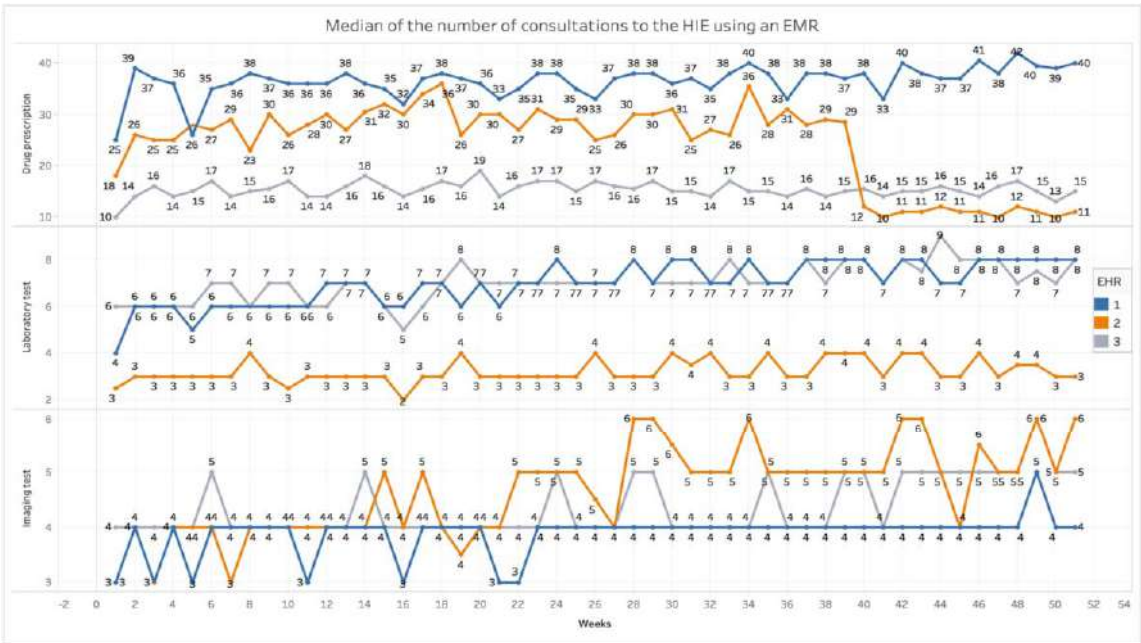

Figure 1 HIE-EHR integration usage: medians of the number of consultations of HIE using an EHR (different accesses) per week, by EHR

Usability problems

The fewest usability problems were observed in the EHR1 (Figure 2)

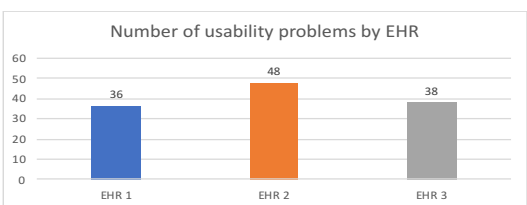

Figure 2 Usability issues by EHR

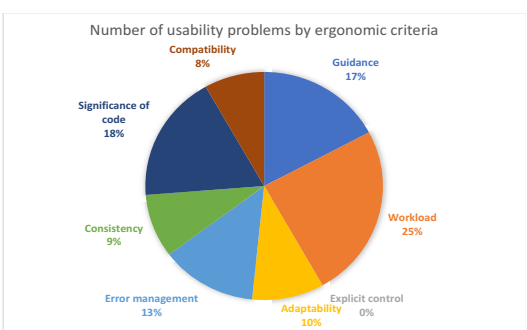

Figure 3 Usability issues by the problem domain (ergonomic criteria)

The main usability issues were code significance, workload, and guidance problems (Figure 3).

Regarding the severity of the identified problems, minor severity problems were the most frequent, followed by major severity problems (Figure 4). High severity, potentially catastrophic problems were rare.

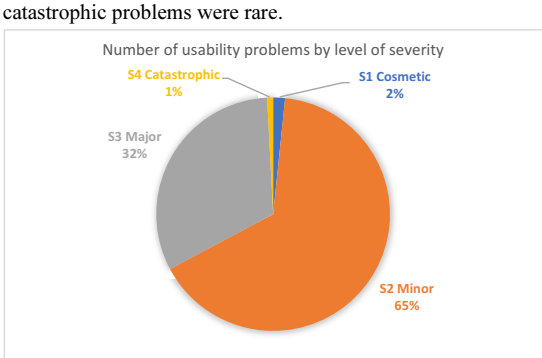

Figure 4 Analysis of the severity of usability problems

Drug prescription was the domain with the highest number of usability problems (43%), and visualization of the medication list was the most problematic feature, with the issues the most important to usability, especially guidance, workload, and code significance problems (Figure 5).

EHR 1 is the drug prescription integration that have fewer usability problems compared to the other two EHRs. We must also remember that drug prescription is the domain with the largest use.

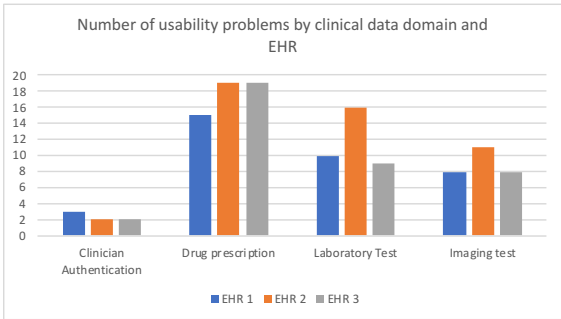

Figure 5 Usability problems according to EHR-HIE integration functionalities

Clinician authentication presented a common challenge. Different logins were needed for the EHR and HIE systems. This generated an extra burden for clinicians.

Perception of usefulness: advantages and barriers

All the physicians perceived that the EHR-HIE integration was meeting, for each clinical data domain, the objectives for which it was designed:

- Drugs: Access to information about prescriptions and dispensations.
- Laboratory: Access to laboratory results.
- Medical imaging: Access to information on imaging results, the status of the examination and the report.

However, there were differences in perceptions of the utility and the number of barriers to its use, and they had an impact on the level of utilization of EHR-HIE integration.

Also, some aspects of the implementation process are important to consider. Lack of familiarity and a lack of knowledge of some functionalities of integration were observed. On the other hand, the progressive availability of the different domains of clinical data in the HIE may have had an impact on perceptions of utility and use.

Medication

The EHR-HIE integration used the most by the physicians was the medication domain.

General practitioners identified groups of patients for which integration had been useful:

- Patients with multiple morbidities and multiple medications or for whom there were doubts about compliance.
- Frequent users of narcotics.
- New patients, patients without an appointment or former patients who had not consulted for a long time.
- Patients who did not know their medications.
- Patients who had seen other specialists or who had medicines prescribed by another doctor.

The most critical barriers were lack of certainty about the information available (the medication list) and the duplication of drugs. One of the main concerns was about whether the information was complete (i.e., the need to have all the information about the medications that the patient is receiving or has ever received). In all three clinics, certainty about having access to an updated medication list was a common theme; especially in relation to all the extra tasks and workarounds and the resulting overload of clinical work needed to develop such a medication list.

Interestingly, there seems to be a threshold beyond which perceived benefits can lower the number of reported barriers, a state which was observed for EHR 1. In contrast, when there was a higher level of barriers, as in the case of EHR 3, there were fewer reported benefits. EHR 2 showed an intermediate position between the other two EHRs. In this domain, greater options for integration functions generated fewer barriers to usage and better perceptions of usefulness.

Laboratory

Although more requests for laboratory tests were generated per patient than for imaging tests, this was the domain that was the least used by the physicians, who preferred the legacy local laboratory systems and data accumulated in their own EHR.

The lack of adaptation to clinical needs was an important factor affecting EHR-HIE use. The functionalities valued in clinical practice included having the ability to observe trends in graphs and the need to record whether the doctor had visualized the exams, and these features were only available in the legacy local laboratory systems and local EHR. These functionalities were not available with the HIE integration.

Some benefits were observed only in the case of EHR 1 (efficiency gains in clinical practice and avoiding repetitions of laboratory tests). The lack of knowledge of some functionalities and a deficit in the availability of some laboratory tests were mentioned as factors diminishing the use of EHR-HIE integration.

Imaging

Consulting reports or results of imaging exams are essential for informed clinical decision-making. Visualizing medical images is not as important a need, especially for complex images, for which a radiologist's opinion is needed anyway. For less complex images, it can be useful to see the images before receiving the radiologist report. In any case, the inaccessibility of images in the HIE remained a barrier, more so since other systems offered such access.

Perceived benefits included avoiding the duplication of imaging exams and developing medical notes on the basis of a copy-and-paste function.

Discussion

The most important finding of this study is the importance of the value added for clinicians by EHR-HIE integration. The medication domain was where we observed the largest number of usability problems, but it was also the domain in which we observed the greatest use of EHR-HIE functionalities.

The aspects of using HIE integration that were the most valued for their usefulness were:

- The opportunity to improve adherence to treatment in the case of chronic conditions.
- The usefulness of prescription and dispensing information on medications for better management of patients who were frequent users of narcotics.
- Avoiding duplicated image and laboratory tests.

The importance of getting access to an updated medication list that was observed in our study is consistent with a study that evaluated the accuracy of drug data in Quebec [15], in which a total of 38% of the information represented discrepancies when the list of references was compared with the list obtained from the HIE. From this perspective, we underline that HIE medication data was the most important source of added value for clinical practice as perceived in the clinics we studied.

In relation to laboratory tests and images, the positive appreciation of EHR-HIE integration as a tool to reduce the duplication of tests is another finding consistent with the literature. A systematic review on the benefits of HIE published in 2018 listed: the reduced duplication of imaging exams, therapeutic medical procedures, total number of orders, and reduced total cost of care, lab test costs and imaging test costs [16].

Our study was focused on the experience of primary care users with EHR-HIE integration. We did not directly study the implementation processes. However, according to the interviews and observations of EHR-HIE integration in use, we observed some barriers resulting from the implementation processes, such as a lack of knowledge of the EHR-HIE integration functionalities and insufficient follow-up activities after the initial training provided when the system was introduced. The literature has shown those factors to be essential to the use of HIE.

This study has some limitations. Given that we did not directly observe the use of the EHR-HIE integration functions, the method chosen to conduct the heuristic analysis can limit the quality of usability problem evaluations. As well, the difficulties encountered balancing the recruitment of participants for each EHR can induce some variations in the analysis of the perceptions of utility, barriers and facilitators associated with the EHR systems studied. Finally, we underline that the dissemination of HIE in Quebec, Canada is not complete. For instance, the availability of data in different domains was still a work in progress. This phenomenon could have affected perceptions of usefulness and usage in the clinics studied.

Conclusions

The deployment of HIE is still in a work in progress in Quebec. Even if usage levels need to improve, clinicians have already identified areas in which system usage proved useful to their clinical practice. There are grounds for hope. To support this hope, it is important to address the problems of usability and barriers to utilisation that we have identified. It is only by improving the design of EHR-HIE integration or its implementation processes that this initiative will be an unqualified success for the province's health system.

Abstract

Natural language processing (NLP) technologies have been successfully applied to cancer research by enabling automated phenotypic information extraction from narratives in electronic health records (EHRs) such as pathology reports; however, developing customized NLP solutions requires substantial effort. To facilitate the adoption of NLP in cancer research, we have developed a set of customizable modules for extracting comprehensive types of cancer-related information in pathology reports (e.g., tumor size, tumor stage, and biomarkers), by leveraging the existing CLAMP system, which provides user-friendly interfaces for building customized NLP solutions for individual needs. Evaluation using annotated data at Vanderbilt University Medical Center showed that CLAMP-Cancer could extract diverse types of cancer information with good F-measures (0.80-0.98). We then applied CLAMP-Cancer to an information extraction task at Mayo Clinic and showed that we can quickly build a customized NLP system with comparable performance with an existing system at Mayo Clinic. CLAMP-Cancer is freely available for academic use.

Keywords:

Natural Language Processing, Information Storage and Retrieval, Electronic Health Records

Introduction

Cancer is a highly heterogeneous group of related diseases with a growing body of evidence that cancer initiation, progression, metastasis, and response to treatment are directly associated with variability at the molecular level [1]. Technological advances have enabled us to identify an increasing number of molecular biomarkers, leading towards personalized oncology [2]. Personalized cancer research relies heavily on large clinical series of well annotated and high-quality data. One emerging research direction is to leverage large, real-world practice data stored in electronic health records (EHRs) to facilitate clinical and translational research [3]. However, much of this information (e.g., tumor characteristics) can only be found in narrative or semi-structured text in EHRs, such as pathology reports. Despite the move towards synoptic reporting by the pathology community [4], uptake of this formatting is not complete and synoptic reports are usually only issued for definitive resections, as mandated by the American College of Surgeon's Commission on Cancer Standard 2.1. Natural language processing (NLP) technologies that can automatically extract and structure information from narrative documents have been extensively investigated in the medical domain and cancer sub-domain [5, 6]. In particular, many studies have focused on named entity recognition (NER), a fundamental NLP task that locates and classifies named entities to pre-defined categories (e.g., diseases, drugs, and lab tests).

Several NLP systems have been developed to process pathology reports, which contain rich information about tumor specimen characteristics [7]. An earlier study by Xu et al. extended the existing MedLEE system to extract information from pathology reports to support cancer studies [8]. Crowley et al. reported the Cancer Tissue Information Extraction System (caTIES), which focuses on de-identification of cancer specimens for research purposes, along with information retrieval and concept coding functionalities [9]. MedKAT (MedTAS/P) is a rule-based system, which aims to extract cancer characteristics from pathology reports including anatomic site, histology, and grade [10]. Recently, Savova et al reported another rule-based system named DeepPhe, which can extract summary of cancer phenotypes including morphology, topology, procedure, and staging information from clinical documents [11].

Despite the success of reported use cases on cancer information extraction from clinical text, NLP has not been widely used for routine EHR-based cancer research, likely due to implementation barriers. Because of the diversity and complexity of clinical documentation, significant effort is required to develop custom clinical NLP systems or to extend existing systems for individual applications. In a study that aimed to locally adopt a smoking module in the cTAKES system [12], users had to write extensive code to re-train modules and re-define rules [13], which could be challenging for programmers without much NLP expertise. Additionally, completeness and the accuracy of the information remain as major obstacles in computational processing of clinical texts.

CLAMP (Clinical Language Annotation, Modeling, and Processing) [14] is a general clinical NLP system that provides not only high-performance NLP components but also user-friendly interfaces for building customized NLP pipelines for individual needs. In this study, we describe our work on developing a library of information extraction modules for

important tumor informiton in pathology reports within CLAMP. Using these built-in modules and user-friendly interfaces of CLAMP, users can quickly build customized NLP solutions to extract cancer information from their local pathology reports, with minimal programming effort. We believe such a tool would greatly benefit cancer researchers to leverage clinical text for their studies.

Methods

CLAMP follows the pipeline-based architecture as defined by the Apache UIMA™ (Unstructured Information Management Applications) framework, where an NLP system consists of multiple components in a specific order. The development of CLAMP Cancer Modules involved building cancer-specific NLP components and extending CLAMP interface that allows end users to customize and assemble different components into an NLP pipeline for their specific needs.

Developing Cancer-Specific NLP components

As the primary goal is to extract important information related to cancer, we limited the scope to the "diagnosis" section of pathology reports and followed these steps to build CLAMP Cancer Modules:

Define an Information Model for Pathology Reports

We reviewed available models including the Cancer Disease Knowledge Representation Model (CDKR) used in the MedKAT [10] and the information model in caTIES [9]. As our goal is to support clinical research, we specified data elements for pathology reports as recommended by the College of American Pathologists (CAP) (Figure 1). We reviewed all available CAP cancer templates (available at http://www.cap.org/cancerprotocols) as of January 2017, including the biomarker templates, and defined a list of minimum elements and relations to be included in CLAMP-Cancer Modules.

We define *Primary-site* (site of the source of the material extracted from the body) as the root concept, with relations to *Specimen* (often numbered in the reports), *Sub-site* (detailed sub-anatomical sites related to the primary sites), *Procedure* (methods for specimen extraction from the body, e.g., biopsy), and *Histology* diagnosis (the morphology of cancer cells, e.g., "squamous cell carcinoma"). In addition, we also extract several important attributes defining histologic behavior and malignant potential, including *Tumor Grade*, *Tumor Size*, *Invasiveness* (invasion status and sites infiltrated by the tumor), *Tumor Margin* (tumor involvement in excisional margins), as well as *Tumor Biomarkers and Values* (e.g., estrogen and progesterone receptors).

Annotate a Corpus of Pathology Reports following the Information Model

Based on the information model, we developed an annotation guideline, which specifies the types of entities and relations for annotation, as well as different examples. We randomly selected 400 pathology reports from patients with a cancer ICD9 code at Vanderbilt University Medical Center (VUMC) in 2010. Four domain experts manually reviewed each pathology report and annotated all the entities and relations following the guideline, using CLAMP. Following a typical evaluation design for NLP studies, the annotated corpus was then divided into a training set (200 reports) and a test set (200 reports).

Develop Various Entity and Relation Extraction Components of CLAMP Cancer Modules

As CLAMP Cancer Modules extract a broad range of entities and their relations from pathology reports, different approaches were implemented to achieve optimal performance. For named entity recognition, we implemented regular expression-based, dictionary lookup-based, as well as machine learning-based approaches. For relation extraction, both rule-based and machine learning approaches were developed. Hybrid approaches that combine rules and machine learning were also used to optimize the performance. All the resources collected for developing these components (e.g., dictionaries, rules, and models) are available in CLAMP Cancer Modules and users can use them as-is or customize them to improve performance on their local data.

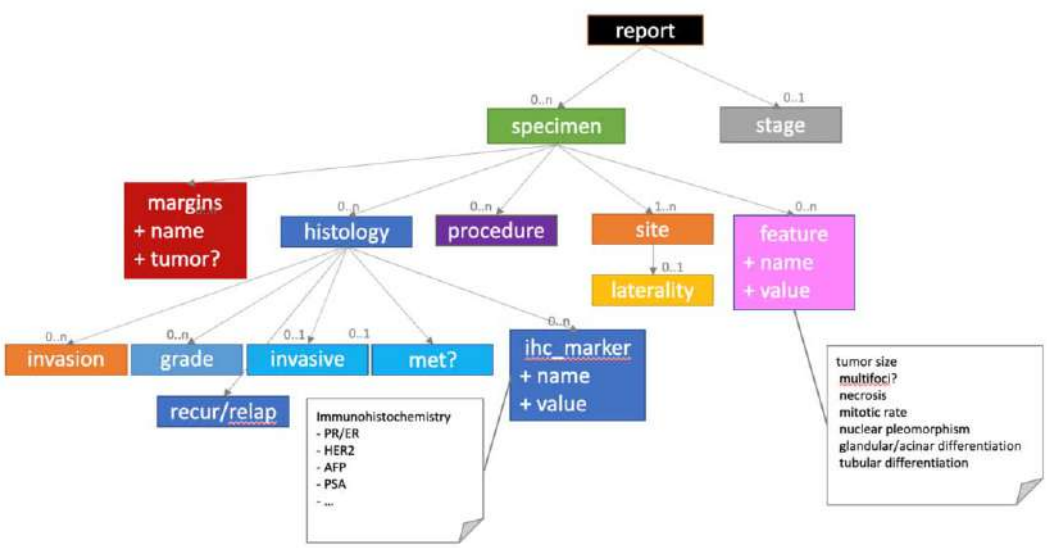

Figure 1. CLAMP information model is based on data element suggestions of College of American Pathologists

Evaluating CLAMP Cancer Modules

The evaluation of CLAMP Cancer Modules has two aspects. First, we developed the default CLAMP Cancer Modules using the training set from VUMC and evaluated them using the test dataset from VUMC. For each type of entity, we report precision, recall, and F-measure on recognizing entities only, using both exact and partial (relaxed) matching criteria [15]. We also report the system performance by considering both entity and relation information (e.g., a detected "sub_site" entity is correct only if both the entity and its relation to the linked "primary_site" are correct). Then, we apply CLAMP Cancer Modules to the same information extraction task as the MedKAT system [10]. Using CLAMP Cancer Modules, we assembled a customized NLP pipeline and compared it with MedKAT, using the same annotated corpus from Mayo Clinic.

Results

The developed CLAMP Cancer Modules consist of several components with machine learning models, dictionaries and rule sets to extract various types of cancer specific information from pathology reports following the CAP recomendations. Figure 2-a shows the cancer-specific modules in CLAMP and how they can be used to build customized NLP pipelines for local pathology reports. In Figure 2-b shows document annotation for cancer specific entities, and relationships among them.

Table 1 – Evaluation results of CLAMP Cancer Modules

Type of information	# of ent.*	Entity only (Exact/Relaxed Matching)			Entity and Relation

Date	1.00	1.00	1.00	1.00	1.00	1.00

(b) Performance comparison of CLAMP Cancer Modules and MedKAT on the same information extraction task from 302 pathology reports at Mayo Clinic

Table 1 (a) shows the evaluation results of CLAMP Cancer Modules for different types of entities and relations. The default components of CLAMP Cancer Modules achieved good F-measures for entity recognition, with a range of 0.87 to 0.99, for exact matching criterion. A quick manual review shows that a fair number of relevant entities are missed by the system (e.g., a low recall in "invasion"), probably due to the complexity of expression patterns of these entities and the relatively limited size of the training corpus. When the relaxed matching criterion was used, CLAMP Cancer Modules achieved higher performance for some entities (e.g., Histology improved from 0.88 to 0.97), indicating some errors were about entity boundary only. When the relationships of entities were taken into consideration, performance dropped as expected (F-measures within 0.82-0.98), because of some known challenges for relation extraction (e.g., long-distance dependency). Table 1 (b) shows the results of the customized NLP pipeline built for Mayo Clinic's pathology reports using CLAMP Cancer Modules, as well as the results from MedKAT. It took 12 hours for a developer to build the customized NLP pipeline for the specified task using CLAMP Cancer Modules, and it achieved comparable performance as MedKAT, indicating high effectiveness of CLAMP-Cancer for building customized NLP pipelines for pathology reports. Although MedKAT has slightly higher performance in certain entities, the production time and the adaptability remain as the major advantage of using CLAMP.

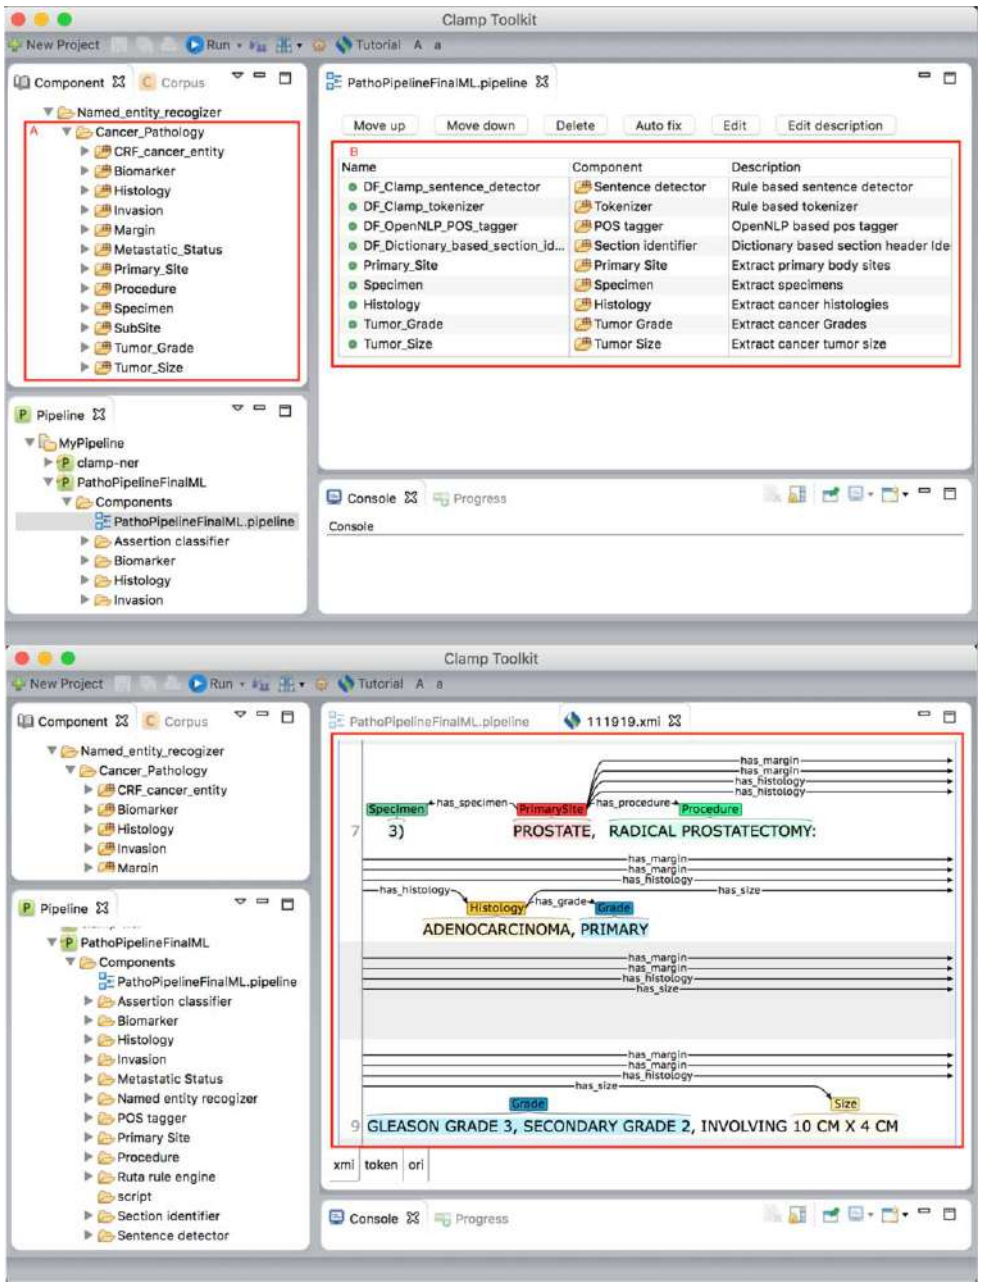

Figure 2. a. CLAMP Cancer module implements several cancer specific components (A), can be used to build customized pipelines (B). b. Pipeline annotates pathology reports to extract entities as well as their relationships.

Discussion and Conclusions

The contribution of CLAMP Cancer Modules is two-fold. First, it is a new NLP system that extracts comprehensive cancer information from pathology reports, including some that are not included by previous systems, e.g., biomarkers. Moreover, CLAMP Cancer Modules allow users to quickly build customized NLP pipelines by leveraging existing components and user-friendly interfaces. To the best of our knowledge, this is the first attempt to build cancer-focused NLP system that integrates into a drag and drop graphical user interface (GUI) for building customized NLP solutions for individualized needs. As pathology reports contain important cancer information, we believe that CLAMP Cancer will facilitate wide adoption of NLP in cancer research.

We acknowledge that cancer knowledge is constantly evolving and new standards, such as the AJCC 8th Edition, may require

re-annotation for additional concepts. As a full-featured NLP system, CLAMP Cancer Modules ease such tasks. To further accelerate EHR-based cancer research, we plan to extend CLAMP Cancer Modules in several directions. First, we will develop an encoding function to further map extracted cancer information to existing terminologies, e.g., ICD-O-3, or to standard value sets. We will then expand CLAMP Cancer Modules to include other types of clinical reports containing rich cancer information, e.g., radiology reports. We also plan to conduct formal usability studies of CLAMP Cancer Modules and iteratively improve the user interface based on users' feedback.

Bridging Documentation and Metadata Standards: Experiences from a Funding Initiative for Registries

Jürgen Stausberg[a], Sonja Harkener[a]

[a] University of Duisburg-Essen, Faculty of Medicine,
Institute for Medical Informatics, Biometry and Epidemiology (IMIBE), Essen, Germany

Abstract

Within a funding initiative for patient registries in Germany, data specifications from 15 projects were collected in a structured format. Subsequently, the data specifications were transferred into a structure following the ISO/IEC 11179-3 standard for metadata registries. The data specifications included a median of 16 documentation objects and 196 data elements per project. Only Common designations were used. The bridging to ISO/IEC 11179-3 revealed several overlaps between the specifications. For example, bridging can be used to align the multifold designations of sex and sex categories as well as to harmonize the respective value lists. Further work intends to create a metadata repository based on a community-driven approach as part of the IT-infrastructure of this funding initiative. Without this infrastructure, comparability of the data specifications is unlikely.

Keywords:

Documentation, metadata, registries

Introduction

From the perspective of medical informatics, registries are a type of medical documentation system aiming at the analysis of research questions regarding a group of individuals, typically patients. From this perspective, registries could be differentiated from health records supporting health care for individuals. In a broader view, registries are projects that maintain staff, rooms, and IT infrastructure and sometimes have a specific legal status [1]. However, even in the broader view, data recorded on the observational units are the assets of registries. The definition of those data in terms of variables and value lists is therefore a main task in the development of registries [1, 2, 3]. Ideally, this definition is supported by documentation standards. Documentation standards guarantee that the data on the one hand cover all information needed to answer the research questions. On the other hand the data must support the analysis methods applied in statistical evaluations in reports and in scientific and public publications. Proposals for those documentation standards are available [4].

On a level going beyond a single registry, the interaction between projects and between different types of documentation systems gains importance. This interaction requires a description of the data independent from individual research questions and individual statistical analyses. Use cases on that level can include the identification of projects sharing the same approach to quality of life or addressing the same population, for example patients suffering from dementia [5]. ISO/IEC 11179 "Information technology - Metadata registries (MDR)" [6] is a standard that relates to such kinds of use cases. ISO/IEC offers an approach to maintain data about data, i.e. metadata, in a systematic and unambiguous approach. Although ISO/IEC 11179 is noticed in health care [7, 8], the relationship between documentation standards and the metadata approach is complex [9].

With the goal of supporting both the development of individual registries and the interaction between different registries, a German funding initiative defined a bridging between documentation standards and metadata standards that will be introduced below. The bridging will be used to establish a metadata repository for the funding initiative in the future.

Methods

Registries

The German Ministry for Research and Education launched a funding initiative for registries in health services research. Sixteen projects were accepted for a concept development phase lasting nine months. At the end of this phase, the projects were invited to submit a proposal for an implementation phase lasting up to five years. In parallel to the funding of individual registries, an accompanying project (abbreviated REGISVF-AP) was accepted that supports the registries in development and implementation. REGISVF-AP started one month later than the registries which began in September 2017 and will last two years. Thus, it covered eight of the nine months of the concept development phase. The decision about funding of the registry implementation will be announced at the end of 2018.

The 16 projects of the development phase covered different areas of health care: rare diseases, oncology, acute conditions, chronic diseases, interventions, and other conditions. Further information about the projects is provided in table 1.

Table 1 – Projects of the development phase

Acronym	Institution	Area
Rare diseases		
sLEGER	University clinics Düsseldorf	Systemic lupus erythematosus in Germany
PAREMIS	University clinics Leipzig	Prader-Willi-Syndrome
Oncology		
HerediCaRe	University clinics Cologne	Hereditary breast and ovarian cancer
BRE-4-MED	University clinics Würzburg	Breast cancer care for patients with metastases
Acute conditions		
RADaR	University clinics Regensburg	Acute respiratory distress syndrome
FieberApp-Register	Private university Witten/Herdecke	Fever in childhood
HIRB	Brandenburg Medical School	Heart attacks in Brandenburg
EMBO-Lung	Ludwig-Maximilians-Universität Munich	Pulmonary embolism
RECUR	University clinics Freiburg	Recurrent urolithiasis of the upper urinary tract
Chronic diseases		
TOFU	University clinics Bonn	Treatment exit options for uveitis
GeCeR	Competence network bowel diseases	German celiac registry
ParaReg	University clinics Heidelberg	Lifelong monitoring of paraplegic patients
Interventions		
INDICATE-TKR	Technical University Dresden	Appropriateness of total knee replacement for osteoarthritis
IISAAR	Saarland University	Vaccination information system Saarland
Other conditions		
SoLKID-GNR	University clinics Münster	Safety of living kidney donors in Germany
CDDD_ENMR	Center for Population and Health Wiesbaden	National mortality registry

Documentation Standard

REGISVF-AP suggested the use of the catalogue of attributes from Leiner and Haux [10] as a format for data definition in the registries' concepts. The registries agreed to use this approach in an adapted structure. The catalogue of data elements offers a view on data definitions that is communicable to domain experts on the one hand and usable for computer scientists to implement the data definitions in the data management infrastructure on the other hand. The catalogue of data elements differentiates between documentation objects like "patient" or "quality of life" and data elements like "sex" or "VAS" (= visual analogue scale). Data elements are assigned to one and only one documentation object. Documentation objects and data elements share several attributes like designation and description. Both could be related to predefined research questions, to project modules, to statistical methods defined in a statistical analysis plan, to health care related categories such as therapies, and to project-related events such as follow-ups. It was furthermore possible to enrich each data element with a) a value set that is either a list or a data type, b) a coding of values within a value list, c) a unit in case of a numerical data type, d) a differentiation between single and multiple occurrences, and e) plausibility checks.

The registries were advised to start the development with the agreement on research questions, to extract target variables, influencing variables and confounders as potential data elements, and to check any proposed data elements according to the following aspects:

- Is the data element needed to answer a research question?
- Does the data element adequately cover the information?
- Is the recording of the data element feasible for the study sites?
- Could the data element be used in the process of analysis?

Templates for the registries' catalogues of data elements were provided as Microsoft Excel and Microsoft Access files. The templates were available in German and English. A short explanation supported the use of the templates. Additionally, a few integrity constraints were implemented in the Access file.

Metadata Standard

The Data Description metamodel and the Concepts metamodel parts of the ISO/IEC 11179 third edition (ISO/IEC 11179-3) were used [6]. In short, a DATA_ELEMENT is defined by a DATA_ELEMENT_CONCEPT (e.g. sex of a patient) which uses a CONCEPTUAL_DOMAIN (sex) combined with a specific VALUE_DOMAIN (e.g. consisting of the PERMISSIBLE_VALUES male, female, diverse, undetermined, and unknown, representing the legislative definition of sex for citizens in Germany). A VALUE_DOMAIN has two possible subclasses, namely the ENUMERATED_VALUE_DOMAIN (represented by a list of distinct values) and the DESCRIBED_VALUE_DOMAIN (represented by a textual definition).

Bridging Approach

The documentation object of the data element catalogue was mapped to the OBJECT_CLASS of ISO/IEC 11179-3. Each data element of this documentation object establishes a PROPERTY leading to a DATA_ELEMENT_CONCEPT combining both. The value set of the data element catalogue was defined as ENUMERATED_VALUE_DOMAIN in case of a list of values and as DESCRIBED_VALUE_DOMAIN otherwise. Values of the value list became PERMISSIBLE_VALUES of ISO/IEC 11179-3. These transformations were automatically performed based on the received specification of the registries. To close the loop between the DATA_ELEMENT_CONCEPT and the VALUE_DOMAIN at the conceptual level of the Data Description metamodel, a CONCEPTUAL_DOMAIN was created in a stepwise-approach. Firstly, all designations of data elements that occur at least twice established automatically a CONCEPTUAL_DOMAIN. This CONCEPTUAL_DOMAIN was assigned to all data elements that share the designation. In a second step, all remaining data elements were assigned to a preexisting CONCEPTUAL_DOMAIN if possible. Otherwise a new CONCEPTUAL_DOMAIN was created. Finally, the CONCEPTUAL_DOMAINS were manually corrected for duplicates and overlaps. To support understandability and retrieval of the results, each CONCEPTUAL_DOMAIN was

related to a single broader CONCEPT via a LINK of the ISO/IEC Concept metamodel region. In the preliminary stage of the presented work, the CONCEPT was arbitrarily defined by the authors.

Table 2 shows an overview of the bridging concept. The bridging was performed semi-automatically using Microsoft Access.

Table 2 – Bridging concept

Catalogue of data elements	ISO/IEC 11179-3	Comment
Documentation object	OBJECT_CLASS	
Data element	PROPERTY	
Value set	ENUMERATED_ VALUE_DOMAIN	in case of a list of values
Value set	DESCRIBED_ VALUE_DOMAIN	in case of data types
	PERMISSBLE_ VALUE	items in the list of values
	CONCEPTUAL_ DOMAIN	semi-automatically determined
	CONCEPT	manually created

Results

Fifteen out of the 16 projects submitted a specification of their data. Two projects submitted a Word file with free text; 13 projects made use of the template of the catalogue of data elements: seven submitted an Excel file, five submitted an Access file, one submitted an Excel and an Access file in parallel. Six projects defined their data in German, six in English, and three in both languages. Nine projects primarily used phrases for the designation of data elements, one used questions, one used phrases and questions, and four used labels.

Catalogues of Data Elements

The catalogues of data elements defined a total of 352 documentation objects. Excluding a project that used 126 documentation objects, the number of documentation objects ranged between 8 and 27 (median: 16, variation coefficient: 0.31). Fifty-one documentation objects were additionally described in a second language (German or English) leading to 403 designations. The most frequent designation was “basis data” (four in English, six in German as “Stammdaten”). A unique phrase or question was present in 385 out of the 403 designations.

The documentation objects included 3,935 data elements (range per project: 48 to 756, median: 196, variation coefficient: 0.73), 842 additionally available in a second language. Excluding duplicates for the combination of designation and language, 4,068 different designations remained from 4,777. From 4,068 designations, 3,929 occurred only once, and 53 occurred several times. The most frequent designations were “Geschlecht” (=sex, six times), “Geburtsdatum” (=date of birth, six), “Pseudonym” (German, five), “date of birth” (five), “Vorname” (=first name, four), “gender” (English, four), and “sex” (four). The range of data elements per documentation object was 1 to 191 (median: 16, variation coefficient: 1.62).

Example - The Data Element Sex

All projects defined at least one data element related to the sex of a patient. In total, 25 data elements occurred for sex with eight different designations. The data elements for sex were assigned to 16 different designations of documentation objects, most frequently to “Stammdaten” (=basis data, five times) or “basis data” (four times). The 25 data elements shared 14 different value lists. The languages and acronyms were mapped to the following seven values: männlich/male/m, weiblich/female/w, intersexuell/intersexual, unbekannt/unknown, unbestimmt/not determined/undecided, anderes/other/a, and unclassified. Only one data element used the value list defined on a national level for routine data in secondary care, and not one used the definition defined in Germany for primary care.

Mapping to ISO/IEC 11179-3

1. Identified by using a well formatted structure as the value list, 1,197 ENUMERATED_VALUE_DOMAINS out of 3,935 value sets were identified (30%) in the preliminary stage of the bridging process.
2. Those ENUMERATED_VALUE_DOMAINS included 4,162 different PERMISSIBLE_VALUES.
3. The remaining 70% of the value sets were regarded as DESCRIBED_VALUE_DOMAIN.
4. With a minimum of two occurrences of data element designations independent from languages or project assignments, 670 CONCEPTUAL_DOMAINS were extracted. Those covered 1,709 data elements out of 4,777.
5. By now, another 761 data elements have been manually assigned to an existing or newly created CONCEPTUAL_DOMAIN.
6. After clearing of duplicates, 464 CONCEPTUAL_DOMAINS remained covering 2,470 data elements.
7. Preliminarily, 325 of the 464 CONCEPTUAL_DOMAINS covering 2,143 data elements were aggregated to 21 CONCEPTS with drug (533 data elements) and disease/symptom (302) as the most frequent ones.

Discussion

Fifteen projects submitted their specifications of variables and values as part of the registry development. Thirteen used the recommended format of a catalogue of data elements for the submission. According to the coefficient of variation, the projects agreed concerning a reasonable number of documentation objects. To the contrary, the total number of data elements varied strongly between the projects. Additionally, the number of data elements that were condensed to a documentation object was quite different. In agreement with a survey including 30 already implemented

registries [11], most of the registries intended to record between 100 and 499 data elements (cf. figure 1).

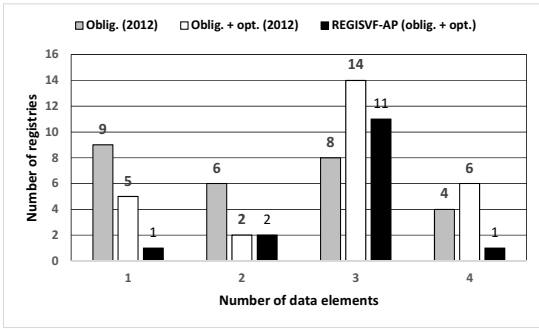

Figure 1 – Number of of data elements per registry (references for 2012 from [11]). Data elements: oblig.=obligatory, opt.=optional.

However, the projects strongly disagreed concerning the designations of documentation objects, data elements and values. They also disagreed concerning the value lists that arise through the aggregation of single values. To some extent this could be explained through the diverse use cases like uveitis, fever, or metastasizing breast cancer. But the example of the values found for the data element sex showed that the projects did not even consider national conventions. An evidence-based recommendation about an appropriate documentation standard was not sufficient to establish homogenous metadata.

Therefore, the results clearly emphasize the need for metadata repositories. A metadata repository can be used for several use cases [11]:

- it makes the creation of case report forms and data models easier,
- it improves the quality of case report forms and data models,
- it harmonizes variables and value lists,
- and it supports the mapping of metadata and data.

Nevertheless, the relationship between metadata approaches and documentation standards is ambivalent [4]. For both, the modelling of health-related information could be different. One might consider “disease” as the main entity and “heart attack” as attribute or “heart attack” as main entity and “existence” as attribute. The implementation of models for complex information objects like “blood pressure” or “quality of life” is unclear for both metadata standards and registry definitions.

The interim results of the bridging between the projects’ specifications of data elements and the structure of ISO 11179-3 underline the value of a metadata repository. For many data elements, counterparts in other projects can be identified. The authors expect a significant stimulus for harmonization of variables and value lists through feedback of this information to the projects. However, the time-consuming effort for the mapping demonstrated the necessity of direct involvement of registry staff in maintaining their metadata themselves. Additionally, the high abstraction level of ISO 1179-3 must be concretized to reach acceptance by those users.

Conclusions

A metadata repository is a core component of an IT-infrastructure for registries as well as for health services and health science research in general. The experiences gained from merging data specifications from 15 registries demonstrate impressively that harmonization and comparability will not arise without explicit metadata services. The high resource consumption needed to align data specifications subsequently underpin that a community-driven approach is essential involving the individual projects in the maintenance of the content. REGISVF-AP will further pursue the objective to implement this approach in the funding initiative of registries for health services research in Germany.

Acknowledgements

The work was funded by the German Federal Ministry of Education and Research under contract 01GY1720B. REGISVF-AP is implemented together with the Technology, Methods, and Infrastructure for Networked Medical Research (Berlin, Germany) and the German Network for Health Services Research. We would like to thank all projects funded within REGISVF who submitted their specifications.

Abstract

In this study, treatment and the serum uric acid (UA) level were compared using medication history generated by prescription order records of antihyperuricemic to examine the treatment success rate. We examined the treatment success rate among these patients based on the serum UA level during 120–180 days after the initiation of treatment, which was set as the endpoint. The number of patients whose UA level before the start of treatment was > 8.0 mg/dL but decreased to < 6.0 mg/dL after the treatment, which is the target treatment success, was 92 (success rate of 14.2%), 50 (53.2%), 76 (41.5%), 35 (31.9%), and 45 (37.8%) in the allopurinol 100 mg/day (A1) and 200 mg/day (A2), febuxostat 10 mg/day (F1) and 20 mg/day (F2), and benzbromarone 50 mg/day (B), respectively. Compared with that of the other drugs, the treatment success rate was high with A2 and low with A1. From the generated medication history, the treatment success rate with antihyperuricemic can be extracted mechanically.

Introduction

Clinical studies include crossover studies in which different drugs are administered to the same patient in an order and the respective results are compared. This study represents one of the methods that can be used in the treatment of chronic diseases [1]. As the effect of a target drug can be compared among different individuals, individual differences in the effects can be eliminated, which is an advantage. However, with long-term administration, a washout period is necessary and that can prolong the study period. Consequently, the economic costs and burden on patients are high; even for established standard drugs, evidence of treatment efficacy that is required in a clinical setting is not adequate.

Pharmacoepidemiological studies that use real-world data stored in electronic medical charts as target are drawing attention. If patients who are eligible for a crossover study can be extracted automatically from the drug ordering information stored in the electronic medical charts using a computer, then, data similar to those of interventional studies can likely be obtained at a low cost. In drug intervention studies, the relationship between a patient's treatment period and the endpoint is important. However, drug information stored in the electronic medical chart system is a record of prescription orders generated during a physician's prescription. Therefore, it is difficult to select subjects while estimating the treatment period for each patient. In this study, we developed a system for estimating the treatment period of patients by drug and dose using a computer to correct overlapping periods and gaps present in prescription order records [2]. We evaluated the treatment efficacy of antihyperuricemic from the treatment periods that were generated using this system, and herein report our findings [3].

Methods

Study environment

The EMR of Tottori University Hospital (TUH) was introduced on September 1, 2002, and by September 2015, the treatment data of 307,944 patients had been recorded. In this study, the treatment efficacy of antihyperuricemic used at the TUH was the observation subject. The target drugs of evaluation were allopurinol (A), febuxostat (F), and benzbromarone (B). All of them tend to be prescribed as antihyperuricemic for long periods. Both A and F inhibit the production of uric acid (UA), whereas B promotes the excretion of UA. Although A and B are present in the prescription ordering database since the start of EMR operations, the use of F in the hospital started in June 2011 and therefore data only from that time are available.

The outline of processing flow of the system that automatically predicts the outcomes of antihyperuricemic from the EMR data is elucidated in Fig. 1. The prescription records are extracted from the EMR prescription database, and then a record of medication history is generated. The generated record of medication history contains the start and end dates of medication. Subsequently, the generated record of medication history and the record of labottory test data that includes the serum UA level are combined. The UA laboratory test data corresponding to before and during (endpoints) treatment with antihyperuricemic become the subject. By this process, a record by which changes in the UA level before and during treatment can be observed is generated. The details of respective processes are described below.

Method of generating medication history

Prescription records are used in generating medication history. Generally, a prescription record contains the patient ID, drug name, prescription start and end dates, unit dose, and method of administration. The outcome of treatment with a drug has a major effect on the dose of the drug, and even with the same

drug, when the daily doses are different, the endpoints have to be distinguished.To distinguish the same drug name present in a prescription record by daily dose, the information on daily dose is combined with the drug name in the prescription record. For example, if A 200 mg/day is prescribed, the drug name will be "allopurinol-200mg." By this process, the same drug that is prescribed at differing daily doses can be distinguished mechanically.The medication history generation program developed in this study was used to generate and process the medication history. With this program, prescription records of the same patient with the same drug name are extracted, and the overlapping periods from records with old prescription dates and remnant drugs that the patient forgot to take are calculated. If there are gaps in the prescription periods, a decision is made regarding whether or not a correction can be made with the remaining drugs. The operations for combining the records are then performed (Fig. 1-1). The record on medication history comprises the patient ID, name of the drug, and dates of start and end of the treatment. The generated records of medication history are stored in the medication history database. The treatment start and end dates of a patient can be obtained from the record of medication history.

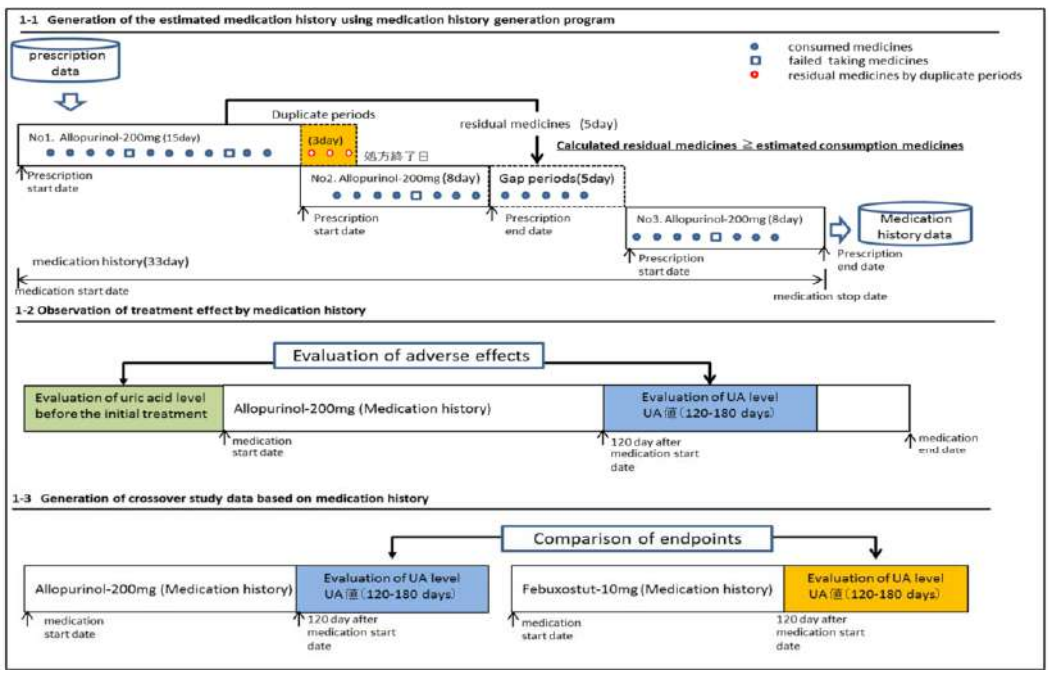

Figure 1 - RCT study based on medication history

Evaluation of treatment outcome based on medication history

The treatment objective of hyperuricemia drugs is to lower the serum UA level to < 6.0 mg/dL between 90 and 180 days by repeated administration. With the treatment start and end dates in the record of medication history as the standard, the treatment efficacy can be observed by comparing data of the serum UA level before and during the treatment, which can be obtained from the EMR sample test data (Fig. I1-2). The criteria presented in Table 1 were used to screen the subject patients.

Table 1 - Screening criteria of subject patients for the endpoint evaluation

	Criteria for extracting subject patients
I	Serum uric acid (UA) level is ≥ 8 mg/dL from 30 days prior to the start of treatment to the day when the treatment is started.
II	From the day when the treatment was started to at least 180 days of repeated treatment, with the same drug and the same dose of hyperuricemia medication.
III	Test records on the UA level during 120‐180 days after the start of treatment are available.

With medication history as the standard, patients on repeated treatment with different antihyperuricemic at different periods were extracted, and a crossover intervention study was performed using the EMR data (Fig. I 1-3). Table 2 shows the screening of subject patients.

Table 2 - Extraction of patients to be subjects of the crossover intervention study with medication history as the standard

	Criteria for extracting the subject patients
I	Serum uric acid (UA) is ≥ 8 mg/dL from 30 days prior to the start of treatment to the day when the treatment is started.
II	From the day when the treatment was started to at least 180 days of repeated treatments, with the same drug and the same dose of hyperuricemia medication.
III	Test records on the UA level during 120‐180 days after the start of treatment are available.
IV	At least two patients meet criteria II and III and have a medication history.
V	During the treatment period between the first evaluation drug and the next evaluation drug, there is no period of concomitant use of another hyperuricemia medication.

To exclude effects due to other antihyperuricemic, with the start and end dates of medication history as the standard, patients on treatment with different antihyperuricemic between the first and next endpoints were excluded from the observation subjects. Moreover, to reduce the effect of treatment with the first drug, as much as possible, the period to the next endpoint evaluation was set at 120–180 days after the initiation of treatment.

Results

Extraction of subject patients for the verification by generating medication history

The number of prescription records of antihyperuricemic extracted from the electronic medical charts was 52,797 (number of patients = 2687), 7400 (675), 5530 (655), 2304 (316), and 10,997 (519) prescriptions of A 100 mg/day (A1) and 200 mg/day (A2), F 10 mg/day (F1) and 20 mg/day (F2), and B 50 mg/day (B), respectively (Table 1). The mean treatment period was 898, 398, 438, 419, and 897 days with A1, A2, F1, F2, and B, respectively. Compared with that of A2, F1, and F2, A1 and B tended to have a long period of administration ($P < 0.01$). A and B were commercialized more proactively than F, and they have a prolonged treatment period. As A2 is commonly a dose increase from A1, its administration period is shorter than that of A1. The number of patients who met the screening criteria in Table 1 and those who could be in the endpoint evaluation were 649 (24%, observation subject patients/prescription subject patients), 94 (14%), 183 (28%), 69 (22%), and 119 (23), for A1, A2, F1, F2, and B, respectively. We examined the treatment success rate in these patients based on the serum UA level during 120–180 days after the initiation of treatment, which was set as the endpoint. Furthermore, 37 patients were confirmed to have received repeated treatments with another drug at a different period for at least 180 days. Among these patients, the serum UA level during 120–180 days after the initiation of treatment was compared.

Comparison of the uric acid lowering effect of hyperuricemia medication based on the estimated medication history

The endpoint of each drug was examined with medication history as the standard. The mean UA level before the initiation of treatment decreased after the initiation of treatment with all the drugs ($P < 0.01$). The number of patients whose UAlevel reached < 7.0 mg/dL by treatment with A1, A2, F1, F2 and B was 346 (53.3%), 78 (83%), 119 (65%), 35 (50.7%), and 63 (75%), respectively. The number of patients whose UA level reached < 6.0 mg/dL by treatment with A1, A2, F1, F2, and B was 92 (14.2%), 50 (53.2%), 76 (41.5%), 35 (31.9%), and 45 (37.8%), respectively. Compared with that of the other drugs, the treatment success rate was high with A2 and low with A1.

Results of the crossover study based on the EMR data

Among patients on antihyperuricemic, those whose treatment was switched to another drug or the daily dose was changed were extracted from the medication history database. The endpoints in the initial treatment and those after the switch in the same patient were compared (Fig. 2).

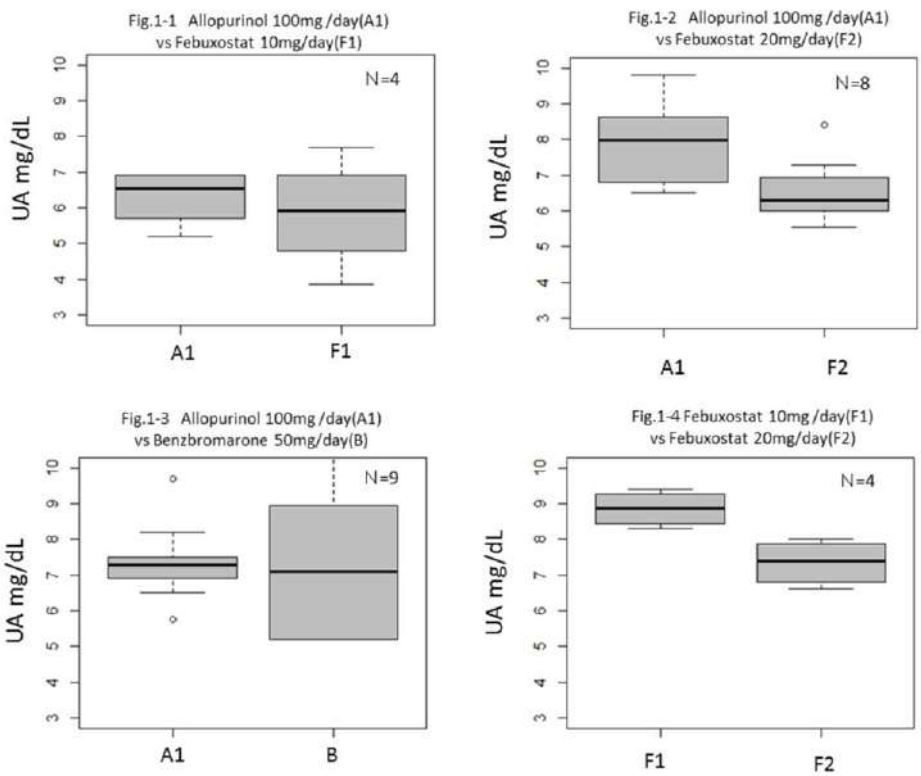

Figure 2 - Results of the crossover intervention study based on the EMR data

With the drug change from A1 to F1, the mean UA level decreased from 6.30 ± 0.8 mg/dL to 5.85 ± 1.6 mg/dL. With the drug change from A 1 to F2, the mean UA level decreased from 7.8 ± 1.1 mg/dL to 6.5 ± 0.9 mg/dL(paired t-test, $P < 0.05$). With the drug change from A1 to B, the mean UA level increased from 7.3 ± 1.1 mg/dL to 7.5 ± 2.5 mg/dL. Among patients in whom the dose of the drug was doubled, with the drug change from F1 to F2, the mean UA level decreased from 8.6 ± 0.5 mg/dL to 6.5 ± 0.9 mg/dL (paired-*T* test, $P < 0.05$).

Discussion

When clinicians observe the effect of drugs from retrospective studies, it is necessary to estimate the medication history of patients. In such a case, clinicians need to estimate the treatment period for each drug from the prescription order history in the electronic medical charts. The number of first-time screening subjects used in this study was 4852 and the number of target prescription records was 79,028. With only a few subjects, it is possible to estimate the treatment period by manual operations. However, with a large number of patients as in this study, it is difficult to extract patients who are required for the endpoint from such a large number. Besides the cost associated with processing human data, there is also the issue with gathering and managing the data. In this study, medication history that was automatically generated using a program that generates such information using prescription orders was used. This enabled us to perform the relevant process of gathering observation data automatically.

With the OMOP method, the effect of drug exposure period can be examined from the prescription records. If the gap between the end of a first prescription record to the start of the next prescription record is within 30 days when the prescription records are consecutive, that gap is also considered a period of drug exposure. Therefore, even when there is a washout, there is a possibility that as an endpoint, it is considered an observation period. Meanwhile, in medication history, by correcting for the remnant drugs in the overlap period, the gap in the prescription order is corrected for, and treatment start and end dates that are close to the actual treatment period of the patient are generated. In this study, this is accompanied by the evaluation of endpoint; the method of generation of medication history is effective.

As shown in Table 2, the number of patients with improved UA level of < 7 mg/dL was 641 of 1108 (57.9%). The percent of patients in whom gouty tophi disappeared as the UA level improved to < 6 mg/dL was 25.7% (285/1108). The rapid decline in the UA level due to antihyperuricemic is the cause for the onset of gouty arthritis, and the sudden increase in UA excretion is the cause of UA calculi and renal failure. Therefore, clinicians start prescription from a low dose to minimize the effect of adverse effects as much as possible. Thus, once there is improvement (UA < 7 mg/dL) from the state of hyperuricemia, fixing the drug and dose is commonly considered. In a report on the outcomes of treatment with antihyperuricemic in a phase III clinical study conducted in Japan, the patients on A2 and F2 whose UA level improved to < 6 mg/dL were 35.2% and 29.6%, respectively. In this study, the results were 33.5% and 27.4%, respectively, which were

similar to those of the previous clinical study. With B 50 mg/day, a postmarketing surveillance was performed and the rate of patients with decrease in UA level was 37% (31.6% in this study). This also supports the data of this study. In other clinical studies, A at a dose of ≥ 200 mg/day and F at a dose of ≥ 40 mg/day are generally used. Therefore, study data showing treatment results of long-term use of low-dose A, F, and B are beneficial while formulating treatment plans.

In a crossover intervention study, a subject is selected, administered various drugs at different treatment periods, and the treatment effects are compared. In this study, highly reliable data were obtained even with a fewer number of patients by removing the diversity among patients. However, with this method, once the final treatment is completed, a return to baseline is necessary. Moreover, a washout period is necessary based on the time of switching the drugs. It is a challenge to completely meet these two criteria when the data of patients attending hospital for the purpose of receiving antihyperuricemic are to be used as subject. Thus, in this study, the endpoint used for making comparisons before and after switching the drugs was set at 120–180 days. As such long-term data were used and as patients on concomitant treatment with other antihyperuricemic were removed, the effect of previous drugs was decreased as much as possible. Therefore, among the 4852 patients, only 37 (0.76%) were used as observation subjects. Of the 37 patients, 28 were patients who had switched from A to other medications. Five were switched from B to F and four were on increased F dose. Febuxostat was launched approximately 30 a fter A. Even in patients with moderate renal impairment, F can be administered with dose reduction. The administration is once daily, and it can be indicated even in the absence of complication of hypertension. This makes it a readily switchable drug. Allopurinol and B are medications that have been in use for a long time, and several studies on their treatment efficacy have also been performed. On the contrary, the fact that a study equivalent to a crossover study using real-world data with F as the subject could be performed is of significance.

Clinical data stored in clinical facilities are an important intellectual resource. These data include diseases with various characteristics. By consolidating these data, the causal relationship between interventions and outcomes can be examined.

In this study, the effect of antihyperuricemic on renal function and diuretics, which are related to adverse events, was not observed. These data that are linked to the unique ID of patients are stored in electronic medical charts, making it easy to extract those patients who can be the subjects of an evaluation. Patients can be classed according to the status of renal impairment and the status of diuretic treatment. By doing so, the relative evaluation of treatment effect and the onset of adverse events can also be performed. One can also expect that the factors affecting treatment efficacy can be investigated using patients who are extracted by this method. With the system developed in this study, data of multiple medical facilities could be handled. Moreover, we were successful in generating medication history from prescription order data using the electronic medical chart of various makers. If the criteria of patients, who will be the subject of observation by physicians based on medication history, can be set using a computer, clinical epidemiology studies will improve dramatically.

Conclusions

In this study, medication hostory for hyperuricemia and the serum uric acid (UA) level were compared using mdeication history database generated by prescription order records. From the generated medication history, the treatment success rate with antihyperuricemic can be extracted mechanically. This method will be useful for comparing drug effects retrospectively.

Abstract

We applied an open source natural language processing (NLP) system "NimbleMiner" to identify clinical notes with mentions of alcohol and substance abuse. NimbleMiner allows users to rapidly discover clinical vocabularies (using word embedding model) and then implement machine learning for text classification. We used a large inpatient dataset with over 50,000 intensive care unit admissions (MIMIC II). Clinical notes included physician-written discharge summaries (n = 51,201) and nursing notes (n = 412,343). We first used physician-written discharge summaries to train the system's algorithm and then added nursing notes to the physician-written discharge summaries and evaluated algorithms prediction accuracy. Adding nursing notes to the physician-written discharge summaries resulted in almost two-fold vocabulary expansion. NimbleMiner slightly outperformed other state-of-the-art NLP systems (average F-score = .84), while requiring significantly less time for the algorithms development.: Our findings underline the importance of nursing data for the analysis of electronic patient records.

Keywords:
Substance-Related disorders, Alcoholism, Nursing informatics.

Introduction

Over the past decade, widespread adoption of health information technology, such as the electronic health record, resulted in rapidly growing volumes of clinical data. Most of these data are stored in an unstructured format, such as text narratives, within electronic health records across diverse healthcare settings. The narrative data require innovative tools that help clinicians and researchers to extract meaning from large databases of text.

Natural language processing (NLP) is a set of powerful techniques that can help in processing and deriving meaning from clinical narratives. NLP has the potential to identify clinicians' detailed documentation of wound information, mentions of gender identity, documentation of poor self-management status and other concerns about a patient expressed as free text [1–5].

Although significant progress has been made within the medical domain, for nursing and allied health professions NLP development and implementation remains relatively challenging and scarce[6,7]. Some of the challenges include lack of large datasets of labeled clinical notes from nursing or allied health professions needed to create machine learning and text mining algorithms. On the other hand, rule-based NLP systems are hard to construct because large curated vocabularies of nursing or allied health professions-specific lexicons are rarely available. Moreover, the importance of nursing data and its contribution to general tasks such as text classification, remains generally under-studied. We found only one study that used information extracted from nursing notes as an indicator of out-of-hospital mortality[8]. Our main contribution is further assessment of the importance of nursing data.

This study focuses on an important domain-identification of alcohol and substance abuse from clinical data. Prior research suggests that alcohol and substance abuse information is often documented as free text[9]. However, previous NLP studies used physician notes to extract alcohol and substance abuse information[10,11]. In this study, we explore the potential added value of nursing data.

In this study we applied our open source NLP application called "NimbleMiner" [12,13] to generate an algorithm that can automatically identify clinical notes with mentions of alcohol and substance abuse. Our system allows users to rapidly specify clinical vocabularies for a certain domain, apply weakly supervised rapid labeling, and then implement machine learning for text classification. In this study, we first used physician-written discharge summaries to generate the NLP algorithm and evaluate the algorithm's prediction accuracy. We then added nursing notes to the physician-written discharge summaries and evaluated the algorithm's prediction accuracy. We compared the performance of the two NLP algorithms to understand whether adding nursing notes resulted in better prediction accuracy when identifying clinical notes with mentions of alcohol and substance abuse. We also compared our system's performance to other state-of-the art NLP systems that were applied on the same documents.

Methods

Dataset

This study used the large, publically available, de-identified dataset MIMIC II which is comprised of data from adult patients admitted to the intensive care units (ICUs) at the Beth Israel Deaconess Medical Center from 2001 to 2012. The data included over 50,000 hospital ICU admissions. The dataset contained several types of clinical notes, including physician-written discharge summaries (n = 51,201) and nursing notes (n

= 412,343). Nursing notes included nursing admission notes, daily progress and status update notes, case management notes, etc. This study received an Institutional Review Board approval from the University of Haifa, Israel.

NLP System Description

Our NLP system NimbleMiner is an open source system developed by our team[12,13]. User manual and download options can be accessed at: http://github.com/mtopaz/NimbleMiner. Other research or clinical teams can use the system under the GNU General Public License v3.0. NimbleMiner includes several methodological stages of clinical note processing that are briefly described below and presented in Figure 1.

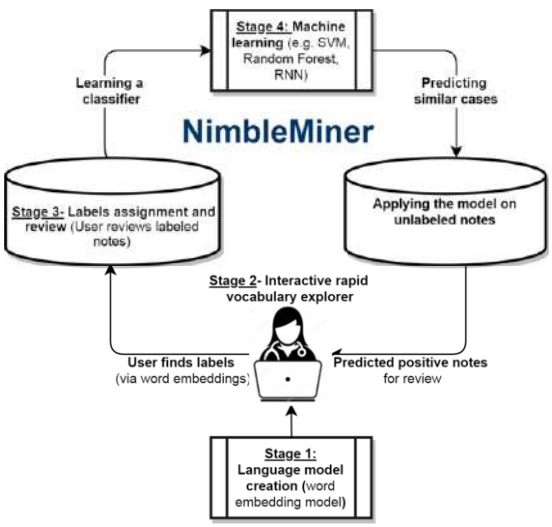

Figure 1– NimbleMiner system process stages.

Stage 1- Language Model Creation:

The user selects a large corpus of clinical notes and defines language model characteristics. We use a word embedding model for language model generation and users can change model settings based on their preferences.

Stage 2- Interactive Rapid Vocabulary

Explorer: The user enters a query term of interest, and the system returns a list of similar terms it identified as relevant. The list of suggested similar terms is based on the cosine term similarity metric extracted from the word embedding model. The user selects and saves the relevant terms. Negated or other irrelevant terms that are not selected by the user are also saved in the system for further tasks, such as negation detection. Figure 2 describes the steps of the vocabulary explorer stage.

Stage 3- Labels Assignment and Review:

The system uses the stage 2 discovered similar terms to assign labels to clinical notes (while excluding notes with negations and other irrelevant terms). Assigning a positive label means that a concept of interest is present in the clinical note. When needed, the user reviews and updates lists of similar terms and negated similar terms. The user reviews the clinical notes with assigned labels for accuracy. This weakly supervised rapid labeling approach is based on a postive labels learning framework validated in previous research [14,15].

Stage 4- Machine Learning:

The user choses a machine learning algorithm to be applied to create a predictive model. The model is then applied to predict what clinical notes might have the concept of interest. The user reviews the predicted notes and can go through stages 2-4 again to add new labels.

NLP System Settings

NimbleMiner's user interface is implemented in R statistical package. To create a word embedding model, we used a skip-gram model implementation called word2vec and phrase2vec in R[16,17]. Parameters of the word embedding model were held constant based on parameters suggested in other studies of word embedding[18]. Specifically, we used a model with window width size = 10, vector dimension = 100, minimum word count = 5, negative sample size = 5, and sub-sampling = 1e-3. For each similar term entered by the user, the system presented 50 potentially similar terms based on the cosine similarity. Our previous experiments [12] showed that the random forest algorithm outperforms other approaches (e.g., J48 Decision trees, Support Vector Machines), hence we used this algorithm in the machine learning stage of this study. The algorithm was trained using only discharge summaries, as was the case in other studies. The Random Forest algorithm was used with default settings (number of iterations = 100, minimum number of instances = 1, minimum variance for split = 1e-3, depth = unlimited).

NLP System Performance Evaluation

The system performance evaluation was performed based on the publically available gold-standard testing dataset generated by Gerhman et al. [19]. To create the gold standard dataset, Gerhman et al. annotated 1,610 discharge summaries for presence of several patient phenotypes, including alcohol and substance abuse. Each discharge summary was labeled by at least two experts in medicine and health informatics [19]. Full agreement about each of the labels was achieved on all the cases. Overall, the annotated dataset included 155 instances of substance abuse and 196 instances of alcohol abuse. For both domains, a relatively high inter-rater agreement was achieved (Cohen's Kappa inter-rater agreement = .86). We applied our NLP algorithms on this dataset to predict alcohol or substance abuse for each of the discharge summaries. We calculated precision (defined as the number of true positives out of the total number of predicted positives), recall (defined as the number of true positives out of the actual number of positives) and F-score (F1, weighted harmonic mean of the precision and recall) to evaluate the performance of our system.

Comparison with Other NLP Systems

NimbleMiner's performance was compared to the results reported by Gerhman et al. who developed a convolutional neural network (CNN) for text classification[19]. CNN is a subtype of machine learning models called neural networks. CNN is built of one or more convolutional layers and then followed by one or more fully connected layers, as in a standard multilayer neural network[20]. CNNs were found to outperform other machine learning methods in several classification tasks, such as image recognition[21].

In addition, NimbleMiner's performance was compared to another open-access rule-based NLP system called the clinical Text Analysis and Knowledge Extraction System (cTAKES)[22]. cTAKES was applied by Gerhman et al. to identify alcohol and substance abuse instances in each of the notes in the testing set[19]. To pre-process the clinical notes,

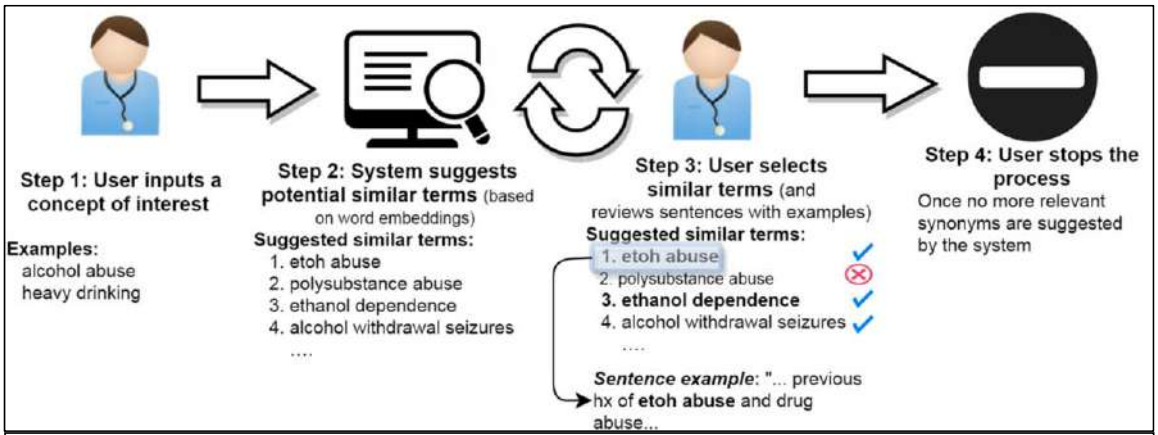

Figure 2– NimbleMiner Stage 2 -Interactive rapid vocabulary explorer process overview.

***Legend**: Interactive Rapid Vocabulary Explorer: The user enters a query term of interest (step 1), and the system returns a list of similar terms it identified as relevant (step 2). The list of suggested similar terms is based on the cosine term similarity metric extracted from the word embedding model. The user selects and saves the relevant terms while negated or other irrelevant terms that were not selected by the user are also saved in the system for further tasks (step 3). The system iteratively identifies new potential similar terms and presents them to the user for review (steps 2-3) and the process continues until there no new similar terms to suggest (step 4).*

cTAKES splits sentences and phrases into individual words (tokenization), normalizes them (e.g., removes plurals) and tags part-of-speech (e.g. noun, verb). Then, the named-entity recognition algorithm is implemented to detect named entities for which a concept unique identifier (CUI) exists in the Unified Medical Language System (UMLS).

Results

Applying NimbleMiner on discharge summaries alone resulted in identifying 73 alcohol abuse-related words and expressions (e.g., "heavy drinker" or "alcohol addiction"). Adding nursing notes resulted in identifying 71 additional unique words and expressions, resulting in a 97% lexicon expansion (total alcohol abuse expressions n = 144). Similarly, 76 substance abuse-related words and expressions (e.g., "illegal drug abuse" or "crack/cocaine abuse") were identified from the discharge summaries alone and 60 additional expressions were identified when nursing notes were added (total substance abuse expressions n = 136). Adding nursing notes enabled 79% lexicon expansion for the substance abuse domain. The lexicon discovery phase for each domain was conducted by one of the study co-authors and took about 4 hours in total to implement (2 hours for each domain) with discharge summaries only and about 6 hours when nursing notes were added (since more potentially relevant words needed to be reviewed). Two more hours were spend on system refinement (e.g., reviewing labeled notes and adding negations) and machine learning algorithm implementation for each domain. Overall, a maximum of 10 hours were spent on vocabulary development and algorithm implementation. Table 1 presents examples of alcohol and substance abuse words and expressions.

In addition, 1,736 terms for substance abuse and 2,255 terms for alcohol abuse were not selected by the user during the interactive rapid vocabulary explorer process (stage 2). These irrelevant terms included a diverse range of negations (e.g., "illicits none" or "not addicted to drugs"), family history expressions (e.g., "family history of alcoholism" or "father used cocaine") and other irrelevant terms that appear in the same context, for example other habits or related diseases (e.g., "tobacco smoker" or "hepatic cirrhosis"). Examples of negated or other irrelevant terms are shown in Table 1.

Table 1– Examples of alcohol and substance abuse expressions

Domain	Examples of relevant terms
Alcohol abuse	"heavy drinker" "alcohol addiction" "etoh [ethyl alcohol] abuse" "ciwa [The Clinical Institute Withdrawal Assessment for Alcohol scale] high" "korsakoff syndrome" [chronic memory disorder common in alcoholics] "alcoholic cirrosis [misspelling of cirrhosis]"
Substance abuse	"ho [history of] ivdu" "heroin withdrawal" "recent crack cocaine" "narcotic overdose" "iv heron [misspelling of heroin]" "cocaine in urine"
	Examples of negated or other irrelevant terms
Alcohol abuse	"drinks alcohol rarely" "occasionally drinks alcohol" "father was alcoholic" "family history of alcoholism" "alcohol abstinence" "social alcohol use"
Substance abuse	"ilicit drug use denies" "denies recreational drug use " "father used cocaine" "illicits none" "drugs none" "not addicted to drugs"

NLP System Performance Evaluation

NimbleMiner's predictive algorithm (Random Forest classifier) slightly outperformed other state-of-the-art NLP approaches in terms of the F-score. The best performing NimbleMiner algorithm was based on words and expressions learned from a corpus of discharge summaries and nursing notes compared to discharge summaries alone. See Table 2 for details on system performance measures

*Table 2– Comparison of system metrics across NLP systems**

Metric	NimbleMiner (discharge summaries+ nursing notes)	NimbleMiner (discharge summaries only)	Best performing Convolutional Neural Network	Text Analysis & Knowledge Extraction System (cTAKES)
Alcohol abuse				
Precision	83	79	85	**88**
Recall	**84**	78	79	79
F1	**84**	78	81	83
Substance abuse				
Precision	87	78	83	**93**
Recall	80	77	**83**	47
F1	**84**	77	83	62

*All systems were tested on discharge summaries only.

Discussion

This study applied a rapid NLP system called NimbleMiner to identify clinical notes with mentions of alcohol and substance abuse. Our approach showed promising results and it performed similarly or outperformed other systems developed for this domain[19]. For traditional machine learning and text mining, large datasets of labeled data are needed to train the system. For example, Gerhmann et al. annotated 1,610 discharge summaries and 70% of these notes were used for system training[19]. This approach required two or more clinicians to read and label the corpus of discharge summaries, resulting in significant time investment of at least 260 hours for data labeling (5 min per note * 1,610 discharge summaries * 2 clinicians= ~260 hours). On the other hand, the strength of rule-based systems lies in carefully curated and developed terminologies and rich hierarchical relationships between the concepts. However, rule-based systems like cTAKES require significant time and expertise investments when creating vocabularies and rules, defining negations, identifying family history, etc.

Our approach offers a hybrid solution where the human expert is interacting with the machine to rapidly create weakly supervised large labeled datasets for further machine learning. NimbleMiner also allows users to create large corpora of negated or other irrelevant terms (such as family history) that should be excluded from the labeled clinical notes processed through machine learning. Using the NimbleMiner, it took less time (4 hours) compared to other systems for algorithm development and implementation with comparable or better results. These findings suggest that for some text mining domains, such as identifying socio- behavioral determinants of health, NLP approaches can be implemented in a rapid, clinician-driven manner.

Our results also demonstrate the added value of extending data sources [23]. to include nursing data for vocabulary exploration. In our approach, adding nursing clinical notes resulted in an almost two-fold vocabulary expansion, leading to better classification performance. Other recent studies confirm our results about the importance of nursing data. For example, a NLP study conducted with the same dataset (MIMIC) has recently found that sentiment presented in nursing notes was significantly associated with a 30-day intensive care patient mortality[8]. Thus, the presence of negative-sentiment related expressions in nursing notes predicted a 30-day patient mortality. These findings underline the importance of nursing data for the analysis of electronic patient records. Other studies conducted in diverse clinical domains should consider using the valuable information from nursing notes to improve text and data mining algorithms.

Limitations

Our study has several limitations. First, our approach might not be applicable to solve more complex NLP challenges, such as word sense disambiguation or relation extraction. Comparing our results with rule-based systems like cTAKES would likely result in biased results in favor of more domain-specific systems like NimbleMiner. In addition, different NimbleMiner users can discover different vocabularies, which might influence the system's performance. Also, the vocabulary discovery phase was implemented by one co-investigator and adding more reviewers to this phase could have resulted in a different vocabulary for alcohol and substance abuse terms. A larger study with more domains is needed to validate the generalizability of our approach.

Conclusions

We applied our open-source NLP system NimbleMiner to conduct clinician-driven concept discovery in clinical narratives. Our results suggest that NimbleMiner can be applied to rapidly discover similar clinical terms and create large datasets of labeled clinical notes required for machine learning. Our system slightly outperformed other state-of-the art NLP systems while requiring significantly less time for the algorithm's development. We believe that NimbleMiner can be used by almost any clinician without special informatics training to create accurate NLP algorithms.

Abstract

Hospitalization expenses account for a high rate of national medical care expenditure in Japan. The Japanese national medical care expenditure was 42 trillion 364.4 billion yen in 2015, in which hospitalization expenses were 15 trillion 575.2 billion yen (36. 8%). Therefore, it is necessary to take measures to reduce hospitalization expenses. The total ratio of the labor cost of physicians and nurses accounted for about 1/3 of all expenditures of general hospitals in 2015. Moreover, the personnel cost of nurses accounted for about 1/5 of all expenditure, showing that the personnel cost of nurses is an element with a large influence on hospital management. The objective of this study was to develop a methodology to reduce the overtime work of nurses accounting for a large rate of personnel expenses by focusing on overtime work, a personnel expense-increasing factor, aiming at hospital cost reduction. First, the cause of overtime work, planning, and recording by nurses were analyzed and an IT application increasing the quality and efficiency of the work was developed. Then, fees for the use and maintenance of the IT system meeting the following conditions were set as a strategy to introduce the system: (1) 50% reduction of the overtime work of nurses and (2) fees 50% or lower than the reduced payment for overtime work. This IT application was introduced to the heads and directors of nursing of 5 hospitals and the strategy was proposed. All heads and directors highly evaluated the system and responded to initiate the process for the introduction. It was suggested that the methodology to reduce the overtime work of nurses proposed by this study is useful and feasible.

Hospitalization, Health expenditures

Introduction

Problems with health care are discussed from viewpoints of safety, quality (in a narrow sense), and cost, and all advanced countries have immense tasks in each issue. Aging spurs an increase in national medical care expenditure to which advanced countries inject large public finance.

In Japan, hospitalization accounts for a high proportion of national medical care expenditure. The national medical care expenditure in Japan was 42 trillion 364.4 billion yen in 2015, in which hospitalization expenses was 15 trillion 575.2 billion yen (36. 8%) [1]. Therefore, it is necessary to take measures to reduce hospitalization expenses, which account for 36.8% of the total medical expenses. For 'reduction of the hospitalization expenses' in medical care, which is an important socio-technology to be possessed by a country, it is necessary to aim at 'improvement of efficiency while securing quality', i.e., improvement of added values for customers while optimizing devoted resources.

Table 1 Ratios of personnel expenses in general hospitals in Japan [3]

	Medical corporation	Local government	Former social insurance-related organization
Ratio of personnel expenses (%)	53.3	63.1	51.8
Ratio of personnel expenses for physicians (%)	13.8	14.2	15.9
Ratio of personnel expenses for nurses (%)	17.7	22.2	18.6
Ratio of personnel expenses for physicians and nurses (%)	31.5	36.4	34.5
Ratio of personnel expenses for others (%)	21.8	26.7	17.3

In data analysis of 773 general hospitals (2015 account settlement) [2], the numbers of workers per 100 patients were 9.9 full-time physicians, 2.4 part-time physicians, 65.7 nurses, and 52.7 other workers. Regarding the rate of cost to the medical revenue, the ratio of personnel expenses was 52.4%. The annual medical revenue per worker was 11,953,000 yen

(about 12 million yen) and the personnel expenses per worker were 6,267,000 yen.

On the other hand, in data analysis of 520 sanatorium-type hospitals (2015 account settlement) [2], the numbers of full-time and part-time physicians, nurses, and other works were 3.3, 1.7, 59.4, and 39.9, respectively. The proportion of personnel expenses was 58.5%, the annual medical revenue per worker was 8,999,000 yen (about 9 million), and the personnel expenses per worker was 5,266,000 yen.

Regarding the personnel expenses of general hospitals by hospitals established in 2015[3] are categorized as follows: 1) medical corporation, 2) local government, and 3) former social insurance-related organization, the overall ratio of personnel expenses was: 1) 53.3%, 2) 63.1%, 3) 51.8%, the ratio of personnel expenses for physicians was: 1) 13.8%, 2) 14.2%, 3) 15.9%), and the ratio of personnel expenses for nurses was: 1) 17.7%, 2) 22.2%, 3) 18.6%, showing that the total ratio of the labor cost of physicians and nurses accounts for about 1/3 of all expenditures. In addition, about 1/5 of all expenditures is the personal cost of nurses, showing that the personnel cost of nurses is an element with a large influence on hospital management.

To realize high-quality excellent services, 'co-creation' [4] by customers and service providers is attracting attention, i.e., greater importance is attached to designing for points of contacting customers. For hospitals, it is necessary to focus on ways of working of physicians and nurses who have many important contact points with patients. Their abilities and numbers influence the operational efficiency of elements other than the humans described above. Therefore, 'the ratios of personnel expenses for physicians and nurses' and 'way of working to create value' may be important.

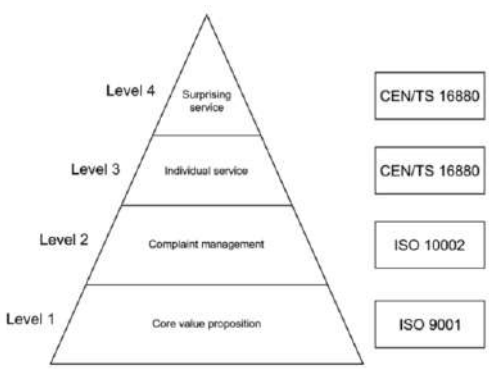

Fig. 1 Service excellence pyramid [4]

This study aims at developing a management method to reduce the hospital cost for the latter. Focusing on a personnel cost-increasing factor, overtime work, reduction of overtime work of nurses, which accounts for a large ratio of personnel expenses, is targeted. In the present study, we proposed the design of digitalization as an innovation of nursing records and investigated its usefulness and feasibility aiming at solving the problem with overtime work in health care.

Methods

We took the following steps for the purpose of a high-quality nurse's record and reduction of the overtime work.

Step1:

We suggested the rate of recording nursing observation of patient condition necessary to deal with individual patients does not reach 50% through a survey to evaluate the quality of nursing records in the current state. Failures of its inclusion in the planning, implementation, and recording have been identified as causes and 'volatizing situation' was suggested [5-7]. Moreover, it was clarified that data production and input depend on individual nurses and many documents are descriptive electronic records, being a long way from re-utilization.

Step2:

To solve failure to include it in a plan, preparation and utilization of many high-quality models of treatment and nursing care plans are useful. Thus, we have developed clinical knowledge content by incorporating NursingNAVI™ (Navigator for Thinking Process in Nursing) into PCAPS™ (Patient Condition Adaptive Path System) as a structured clinical knowledge content [8-12]. In the process of this development, using the Standard Terminology for Nursing Observation and Action (Ministry of Health, Labour Standards since 2016) for electronic medical records, the content of structured nursing care plan was developed.

Step3:

The result of two hospitals carried out record reform for problem-solving was shown five hospitals.

Case1: An acute hospital

A system application to support recording the structured nursing care plan was designed and implemented in a large-scale acute-care hospital with 1,000 beds. The proportion of nurses who took 30 minutes or more to identify the condition of patients in whom they were in charge of decreased from 45.4 to 5% after 3 months. It was suggested that utilization of the high-quality structured nursing care plan, which is clinical nursing knowledge, supports the thinking process of nurses and shortens the work time. After 3 years, 40% of patients applied clinical path, 60% of patients applied NursingNAVI®. It became zero in the overtime for records. The overtime work markedly decreased in the hospital and overtime work for recording was mostly resolved.

Case2: A non-acute hospital

We analyzed the nurse's record. Physicians satisfied the nursing record of observation. Only the PCAPS introduction ward was able to maintain a decrease of the overtimes.

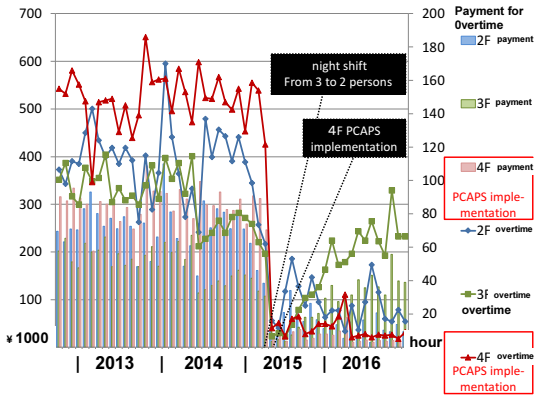

Fig. 2 Overtime and the payment every month

Step4:

These five hospitals carried out follows two surveys. The aim of Survey 1 is to remark the problem of quality of nursing record using our survey sheet[7]. It is set elements of nursing observation in the acute phase after colectomy. We used the 'Master File of Standardized Nursing Practice Terminology'. It is standard terminology for nursing practice by the Ministry of Health, Labour and Welfare in Japan. The set of elements was developed after reviews using the framework of NursingNAVI® [6-8] by multiple clinical nursing specialists. The availability of the survey sheet was verified by comparing surveys among four and fifteen hospitals. The aim of Survey 2 is to remark the problem of the overtime work. It was conducted in each hospital. We prepared output-table of each month and each nursing unit. Senior nursing officers of five hospitals gathered data in each hospital, and input the output-table sum of overtime and sum of overtime payment.

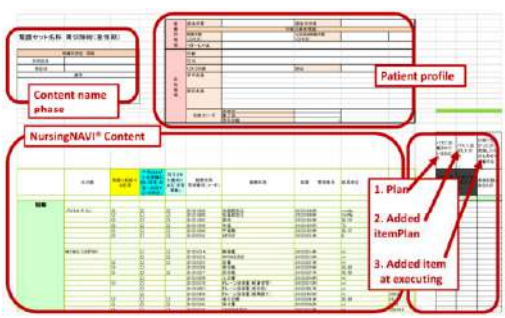

Fig. 3 Survey 1: Surve sheet of nursing documents using NursingNAVI® Content for quality evaluation of nursing observation

Results

Survey 1: Quality of nursing record using our survey sheet

Vital signs, in/out, was relatively recorded, but the observation to affect the monitoring of a symptom, complications of the disease was less than 50%. A certain hospital investigated record time and the number of record letters using log data of HIS. As a result, we understood that they recorded it until the night after daily service duties of 2 change were over. In addition, the actual situation that wrote an enormous amount of description record became clear.

Survey 2: the overtime work

Each hospital surveyed the payment amount and time of overtime work by month and ward for one year. The annual payment was 20-90 million yen in acute-care general hospitals with about 400 beds, 150 million yen in acute-care general hospitals with about 490 beds and 250 million yen or more in university hospitals with about 1,000 beds. In contrast, the payment for overtime work in the large-scale hospital with 1,000 beds described above which introduced the support system for the structured nursing care plan recording was about 25 million yen, confirming that recording work necessary for medical treatment is performed in overtime work.

Five hospitals started activity for the innovation of the nursing record system after having confirmed the results of this investigation.

Discussion

Standardized care plan using structured nursing knowledge is effective and efficient for nursing practice. Nurses can observe systematically using the structure. They can gather data and information for analyzing own nursing. We could introduce NursingNAVI® and PCAPS in the hospital information system. It was suggested that hospital nursing can use two types of systems as structured nursing knowledge.

Even though an excellent system is designed and developed an actual practice sites request its introduction, if the contribution to management cannot be claimed, the realization is difficult. For a strategy to introduce the system, we investigated a business model (1) targeting 50% reduction of overtime work time of nurses and (2) setting fees for the use and maintenance of the system and content at 50% or lower of the reduced payment for overtime work.

It is possible to set a business model in which this system can be introduced into acute care hospitals with 400 beds paying 20 million yen for overtime work a year, which is a relatively small payment, and the hospital income can be increased. For large-scale acute care hospitals, contribution to management increases because the payment for overtime work is high.

Hospitals introducing the system are requested to provide information on 'overtime work time of nurses and payment for it in each ward' as Key Performance Indicators (KPI), and changes in improvement are presented as numerical values.

Conclusions

This strategy and scenario were provided to nursing administrators and hospital administrators of five hospitals, and all hospitals responded to initiate the process for introduction, suggesting that the strategy proposed by this study is highly feasible.

Abstract

Social media presents a rich opportunity to gather health information with limited intervention through the analysis of completely unstructured and unlabeled microposts. We sought to estimate the health-related quality of life (HRQOL) of Twitter users using automated semantic processing methods. We collected tweets from 878 Twitter users recruited through online solicitation and in-person contact with patients. All participants completed the four-item Centers for Disease Control Healthy Days Questionnaire at the time of enrollment and 30 days later to measure "ground truth" HRQOL. We used a combination of document frequency analysis, sentiment analysis, topic analysis, and concept mapping to extract features from tweets, which we then used to estimate dichotomized HRQOL ("high" vs. "low") using logistic regression. Binary HRQOL status was estimated with moderate performance (AUC=0.64). This result indicates that free-range social media data only offers a window into HRQOL, but does not afford direct access to current health status.

Keywords:

Quality of Life, Social Media, Natural Language Processing

Introduction

Social media platforms are increasingly used for clinical research. Investigators now harness social media data for many purposes, including recruiting patients into clinical trials [1], measuring mood and sentiments [2], educating patients about social and medical concerns [3], and many others [4–9]. Although these applications expand the ability to perform health outcomes research on a broad scale, there is currently no reliable technique to measure patient reported outcomes (PROs), such as health related quality of life (HRQOL), using social media data.

The availability of a psychometrically valid, automatically generated social media PRO instrument would offer researchers and clinicians a new method to measure the "real life" effectiveness of interventions, behaviors, and therapies outside the confines of traditional research. Ideally, such a PRO would not require explicitly prompting users to speak specifically about health-related issues. Instead, the PRO would rely on existing social media posts and then estimate HRQOL using techniques such as natural language processing (NLP) and sentiment analysis.

An important step toward using social media for HRQOL estimation is to develop a method for translating diverse, unprompted, unstructured social media posts into information useable by clinicians and researchers. Given concerns about the representativeness and validity of social media data, there are limitations to measuring "true" HRQOL using social media analytics. Specifically, social media users may be systematically different from non-users, and even among users, many likely display a version of themselves that does not reflect their true functional state. Nevertheless, it would be useful to develop a method of extracting meaningful information from social media posts that operates within these limitations.

Several previous studies have looked at whether information about various components of an individual's health status could be inferred from unprompted social media use. For example, one study found that language used in Facebook posts could predict depression [10]. Another study found that aggregated Twitter data could predict county-level mortality from heart disease [11]. Others still have looked at PTSD [12] and county-level life satisfaction [13] with positive results. To the best of our knowledge, however, this is the first study that has tried to directly predict HRQOL measured by a validated PRO instrument using unprompted social media data.

In the present study, we collected social media posts from users of Twitter (http://www.twitter.com/), a web- and smartphone-based tool for users to express comments in short statements ("Tweets"), often appended with images or embedded with links to websites. We contacted users and administered a brief, empirically validated questionnaire that assesses HRQOL. We then used multiple analytic methods to develop predictors of their ground-truth HRQOL scores using data solely from their "Tweets". We hypothesized that, despite the limitations of free-range social media data, HRQOL could be classified with a degree of accuracy greater than chance.

Methods

Study Overview

We recruited a cohort of 1,831 Twitter users between May and December of 2015 through a combination of online solicitation and in-person contact. All participants were asked to complete the four-item Centers for Disease Control Healthy Days Questionnaire (CDC-4) questionnaire [14] at the time of enrollment and 30 days later to measure "ground truth" HRQOL. We then collected their tweets over a period of 60 days: 30 days before and after enrollment. Next, we collected and analyzed the tweets to determine characteristics that distinguish users with low or high HRQOL, using the CDC-4 as a gold standard. Of the 1,831 participants recruited, 878 had at least one accessible tweet during the analysis period, and the remaining participants were not used for analysis.

Participant Recruitment

We recruited participants through three mechanisms. First, we recruited general Twitter users by tweeting announcements through our institutional Twitter account (@CedarsSinai). Second, we recruited a general population sample through Cint, a survey research firm that recruited a sample of Twitter users from its survey cohort. Third, we supplemented our cohort of general Twitter users with a defined group of patients seeking care by recruiting individuals seen at the University of Pennsylvania Emergency Department for non-life-threatening, ambulatory conditions. Subjects in all cohorts were required to be 18 years of age or older and able to read English. Participants were entered into a drawing for one of two randomly selected $500 USD prizes. Participants with Twitter accounts who consented to participate completed the CDC-4 and provided their Twitter handle. Additional information about the University of Pennsylvania cohort has been published previously [15].

Study Measure

The CDC-4 Healthy Days Questionnaire [14] is a brief measure that assesses a number of factors, including general HRQOL on a five-point scale. This measure has been rigorously validated, demonstrating criterion validity with the Short Form 36-item health survey (SF-36) [16] as well as content, construct, and predictive validity, internal consistency, and test-retest reliability across diverse populations. The measure was chosen for its simplicity, reducing respondent burden to a minimum.

Acquisition and Preprocessing of Twitter Data

All tweets were acquired from the Twitter website. Tweets collected from each participant were segregated into two "collection waves": tweets from the 30 days prior to enrollment, and tweets from the 30 days including and subsequent to enrollment.

In order to reduce the proportion of marketing-related tweets in our dataset, we filtered out tweets containing any of a set of key phrases (any URLs, or the strings "sponsored", "my echo", "#mpoints", "giveaway", "@youtube", "giftcard", and "gift card.") that were determined to be associated in our dataset with marketing tweets by manual review of a random tweet sample. In addition, any users who tweeted more than 300 times in a given 30-day collection wave were removed from analysis in that period. This threshold was determined manually in order to remove accounts that were predominated by spam.

We then applied an initial preprocessing pipeline consisting of custom filters as well as Natural Language Tool Kit (NLTK) [17] tools to all tweets. The pipeline consisted of the following steps:

1. Unicode normalization form C (NFC) was applied
2. The Penn Treebank tokenizer was applied to generate tokens
3. Mention and reply tokens (e.g., @username) were removed
4. All tokens were converted to lower case
5. Repeated characters were removed iteratively until either no additional repeat characters existed or the token was transformed into a word in WordNet [18]
6. A Lancaster [19] stemmer was applied to each token

After preprocessing, we created “tweet sets” consisting of the concatenation of all of the tweets from each of the two collection waves (thus creating two tweet sets per participant). We then applied a term frequency-inverse document frequency (TF-IDF) transformer to each tweet set. For each of these tweet sets, we also computed several additional features. We fed each acquired tweet in each document set into the SentiStrength sentiment analysis tool, a validated opinion mining toolkit that computes positive and negative sentiment scores [20–22]. Then, we computed the mean, median, standard deviation, maximum, and minimum of the SentiStrength scores across all tweets in the set, and added them to the set’s data vector. We also added the number of tweets in the set to the vector.

In order to conduct semantic processing on the large volume of tweets, we utilized Latent Dirichlet Allocation (LDA), an automated method for discovering semantic themes in unstructured text [23]. For each concatenated tweet set, a vector representing the topics contained in the set was generated and added to the set’s data vector. Selected examples for demonstration are presented in Table 1.

Finally, we used the cTAKES processing engine [24] to map words in each tweet to concepts found in the Unified Medical Language System (UMLS) Metathesaurus and to detect concept negation. Instances in which the concepts were negated were considered to be separate concepts from non-negated versions. After determining the list of all concepts present in our dataset, for each 30-day tweet set, we created a data vector representing whether or not each concept was present or absent in the set. We then added this vector to the set’s data vector.

Statistical Analysis

We first dichotomized survey responses to HRQOL question 1a – a single 5-level global measure of HRQOL – into a “high” (>3) or “low” (<3) HRQOL binary variable; responses of exactly 3 were discarded. Next, we applied several machine learning techniques to produce a model that predicted this variable using the input vectors described above and 5-fold cross-validation. We employed the following techniques: standard logistic regression, random forest classifiers, and bagging generalized linear models (GLMs) trained using stochastic gradient descent (SGD).

We also applied a range of explicit and implicit feature selection techniques. Explicit methods included the use of a variance threshold for each column, principle component analysis (PCA), selecting the K best columns based on a univariate t-test, a unit origin transformer, and class balance subsampling. The random forest and bagging GLMs also used implicit feature selection, in which random subsets of the feature space were used to train classifiers which were then combined to produce an aggregate prediction.

We analyzed overall model performance in predicting our dichotomized HRQOL measure by conducting receiver operating characteristic (ROC) curve analysis. We evaluated resulting models using a held-out test set of 20% of the dataset. We generated accuracy scores, confusion matrices, and ROC curves for each test. Our main analysis was performed using data from subjects recruited from Cint or Cedars-Sinai. A follow-up analysis was also performed combining this data with data obtained from the University of Pennsylvania.

Results

Participant Characteristics

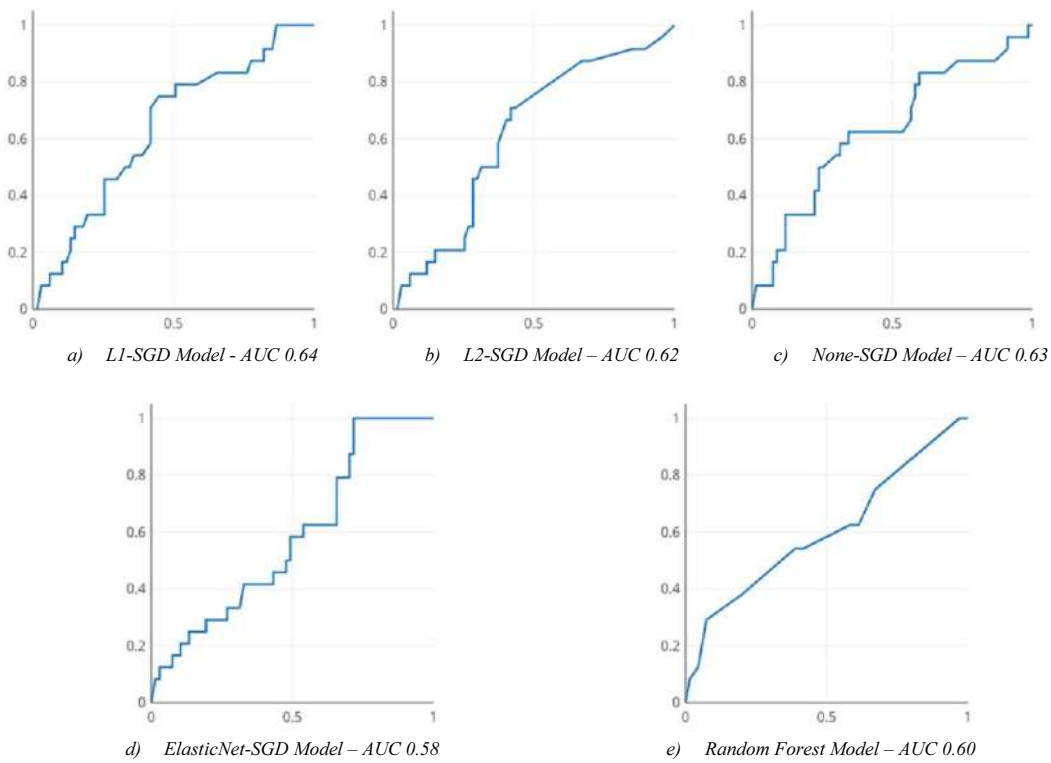
Table 2 presents demographic information of the participants recruited from Cedars-Sinai, Cint, and the University of

Pennsylvania. Because some users signed up multiple times through multiple accounts, we removed duplicate entries from the study. In addition, we removed participants who had protected (i.e., non-public) Twitter accounts that could not be analyzed, or who had zero tweets in the analysis period. In the end, recruitment efforts yielded 1,831 users who completed the survey at enrollment.. We could retrieve at least one tweet from 835 of the original 1,831 subjects. The remaining 996 subjects either did not tweet during the 60-day period or had a protected or deleted twitter account when tweet collection was being performed. Of the 835 subjects with tweets, 581 of them completed both surveys, and the remaining 254 only completed the first survey. The latter subjects were discarded from the analysis. In the follow-up analysis, data obtained from the University of Pennsylvania for 43 patients (with accessible Tweets) was added to the data from Cedars-Sinai and Cint.

Over each 30-day period, participants posted an average of 99 messages (range 0 to 4880). The rate at which patients posted did not significantly differ between the pre-enrollment period and post-enrollment period (p=0.19). The initial tweet corpus had neutral sentiment overall, as measured by the difference of the average positive and negative SentiStrength score across all Tweets in this analysis (M(Pos) = 1.58, SD(Pos) = 0.81, M(Neg) = 1.43, SD(Neg) = 0.84).

Predictive Model Accuracy

To develop our model, we employed a grid search to test various combinations of model designs and subsets of our data. The tested model designs included generalized linear models with varying forms of regularization, as well as a random forest model. We also tested subsetting our data to include or exclude each of the three data sources (Cedars-Sinai, Cint, and UPenn). We also tested different methods of handling subjects who completed both surveys, including using only the first collection wave and survey, and using both collection waves and surveys. The resulting models achieved AUCs ranging from 0.58 to 0.64 for predicting the ground truth binary HRQOL status (Figure 1). The highest AUC of 0.64 was achieved using a bagging GLM model with L1 regularization, using all three datasets and all available collection waves. The model used 100 estimators with a maximum sample and feature proportion of 0.75 with bootstrapping, and was trained with 500 iterations of SGD. Further optimization of logistic regression parameters, model design and feature selection, or tweet subsets was unable to achieve a greater AUC than 0.64.



a) L1-SGD Model - AUC 0.64 *b) L2-SGD Model – AUC 0.62* *c) None-SGD Model – AUC 0.63*

d) ElasticNet-SGD Model – AUC 0.58 *e) Random Forest Model – AUC 0.60*

Figure 1 - Best ROC Curves for Five Classes of Prediction Models. Models evaluated included bagging generalized linear models using a) L1 regularization, b) L2 regularization, c) no regularization, or d) ElasticNet combination regularization, as well as e) a random forest model. The best performance was obtained from the bagging GLM model using L1 regularization, with an AUC of 0.64. This model used 100 estimators with a maximum sample and feature proportion of 0.75 with bootstrapping, and was trained with 500 iterations of SGD. As can be seen from the ROC curves, the three standard logistic regression models outperformed the random forest model and the combination ElasticNet model.

Table 1 – Selected LDA-generated Topics and Highly Related Tweets

Topic Words (First Three)	Example Tweet
data, health, gt	@[redacted] Yes, we needs a digital platform between patients & medical professional to work 4 better outcome with medication / treatment
t, patient, patients	T4 Patients who are actively engaged should get priority but if a patient wants they should go. 5% of attendees! ideally. #hchlitss
cell, sickle, does	@[redacted] Sickle Cell Disease: underfunded, underresourced, underappreciated
lupus, lupuschat, w	@[redacted] I am in DC to advocate for #Lupus Research. From Culver City to Capitol Hill, here to share my journey of 33 years.

Table 2 – Demographic Characteristics of Twitter Users in Study

Demographics	Value (Cint/CSHS)	Value (UPenn)
Number of Subjects	835	43
Age (Mean ± SD)	40.0 ± 12.6	26.9 ± 7.4
Gender (%)		
Male	31.6%	27.9%
Female	68.1%	72.1%
Transgender/Other	0.3%	0%
Race (%)		
American Indian / Alaskan Native	3.0%	0%
Asian	5.6%	0%
Native Hawaiian / Pacific Islander	0.4%	0%
Black or African-American	11.9%	62.8%
White	76.6%	34.9%
Other / Unknown / Declined to answer	2.5%	0%

Discussion

The goal of this study was to develop a PRO instrument that estimates HRQOL from a user's social media posts on Twitter. Further, we studied the feasibility and validity of measuring HRQOL without prompting users to talk specifically about health-related issues. After using a wide range of text processing methods, the best achievable AUC in predicting ground-state HRQOL was 0.64. Although this performance may be considered sub-optimal, it is better than chance and suggests there is at least a correlation between the language used in Tweets and actual HRQOL; a notable finding considering that the data collected was not posted with the intent to provide insight into the HRQOL status of the participants. However, the results also indicate that free-range social media data only offer a window into HRQOL, but do not afford direct access to current health status. Despite the inherent limitations in this pragmatic, naturalistic study, our classification algorithm exhibited moderate performance in estimating true HRQOL status (i.e. high vs. low using CDC-4 as the gold standard) with an AUC of 0.64 by evaluating the language used in 140 character Tweets, the allowable size of microposts during the time this study was conducted. Of note, Twitter currently allows 240 characters, so it is possible that longer posts could include more health-related data and demonstrate a stronger relationship with ground-truth HRQOL.

We hypothesize that the sub-optimal performance of our classifier is due to a poor signal to noise ratio in the dataset. Most people do not routinely post about their health status, including patients undergoing active care (e.g. the ED patients in this sample). In addition, the subjects from the Cint cohort may be more likely than the baseline Twitter user to tweet about marketing-related subjects rather than personal subjects, because they are paid Twitter marketers for Cint. Considering that subjects in this study were obtained from a variety of sources, received no instructions about what to post, included a combination of patient and general population samples, and were limited to a maximum of 140 characters at a time per tweet, the ability to predict HRQOL above chance suggests that this approach – albeit imperfect – still has merit. Despite the inherent limitations in this preliminary study, our classification algorithm exhibited moderate performance in estimating true HRQOL status (i.e. high vs. low using CDC-4 as the gold standard) with an AUC of 0.64 by evaluating the language used in 140-character Tweets.

Other investigators have encountered sub-optimal performance using social media data to estimate health status. For example, Nascimento and colleagues [9] note that their automated processes for identifying "migraine" versus descriptions of an actual patient's migraine experiences were difficult to separate. Indeed, in much of our own dataset, even topics generated using NLP that appeared to be health-related were often about commerce (i.e., other users should consider buying product X, rather than the user attesting to how product X treated their condition). Future research could attempt to more specifically recruit "high-volume" non-commercial Twitter users in order to obtain richer features that maybe more predictive, though this may compromise the generalizability of the method. In addition, future efforts could aim to use a larger patient-specific cohort via targeted recruitment, rather than a general population sample. Nevertheless, the challenge of gaining health insights from unstructured "free-range" social media posts is formidable; additional studies are needed to assess the potential for this data to achieve sufficient accuracy for real world clinical and interventional applications.

Conclusions

In conclusion, we found that analysis of free-range social media posts can predict HRQOL better than chance, but that this technique remains an imperfect method for assessing current health status despite testing a wide range of text processing methods. The best performing model (AUC = 0.64) was a bagging GLM with L1 regularization; this may be helpful when selecting among semantic processing techniques. We hope this study may serve as a template for future research in extracting health data from unstructured social media posts, and believe future studies could improve upon our work by refining recruitment efforts to avoid commercial accounts, expanding the cohort size, and making use of a broader spectrum of social media data from additional platforms.

An Evaluation of the Technical Quality Within the Belgian Electronic Prescription: A Cross-Sectional Study

Sven Van Laere, Ronald Buyl

Department of Public Health (GEWE), Vrije Universiteit Brussel, Brussels, Belgium

Abstract

The increased use of eHealth services has shifted focus towards quality and interoperability. This study quantifies the technical quality of the ePrescription in Belgium by validating the construction of the Kind Messages for Electronic Health Records (KMEHR) used for communicating between prescriber and pharmacist, and by validating the digital signature within the ePrescription. A two-way cluster randomized subset of prescriptions of the tarification service Koninklijk Limburgs Apothekers Verbond (KLAV) is used (n=82,952). Here, 38,032 prescriptions (45.85%) were handled electronically, but 180 prescriptions (0.22%) contained an empty KMEHR message at tarification. All 37,852 ePrescriptions (100%) passed the XSD Schema validation, but only 29,428 ePrescriptions (77.74%) passed the Software Development Kit (SDK) XPath validation rule set of the national Recip-e project. 37,622 ePrescriptions (99.39%) passed the validity test for having a correct digital signature. Improvement towards the construction and the digital signature is required in order to fully dematerialize the ePrescription workflow.

Keywords:

Electronic Prescribing, Quality Control, Community Pharmacy Services.

Introduction

In general, an electronic health (eHealth) system on a national basis can help in making healthcare systems economically sustainable. An increased use of eHealth services and in particular the usage of electronic prescriptions (ePrescriptions), has shifted focus towards quality [1] and interoperablity[2].

Electronic prescribing, or "ePrescribing" is the computer-based electronic generation, transmission and filling of a prescription, taking the place of paper and faxed prescriptions [3]. In the flow of ambulatory ePrescribing, there are often three human actors (the prescriber, the patient and the pharmacist) and two system actors (prescribing and dispensing providers).[4] Sometimes, a reference to the 3 Ps will be made in literature when addressing these human actors.[5] In Belgium, a third party payment applies, where the patient only pays the amount to the pharmacist that is not reimbursed by healthcare insurance. That is why in this flow of digital communication, the tarification services –responsible to invoice the remaining amount of medication costs to the healthcare insurance of the patient– might be added.

In Belgium, ePrescribing made its entrance in April 2007, where the Belgian government launched the e-MED project with the intention of developing a coherent action plan for making the ePrescription of medicines in ambulatory care possible.[6] After a national pilot phase in the years 2009-2012, the national project was introduced to the public in 2014. From then on, patients that visited a general practitioner (GP) to prescribe his medication, using the integrated electronic health record (EHR) of the patient, would get a proof of electronic prescription when the GP's software was connected to the national ePrescribing services. Independently, the national project Recip-e is responsible for the temporary storage of the encoded ePrescriptions on a national server. Both the paper-based prescription and the ePrescription were –and are still– accepted as a medium for communication between the prescriber, the patient, the pharmacist and the tarification service.

In a later stage, the national project evaluated the authentication methods used when prescribing. With paper-based prescriptions, the combination of the healthcare party identifier (RIZIV number provided by Rijksinstituut voor Ziekte- en Invaliditeitsverzekering (RIZIV)) and the signature was used to identify the prescriber. When using the ePrescripion, the combination of the RIZIV number with the digital signature, in an encrypted and timestamped message was chosen as evidential value to show that the prescriber made the ePrescription. In 2016, the project opted for using an additional SAML-token (Security Assertion Markup Language token) included in the encrypted message based on the RIZIV nr of the prescriber, to allow healthcare providers to have a single sign-on for a couple of hours.

The RIZIV number for each care provider is provided by the RIZIV organisation. This number serves as a unique healthcare identification number and is constituted of 11 numerical characters. This number can be broke down into 4 groups with each having a function for identification. The structure of the number consists of (1) a professional number, (2) a serial number, (3) a checksum number and (4) a qualification number, e.g. 1-12345-12-123. With the professional number, a distinction can be made between physicians, dentists, hospitals, pharmacists, etc. Since the qualification number (last 3 digits) is, in fact, a reference towards the specialisation and not really identifying as such, one could consider the first 8 numerical characters as identifying for the healthcare provider. However, for reimbursement purpose, it is necessary that the KMEHR message contains the correct RIZIV number consisting out of 11 numeric characters.

As of 2017, an additional change compared to the paper-based prescription came into place, where an extra barcode on top of the electronic proof of prescribing was placed, i.e. the Recip-e ID (RID). This RID barcode is used to uniquely identify an ePrescription and to prevent patients from frauding with their medication prescriptions. In Belgium, people still get a paper-based proof of prescription where this RID is printed on, in case of an ePrescription. It does not fulfill the function of prescription, but can only be used by the community pharmacies in combination with the patient's electronic identity (eID) to get dispensed. The Belgian government is thinking

about dematerialising the prescription process. This means that this paper proof, that is actually used in the transition phase towards dematerialisation, will be removed in this process of ePrescribing.

When digitalising the healthcare sector on a national basis, one needs to adapt to healthcare standards. Healthcare standards often used for ensuring the interoperability are ISO 13606 [7], HL7 [8] and SNOMED CT [9]. In Belgium, the KMEHR standard [10] is used as a communication standard to be able to send messages and the CNK (Code National(e) Kode) standard [11] for identifying the medication. In essence, the KMEHR standard is a structured XML message.

The Belgian government is responsible for the maintenance of both standards and sending updates when necessary, e.g. when a new medication is brought to the market. Proper versioning of these standards among different eHealth initiatives on a national basis is thus required in order to be able to interpret the ePrescription in a uniform way.

In Belgium, a free market for the generation of software for both prescriber and community pharmacist additionally complicates the eHealth story. However, to be able to talk health informatics in a uniform way for ePrescriptions, the Recip-e party developed a software development kit (SDK) for software vendors.[12] The usage of this SDK is not an obligation, but it is a recommendation for software vendors providing software willing to interpret the electronic KMEHR messages in a uniform manner. An incorrect creation of an ePrescription, possibly caused by a software not integrating the SDK, can lead to an incorrect interpretation of the ePrescription KMEHR message at the community pharmacist's side and maybe lead to the pharmacist incorrect dispensing the patient's medication.

Currently, the patient still has a paper proof of prescription that he receives in order for the community pharmacist to read in the RID printed on top of the ePrescription. The patient will then be able to retrieve the prescribed medication. This RID barcode on top facilitates the reading in the software of the community pharmacist. When dematerialising, only the eID of the patient will be used to retrieve ePrescriptions linked to the patient's eID. Therefore, it will be necessary for KMEHR messages to not contain any technical errors. In this study, the soundness of the Belgian ePrescription will be investigated. The focus will not be put on the correct medication prescribing as such, but rather on the technical construction of these messages and the correct use of digital signatures in Belgian ePrescriptions.

Methods

Data of the tarification service Koninklijk Limburgs Apothekers Verbond (KLAV), one of the bigger tarification services in Belgium, was used in order to obtain a randomized subset. Since this tarification service provides services all over Belgium, location was used as a first randomization factor. A second randomization factor used was the amount of prescriptions a community pharmacy sends to the tarification service. These factors are now combined in a two-stage cluster random sampling technique, where randomization was first performed over the location (province) within Belgium and secondly over the community pharmacies within the selected provinces based on their number of prescriptions.

With this sampling technique, a random sample of 50 community pharmacies was selected. The prescriptions retrieved by KLAV from the month June 2018 were used for observing the technical quality of both the KMEHR message and the digital signature within the retrieved ePrescriptions.

Tarification services do not receive these KMEHR messages in plain text. Pharmacists use multiple encryptions to encapsulate the message in different constructs in a time-stamped manner before sending it for tarification. Different elements within different levels of encryption will be required to verify the quality.

Ethical approval for this study was obtained from the ethical committee of UZ Brussels (nr. 2018/218).

Quality of the KMEHR Message

Since the KMEHR message is a structured XML message, the construction of it can first be validated towards an XSD Schema. However, the quality of the KMEHR message was mainly checked by applying the validations that are found in the SDK provided by Recip-e.

These validations exist of XPath validations rules to verify the construction of the KMEHR messages. In these rules a minimum and a maximum number of occurrence for a specific tag or attribute were used, see Rule example below. These rules are normally used in the prescriber software to validate the message before sending it to the national server in an encrypted way. However, since two different KMEHR structures are accepted in this validation of the SDK, i.e. against KMEHR version 1.17.1 and KMEHR version 1.19.0, different validation rule sets applied.

Hereunder, an example of an XPath validation rule is explained.

```
/kmehrmessage/folder/patient;1;1
```

This rule states that within the folder element of the KMEHR message, there can only be one patient element (minimum = 1; maximum = 1). When no or more than one patient element is specified, this XPath expression will fail.

Quality of the Digital Signature

The evidential value of a digital signature in the Belgian eHealth system is two-fold. First of all the certificate within the sealed KMEHR message has to match the holder of key (HOK) certificate within the SAML message. Secondly, also the healthcare identifying RIZIV numbers within the KMEHR and SAML have to match, with an extra requirement of having an 11-character RIZIV number used in the KMEHR message.

One exception applies to hospitals. Within the hospital, you have different specialist physicians. To lower the administrative burden within the national ePrescribing project a "circle of trust" is organised between the organization, which is the hospital, and the employer working for the organization, which is the specialist physician. Since there is a circle of trust relationship, the prescriber will use the certificate of the hospital. When verifying the quality of the digital signature, the certificates should match with that of the hospital organization and in the KMEHR message the hospital should correspond as being the sender and the physician should act as an author. Both are elements in the KMEHR XML structure. In an ePrescription of a healthcare provider not working at a hospital, both the sender and author element should represent the same person.

One should note that June (month of inclusion) is one of the first months in Belgium where also ePrescriptions are used in the hospital context.

Results

In Belgium, the population of community pharmacies exists of in total 4,943 community pharmacies (source Sirius Insights, 2017 - [13]). In the month June 2018, 563 community pharmacies (11.39%) used the KLAV tarification services (see Table 1). In that month, this tarification service collected a total

of 794,724 prescriptions, for which no special tarification rules applied.

Using the two-stage cluster random sampling technique, where a selection of 50 community pharmacies was chosen, a total subset of 82,952 prescriptions was observed. Here all prescriptions of these 50 pharmacies were included (both paper-based prescriptions and ePrescriptions). Within this subset, a total of 38,032 prescriptions treated as ePrescriptions was found (see Table 1). An ePrescription rate of 45.85% was observed within this randomized subset.

However, when analysing the content of these messages that were retrieved at the side of the tarification service, 180 ePrescriptions (0.48%) appeared to have no KMEHR message (see Figure 1). This can be explained by a possible fallacy in the Belgian eHealth system when trying to consult eHealth services of the national eHealth platform when transmitting the data to the tarification service or due to a software error at the side of the pharmacist. These errors are solved by retransmitting the data for tarification in the next month.

In these messages, both the quality of the KMEHR message as the quality of the digital signature was checked (see Figure 1). Quality of the KMEHR message is evaluated in terms of the XPath validation rules provided in the SDK of Recip-e that serves software vendors for prescribers, and in terms of the XSD Schema evaluation. Quality of the digital signature was mainly dependent on the prescriber type (GP, hospital or dentist).

Table 1. Community pharmacy and KLAV's subset of prescriptions characteristics

Community pharmacies		
Level	**N**	**%**
National	4,943	100.00
KLAV (total)	563	11.39
KLAV (random sample)	50	1.01
Prescriptions at KLAV		
Level	**N**	**%**
Total in June 2018	794,724	100.00
Prescriptions within randomized group of community pharmacies	82,952	10.44
ePrescriptions within randomized group of community pharmacies	38,032	4.79
ePrescriptions with no KMEHR message	180	< 0.01

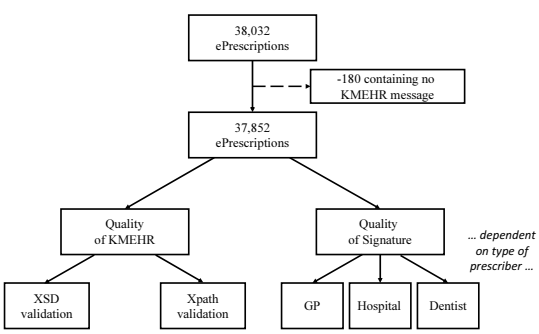

Figure 1. Flow chart of quality validation for the KMEHR and the digital signature

Quality of the KMEHR Message

Currently, KMEHR version 1.19.0 is the latest version that is accepted to communicate with in terms of the ePrescription. Version 1.17.1 is also acceptable in the Belgian context, but preference is given to the later standard. Since the versioning plays an essential role in the XPath validation of the KMEHR message, the distribution of KMEHR standards used over the different software packages at the prescriber's side is represented in Table 2. This versioning is retrieved within the KMEHR message using the SV attribute (scheme version). When no KMEHR message was observed, the versioning was not able to be retrieved.

Table 2. Distribution of different versions of KMEHR communication standard (n = 37,852)

Versioning	**N**	**%**
SV=1.1 – KMEHR version 1.0.0	601	1.59
SV=1.3 – KMEHR version 1.1.0	85	0.22
SV=1.6 – KMEHR version 1.5.0	47	0.12
SV=1.8 – KMEHR version 1.7.0	14	< 0.01
SV=1.18 – KMEHR version 1.17.1	*6,906*	*18.24*
SV=1.19 – KMEHR version 1.18.0	328	0.87
SV=1.20 – KMEHR version 1.19.0	*23,470*	*62.00*
SV=1.23 – KMEHR version 1.22.0	6,401	16.91

Validation against the XSD Schema of KMEHR version 1.19.0, resulted in a 100% success rate, see Table 3. However, when looking at the XPath validation rule set, a lower validation rate of only 77.74% in total was found. This result was split into two parts, according to the version of the KMEHR standard.

Table 3. Prescriber type for ePrescription (n = 37,852)

XSD validation	***SUCCESS***		***FAIL***	
Version	**N**	**%**	**N**	**%**
1.19.0	37,852	100.00	0	0.00
Total	*37,852*	*100.00*	*0*	*0.00*
XPath validation				
Version	**N**	**%**	**N**	**%**
1.17.1	6,710	17.73	31,142	82.27
1.19.0	22,718	60.02	15,134	38.98
Total	*29,428*	*77.74*	*8,424*	*22.26*

Quality of the Digital Signature

Verifying the evidential value of a digital signature on an ePrescription requires to know the prescriber type of it, since physicians working in a hospital are treated as working within the circle of trust of the hospital. Table 4 provides descriptive statistics about the prescriber type within the ePrescriptions in the retrieved subset. When no KMEHR message was observed, the prescriber type was not able to be retrieved.

The majority of ePrescriptions was generated by a general practitioner (GP) (n=34,455; 91.03%). The physicians working in a hospital prescribed 3,061 ePrescriptions (8.09%). Dentists prescribed only 336 prescriptions (0.89%) electronically.

The evidential value of a digital signature in Belgium consists of correct use of certificates and correct use of the identifying RIZIV number of the prescribing healthcare party. In Table 4, the matching percentages for the RIZIV number within the SAML versus the RIZIV number within the KMEHR message and the HOK certificate within the SAML versus the certificate in the sealed KMEHR message are represented.

When observing the use of the certificates (see Table 5), a 100% matching rate was observed. When looking at the identifying RIZIV number of the prescriber, a matching rate of 99.39% between the SAML and the KMEHR message was observed. These rates varied across different types of prescribers.

The mismatch between RIZIV identifiers, where an 11 numeric character string is required in the KMEHR message (see Table 5), occurred most frequently when prescribed by dentists (1.79%), followed by an ePrescription generated by a GP (0.65%). No mismatch between RIZIV identifiers occurred within the hospital setting.

Table 4. Prescriber type for ePrescription (n = 37,852)

Prescriber type	**N**	**%**
General practitioner (GP)	34,455	91.03
Hospital	3,061	8.09
Dentist	336	0.89

Table 5. Evidential value of digital signature (n = 37,852)

Certificate match	***SUCCESS***		***FAIL***	
Prescriber type	**N**	**%**	**N**	**%**
GP	34,455	100.00	0	0.00
Hospital	3,061	100.00	0	0.00
Dentist	336	100.00	0	0.00
Total	*37,852*	*100.00*	*0*	*0.00*
RIZIV number match with 11 characters in KMEHR				
Prescriber type	**N**	**%**	**N**	**%**
GP	34,231	99.35	224	0.65
Hospital	3,061	100.00	0	0.00
Dentist	330	98.21	6	1.79
Total	*37,622*	*99.39*	*230*	*0.61*

Discussion

A two-stage cluster randomized subset of prescriptions was used from one of the biggest tarification services in Belgium, i.e. KLAV. In total, 45.85% of the prescriptions (38,032 out of 82,952 prescriptions) were handled as ePrescription by the community pharmacist. 180 prescriptions were excluded, since not containing a KMEHR message at the side of the tarification service. This study shows that the construction of the Belgian ePrescription is 100% valid towards the XSD Schema, but is only valid in 77.74% (29,428 out of 37,852 ePrescriptions) of the cases when comparing the KMEHR messaging standard used to the national ePrescription project validation rule set. Secondly, a higher validation rate of 99.39% (37,622 out of 37,852 ePrescriptions) was observed when observing the digital signature.

The low validation rate of 77.74% for the KMEHR standard can partly be explained by the free market of software vendors in Belgium for both the prescriber and community pharmacist. Using different versions of the KMEHR standard over the different vendors might cause problems interpreting ePrescriptions in different software at the pharmacist side.

However, since the XSD validates all prescriptions correctly, one may state that the Belgian KMEHR standard is used quite loosely when validated towards its schema. A technique like Java Architecture for XML Binding or JAXB [14], might help to capture data in a uniform way using the XML of the KMEHR message in the back-end of the software.

However, since the validation rules do not always apply to the KMEHR message and most software programmers use only a limited subset of test case ePrescriptions to work with when writing the software, the Belgian ePrescription might give problems in reading and interpreting them correctly once entered in the working field.

A study by Anderson, reveals a possible reason why this discrepancy might be observed between the actual ePrescription (KMEHR) and its validation rules. In his work [15] about barriers to eHealth adoption in the practice of the physician, 79.3% of the physicians named the vendor's inability to deliver acceptable products as a significant barrier to implementation of IT in their practice. In Belgium, a prescriber might think that by using his EHR software, he produces standard ePrescriptions in the front-end and standard KMEHR messages in the back-end. However, this study demonstrates this is not always the case.

The benefits of putting a digital signature are first of all that it ensures the identity of the sender. Secondly, compared to the manual signature on the paper-based prescription, it saves time since the use of a SAML-token lasts for a couple of hours. Thirdly, the digital signature will ensure the validity of the content of the prescription. The slightest change to the digital content will revoke the validity of the digital signature.

Plans of dematerialisation for the Belgian ePrescription require the validity of the digital signature in order to guarantee the authenticity of the sender. In Belgium, the digital signature was introduced at the beginning of the existence of the ePrescription. However, not all prescribers support the idea of using a digital signature using an ePrescription. For example, in Turkey [16] 78.23% (194 of 248 prescribers) reported that they did not use an electronic signature to sign ePrescriptions and 52.42% (130 of the 248 prescribers) doubts or does not support the use of an electronic signature.

Sometimes an invalid signature might lead to errors in the workflow of the community pharmacist. In a study by Reed-Kane et al. [17] over a four-week study period for pharmacy compounding, they observed the most frequent error was an invalid signature (31.25%; 10 of the 32 errors identified within 138 ePrescriptions). This potentially leads to an increase in working time handling the ePrescription. In that same study, the most frequent used error resolution method was a phone call to the physician (59.38%; 19 of the 32 errors identified within 138 ePrescriptions).

To the best of our knowledge, this is a first study that evaluates the technical construction of this kind of messages. Lots of studies in the field of ePrescriptions evaluate the number of prescribing errors and its causes, in different settings [18-21]. However, this study also has some limitations. Due to the cross-sectional nature of this study, it is not able to sort out the exact reason for this rather low validity. For example, the author of the prescription is responsible for the placing of a valid signature using the right certificate, but the vendor is responsible for a good implementation of it when using the identifying RIZIV numbers. Multiple aspects are thus expected to be at the basis of these validation rates. A second limitation is that this study uses prescriptions of community pharmacies affiliated with one tarification service in Belgium. However, due to the fact that KLAV delivers services to all provinces in Belgium and since a two-stage cluster randomized subset was used, the conclusions may be generalized to the population of ePrescriptions in Belgium. Another limitation is the low number of ePrescriptions coming from hospitals, limiting the generalizability of the study.

Future research should focus on a timely review of these validations in order to be able to continue towards a national dematerialisation. This study only focuses on the construction of the KMEHR message and the validity of the digital signature within the Belgian ePrescription. An important part of the ePrescription lies in the validity of the medication section of an ePrescription. This part of the prescription should undergo a similar evaluation towards the CNK standard, which is the identifying code in Belgium for medication products. Currently, pharmacy compounding prescribing within the Belgian ePrescription occurs in plain text in the KMEHR standard. A future extension of the KMEHR standard to integrate this in a structured way is required. Validation towards

this future standard is also required before removing all paper (proof of) prescriptions.

Conclusions

This study evaluates the quality of the Belgian ePrescription by looking at the validity of the construction of the KMEHR message and by looking at the validity of the digital signature of the prescriber. The construction of the KMEHR message showed a 100% validity towards the provided XSD Schema, but only 77.74% succeeded to validate against the Recip-e project validation rule set. When looking at the validity of the digital signature, a rather successful validation rate of 99.39% was observed.

The incorrect construction of the underlying KMEHR message might lead to an incorrect interpretation of certain fields represented in the software of the pharmacist, whereas incorrect signatures might lead to errors and an increased workload in the pharmacist's workflow. Timely review of these validations is required in order to dematerialize the ePrescription in a safe way.

Acknowledgements

We would like to thank Koninklijk Limburgs Apothekers Verbond (KLAV) for the provided electronic prescriptions of community pharmacists, using their tarification services.

Development and Progression in Danish eHealth Policies: Towards Evidence-Based Policy Making

Sidsel Villumsen[a], Arild Faxvaag[b], Christian Nøhr[a]

[b] Faculty of medicine and health sciences, NTNU, Trondheim, Norway

Abstract

In order to realise the potential benefits of eHealth, governments develop eHealth policies to define and prioritise initiatives, the strategic goals and the resulting benefits. During the 23 years with eHealth policies in Denmark only a few status reports with a systematic and transparent evaluation have been made. This paper advocates a more systematic approach to strategic planning of development and implementation of eHealth systems, by encouraging the concept of evidence-based policy making through analysis of how focus of the Danish eHealth policies have evolved. The Danish eHealth policies have very different framings following the different focus points for the policies. Interestingly, strategies for evaluating the development of eHealth and eHealth policies were very sparcely noted in the policies. For the first time the de-emphasising of evaluations of eHealth policies in Denmark has been empirically demonstrated, thus undermining the objective of obtaining evidence-based eHealth policies.

Introduction

Health information technologies (HIT) are viewed as a means to easing the everyday life for patients, relatives and health professionals, modernizing and better utilising the resources of the healthcare system [1,2]. The promise of HIT has been profound. In Denmark in 1968, the vision was that within a couple of years, there would be no paper on the doctor's desk, and the patient record could be retrieved on a 'data screen' in a split second [3]. In order to realise the potential benefits, governments develop HIT or eHealth strategies to define and prioritise initiatives, the strategic goals and the resulting benefits [1]. Policies have been a tool for reaching consensus on the prioritisation of eHealth service development and large scale implementations in Denmark since 1995 [4], where the white paper "From Vision to Action: Info-society in Year 2000" described guidelines for national developments towards the information society and pointed out a number of specific priority areas – one of which was health care [5]. The first national eHealth policy, called "Action Plan for Electronic Patient Records" (The HEP-program), was published by the Ministry of Health in 1996 [6]. Since then, five additional national eHealth policies have been published (see Table 1).

During the 23 years with eHealth policies in Denmark only a few systematic and transparent evaluations have been made. In the absence of a firm base for the next policy, the subsequent policies have randomly involved data from the past and have mainly been designed as political documents without references. They seem to reflect the current balance of power between the municipal, regional and central levels.

It is now an established practice within healthcare to review clinical practice, in order to learn and improve [7]. eHealth is no different from other tools for improving healthcare systems and the development, implementation and use hereof needs to be based upon best available knowledge. In order to ensure learning and continuous improvement, evaluations identifying successes and failures and their causes are paramount [7]. Both policy and practice in eHealth should be based on scientifically obtained facts, as they are in healthcare in general [7], and evaluation is the only way to obtain knowledge on the effects of eHealth. Best practice for using evidence to develop a policy include assessing evidence of the likely effectiveness of policy options in order to inform decisions on future policy actions. Moreover, planning for collection of evidence from evaluations of implemented policies to inform decisions 'on whether to continue or how to adjust and improve policies and to contribute to the evidence base to inform future consideration of policy options' [8] is essential.

It has been the ambition of the authors to introduce a more systematic approach to strategic planning of development and implementation of eHealth systems, by encouraging the concept of evidence-based policy making. Figure 1 shows a model for strategic management [9] inspired by the continuous learning cycle of PDSA (Plan-Do-Study-Act) and applying this rationale to the process of strategic management of eHealth policy, development, and implementation. Strategic planning and development starts with formulating strategic goals. These strategic goals are the basis for reaching consensus among the involved interests and hence ensure commitment. As a result, a specific plan is drafted specifying operational and specific goals. These operational goals can point at particular

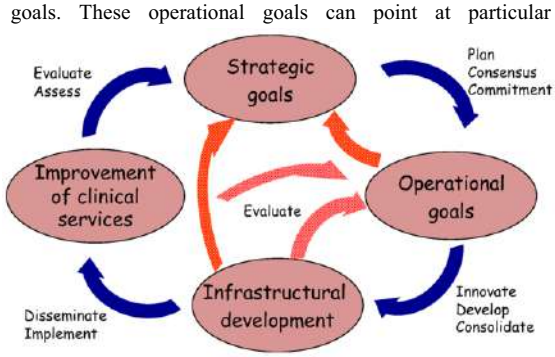

Figure 1 – Strategic management of eHealth policy, development

technology innovations or issues that need to be consolidated to achieve these goals. The third step is to develop infrastructural elements and prepare them to be implemented and disseminated in the healthcare system. The aggregate aim is to improve clinical services which must be assessed and evaluated to determine how well the strategic goals have been achieved.

In order to learn from the development of previous policies, the first step is to analyse how the policies have evolved and how the focus has changes over the years. Such an analysis was published in 2008 analysing the four national Danish policies for IT in the healthcare sector at the time [4]. Since then, ten years have passed, and two more policies have been launched. This paper aims at analysing how focus of the Danish eHealth policies have evolved from the first eHealth policy published in 1996 to the current policy published in 2018. The analysis shall reveal to what degree evaluation of each step in the model of strategic management in figure 1 has been carried out. It is the hope that other nations will adopt a similar approach to strategic management of eHealth development and contribute to a more rational and evidence-based policy making regarding eHealth.

Methods

By using the model of strategic management (figure 1) as a reference, the policy documents were analysed by means of a text analysis tools by two researchers following three steps. Using the text annotation tool NVIVO (NVIVO 12 for Mac), the first researcher (SV) annotated the texts. Sentences and sections that contained statements about the five factors: Strategic goals, Operational goals, Infrastructural development, Improvement of clinical services, and Evaluation were identified and coded. Examples of coded text are presented in the results. As the policies were annotated, the codebook was extended to cover two aspects of evaluation: a) references to previous evaluations or follow-up, and b) references to ongoing, planned or desired evaluation or follow-up. Thereafter, a second researcher (CN) validated the coding based on the codebook. Common consensus on whether the document section deserved a particular code was reached through discussion between the researchers. Coded statements were sorted within the five focus areas and the frequencies counted.

Results

Some difficulties were encountered when coding the policies within the five facets. Strategic goals were most often formulated as either broad/vague initiatives and their supposed benefits (i.e. '*The vision is that IT is easy to use for the staff, gives access to necessary information and facilitates recording and documentation of delivered professional health care*' [10]), or as an imperative need or problem that needs to be addressed or solved (i.e. '*It must not be necessary to give the same information each time you encounter a new instance of care* […]' [10]). A more clearly defined example is found in [10]: '*To some extent, physicians, patients and pharmacies all lack an overview of what medication is prescribed and actually taken by the individual patient* [Strategic goal – need based]. *One way to generate such an overview is to provide safe access to the personal electronic medicine profile through the public health portal* [Operational goal]. *The portal will host information concerning prescribed medicine, dosage, indication, delivery, etc.* [Infrastructural development]. *This will lead to better utilization of drugs with subsequent consequences for the entire health care system and the public finances* [Improved clinical services].'[10]. Ideally, improvements of clinical outcomes should be described as SMART-goals. However, only few of the benefits described in the policies render this granularity (i.e. '*Before the end of 2015, 80% of all applications, reporting, letters and written communication between the healthcare system and the citizen should be digital.*' [11]).

The first national eHealth policy HEP from 1996 was focussed on collecting and sharing data electronically. Connecting local systems to national registers had high priority – creating a health data network. Using national and international standards and terminology was a central point to be explored further [6]. The policy included a national survey of the counties' status on Electronic Patient Records (EPR) and local eHealth strategies. The action plan focused on local pathfinder projects aiming to exploit IT to gain better service and faster and more efficient treatment of patients. Interestingly, this policy had a high proportion of operational goals in relation to strategic goals as well as notations of specific IT/IS functionalities and focus on changes in the organisation, collaborations, workflow and documentation (infrastructural development), which might reflect the document's status as an action plan rather than a policy (figure 2).

The action plan was followed by the first 'National strategy for IT in the Hospital system 2000-2002' published by the Ministry of Health, the National Board of Health, the Counties, and the Capital Area's Hospital Corporation (H:S) [12]. This policy pointed out initiatives to support the national goals for the hospital sector. Great emphasis was put on developing and testing a 'Basic Structure for Electronic Health Records' (BEHR) with the aim of complete EPR coverage on all Danish hospitals within 2005.

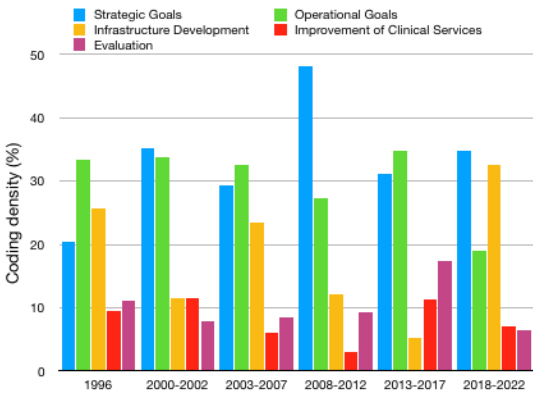

Figure 2. Density of annotations of strategic management factors in the six Danish eHealth policies

The 2000-2002 policy had a strong focus on standards and integrations, but also on the organisational aspects of implementing such as organisational changes and training of staff – formulated as strategic goals and operational goals mainly. The need for research within health informatics was stated explicitly in this policy.

The succeeding policy 'National IT Strategy 2003-2007 for the Danish Health Care Service' broadened the scope to cover the IT initiatives necessary for not only the hospitals but the entire health sector to support the realisation of the national health policy goals [10]. The 2003-2007 policy further supports the development of BEHR as a generic information model that sets the national standard for EHRs. The central vision was '*that citizens, health care professionals, authorities and administrators have access to updated information through channels perceived to be free of any undue obstructions'* [10]. The 2003-2007 policy refers to the independent EPR-Observatory for objective follow-up on the national status on eHealth. In 2005 a status report from the EPR-Observatory concluded that complete EPR coverage would not be obtained before 2013 at best [13], and in 2007 two reports (one by the Public Accounts Committee) raised critique of BEHR and the general level of IT support in the hospital sector [14,15], stating that national use of BEHR would not be feasible within the desired time span [14]. That might be one of the reasons why the 'National Strategy for Digitalisation of the Danish Healthcare Service 2008-2012 - to promote public health as well as prevention and treatment' did not comment further on the BEHR [16].

The 2008-2012 policy was very different from the previous ones, setting a new course for eHealth in Denmark. Focus turned towards consolidating the IT systems to ensure that diverse solutions could act together and exchange or share data. This policy described the ways of working towards joint digital healthcare services rather than describing the specific initiatives [16], which is reflected in the proportion of strategic goals compared to operational goals (figure 2). The 2008-2012 policy presented the national goals for the healthcare system in general (agreed on in other policies) and specified the eHealth contribution of the eHealth policy in attaining these visions. In 2007 the 14 Danish Counties were merged into five Regions. Each Region is responsible for the secondary healthcare services (i.e. hospitals). This implied that the different IT-solutions in the counties now needed to be consolidated within the Regions. The Regions were charged with setting specified goals for use and value of eHealth and to work towards attaining these goals [16]. Consolidating initiatives became a focus point not only for the Regions, but also for the municipalities and General Practitioners. Interestingly, the 2008-20012 policy includes an appendix presenting the conclusions of an external review of the EPR status in Denmark.

'Making eHealth Work - National Strategy for Digitalisation of the Danish Healthcare Sector 2013-2017' focused on exploiting the digital possibilities to the fullest and create better coherence in the digitisation effort [11]. The strategic goals where to ensure that patients and staff would profit from the benefits of ongoing IT projects through an increased focus on full dissemination and use, reflected in the higher proportion of operational goals (figure 2). This policy had a stronger focus on benefits realisation than the previous policies (figure 2 - Improved clinical services), and indicators, follow-up, and evaluation was distinctly more prominent in this policy than in any of the others. This may be due to the strong focus on consolidating and "making eHealth work" through learning and taking actions to improve the dissemination and use of health IT.

The present policy, 'A Coherent and Trustworthy Health Network for All - Digital Health Strategy 2018–2022', reflects two main aims: putting the citizens' needs at the centre and easing the everyday work for healthcare staff [2]. The 2018-2022 policy is framed differently than the others. Focus lies on five specific areas, identifying 27 initiatives. The initiatives are described with respect to the technological and implementational deliveries needed, which is reflected in the high proportion of Infrastructure Developments mentioned (figure 2). The 2018-2022 policy concludes with a section on follow-up, where it is described how the National Board of eHealth will continuously follow the progression of the initiatives and adjust. However, evaluation is not mentioned specifically and does not play a central role in the current eHealth policy.

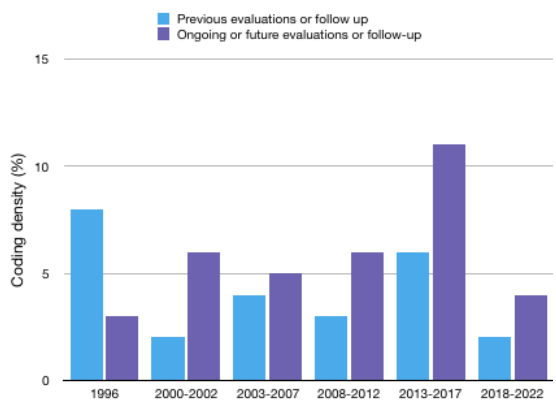

Figure 3. Density of annotations of references to evaluation in the six Danish eHealth policies

A prerequisite for strategic evidence-based management of eHealth development is evaluation [7]. In order to ensure learning and continuous improvements, systematic and transparent evaluations must be performed throughout the stages of the management process described in figure 1. When looking only on statements specifically mentioning evaluation, only a few counts can be made. In this analysis, evaluations have therefore been recognized in broad terms, spanding hearings on the policies, descriptions on follow-up activities, referencing to statistics on EPR dissemination status etc. It is interesting to note that the first Danish national eHealth policy (1996) had a high proportion of references to previous evaluations and follow-up, and planned on presenting yearly

statusreports and adjusted action plans for the Danish Parliament [6] (figure 3). The 2000-2002 policy had only few references to past evaluations but highlighted the need for creating a National Strategy Group for IT in the hospital sector and a National Reference Group for health informatics, specifying the roles and responsibilities for these groups [12]. The following two strategies (2003-2007 and 2008-2012) aimed the evaluation towards the initiatives described in the policies, thus delegating the evaluation to steering groups and centers of excellence. In the two latest strategies (2013-2017 and 2018-2022) the responsibility of follow-up and evaluation has been chartered to the National Board of eHealth primarily. In the 2013-2017 policy, follow-up had a more prominent role than in any of the other policies, with a strong focus on designing and monitoring indicators for eHealth availability and use in order to inform future planning of development and implementation. This strong focus on follow-up and evaluation was not continued in the 2018-2022, where notions on following the status and progress on the initiatives are found in the last chapter .

Is has not been possible to map the statements on evaluation across the policies to the steps in the model of strategic management (figure 1) due to the vast differences in how evaluation and follow-up were described and defined. When looking at ongoing and future planning of follow-up and evaluation, the policies point to boards and groups responsible for this task. The responsibility has changes over the years, but since 2013, the National Board of eHealth has been the coordinating organ (table 2).

Table 2 - Groups and boards responsible for evaluation of eHealth policies

Policy	Responsible groups and boards
1996	The Danish Ministry of Health
2000-2002	National strategy group for IT in the hospital sector (The Danish Ministry of Health and hospital owners). National reference group for health informatics
2003-2007	EPR Observatory National strategy group for IT in the health care service (National Board of eHealth, the hospital owners and the National Association of Local Authorities). Steering groups for initiatives of the IT strategy.
2008-2012	Connected Digital Health in Denmark Centres of expertise
2013-2017	National Board of eHealth Danish Regions
2018-2022	National Board of eHealth Existing boards (e.g. MedCom) New boards

Discussion

In this study, we found that Danish eHealth policies have significantly shifted focus and it has been impossible to deduct any rational reasoning behind the shifting focus. An evidence based approach would have based the visions of a new policy on references to former policies or at least some reported knowledge about former experience or documented needs. The scoring of the content of the policies also show a very low occurrence of evaluation activities – in fact our analysis revealed that evaluation is the least mentioned theme. The Danish policy makers have obviously not laid importance in establishing learning loops which would require evaluation – a situation which is not unique to Denmark, as it is seen in other countries as well [7]. However, to establish evaluation introduces a risk to the policy makers. The purchase and implementation of eHealth technologies e.g. an EPR system, is a massive expense and time commitment. If there are major problems - and there usually are - no one in charge wants to have that publicized. Hence: evaluation might not be desired.

As the analysis shows, there is no clear tendency in the policies over the years. Each policy appears as a unique new policy based on prevailing trends. The strategic goals are formulated as relatively abstract visions with only limited connections to specific changes in clinical services or the workflows that produce them. '*If you don't know where you are going, any road will take you there'* (Alice in wonderland). For the policies to point at a specific road to follow, the destination has to be formulated in continuation of the visions. Nonetheless, the analysis shows that relatively little attention has been payed to explaining how specific clinical services should be changed. In the implementation of such strategies the primary actors need to fully agree on why they find it important to implement [17].

An approach to support the Strategy Management Model in developing and implementing eHealth policies is framing a benefit dependency network (BDN) as described by Ward and Daniel [18]. A BDN visualises the dependencies between the strategic goals (*Why*), the operational goals and intended clinical improvements (*What*) and which changes are warranted in the organisation and workflows in order to reap the benefits of a eHealth system or functionality (*How*) [17]. The operational goals define the roads to take, and hence should translate to the infrastructure development – what is necessary to innovate and design in order to realize the organisational and technological change. And finally, how should this be implemented and disseminated. The policies display a significant variability in how each of the steps in the strategy management model are prioritized. This constitutes an impediment, since progress and improvements require continuity and persistence. Because evaluation activities are prioritized so low it becomes very challenging to identify inadequacies and insufficiencies, and realigning a failed course or refining the approach in order to obtain the goals and visions aimed for.

The strongest focus on monitoring and evaluating eHealth was found in the 2013-2017 policy, where benefit realization and national indicators were central themes. In this period a sub-page on the National Health Data Authority official website was dedicated to indicators of eHealth (figure 4). However, the sub-page was empty – updated last time in 2016 and now it does not exist anymore. The unresolved situation around monitoring indicators was silenced, and indicators were not mentioned in the 2018-2022 policy. However, indicator work has been continued and in March 2019 the first follow-up on the current policy was published [19]. The status report contains data on three of the five areas mentioned in the policy, but does not inform why there are no indicators on the remaining two focus areas.

Evaluation of eHealth can be difficult to quantify and is both nuanced and profoundly complex. Policymakers must understand the powers, problems, and implications of eHealth services in order to evaluate the effects. That is a daunting challenge, but no viable alternatives exist [7]. A method for monitoring the progression and effect of eHealth policies are by viewing the strategic goals as constructs. To every construct a series of indicators reflecting the construct can be developed and monitored.

Figure 4 - National Health Data Authority official website dedicated to indicators of eHealth

If a clear strategic management approach and BDNs have been framed, indentifying indicators reflecting the intention of the strategic goals will be feasible.

Allthough awareness on the value of evidence-based policy making is increasing, evaluation studies on national eHealth policies are not carried out frequently or consistently in the Nordic countries. Since 2012 the Nordic eHealth Research Network, supported by the eHealth group of the Nordic Council of Ministers, has been developing, testing and assessing a common set of indicators for monitoring eHealth in the Nordic Countries. The overall goal is to support national and international policy makers and scientific communities to develop Nordic welfare.

The Strategy Management Model and the insights gained from the analysis of the Danish ehealth policies may serve as an inspiration and example for managing eHealth policies, thus aiming at creating a learning healthcare system [20] and evidence-based eHealth policies that will increase the value of eHealth.

Conclusions

The Danish eHealth policies have very different framings following the different focus points for the policies. Interestingly, strategies for evaluating the development of eHealth and eHealth policies were very sparcely noted in the policies. For the first time the de-emphasising of evaluations of eHealth policies in Denmark has been empirically demonstrated, thus undermining the objective of obtaining evidence-based eHealth policies. In order to realise evidence-based policy making it is neccesary for the eHealth policy makers to focus on continous learning and evaluation of the previous and current eHealth policies. This work may be leveraged by using the Strategy Management Model aimning at supporting learning healthcare systems and optimizing the value of eHealth.

Acknowledgements

The Strategic Management Model presented in figure 1 was developed in cooperation with Søren Vingtoft, MD. Concepts presented in this paper originates from fruitful discussions in the Nordic eHealth Research Network.

Abstract

There are more than 300 research groups for rare diseases in Japan. Although various clinical and genomic information of patients are being collected by the groups, the information is managed individually by each research group and the current practices for managing and sharing research data are not very efficient. Since "rare diseases" are literally rare, the understanding of the underlying disease mechanisms are incomplete and collecting a sufficient number of patients for clinical trials is difficult. Therefore, there is a need to collect and integrate the data and construct a data integration platform for rare disease research. Funded by the Japan Agency for Medical Research and Development, a national research and development project to establish a standard platform and supporting organization for rare disease registries in Japan is currently under way. In this article, we report the background, purpose, process, results, current status, and future plans of this project.

Keywords:

Rare diseases, registries, data sharing.

Introduction

In Japan, research studies on rare diseases have been conducted for over four decades, and the Ministry of Health, Labour and Welfare of Japan (hereafter, referred to as "MHLW") has been supporting these studies.

The MHLW or the Japan Agency for Medical Research and Development (hereafter called "AMED" and was established in 2015 as a funding agency for medical research in Japan) supports about 300 research groups for rare diseases in Japan. In addition, there are research groups of various sizes that are not funded by MHLW or AMED.

All of these research groups are collecting various kinds of clinical and genomic information from patients for their own purposes. However, in most cases such data are managed individually by each research group, and long-term stable management of the data or effective data sharing among research groups are not sufficiently achieved because of the burden on each research group.

Since the number of the rare disease patients is low, collecting a sufficient number of patients for clinical trials is frequently difficult. As a result, the quantity and quality of the information about rare disease patients which a single research group can collect is limited, and the understanding of the underlying disease mechanisms for rare diseases is largely unknown.

Therefore, there is a strong need for collecting and integrating the data from rare disease patients and constructing a data integration platform for rare disease research in Japan. Such a platform will contribute greatly to the advance and expansion of rare disease research.

With this in mind, a research project was launched by AMED in 2017 to establish a national research infrastructure for rare disease registries in Japan, and our research group was placed in charge of the project [1].

Methods

The purpose and the goal of this research project is to establish a national information infrastructure and management organization to enable: stable longitudinal management; effective sharing among research groups; and integration, analysis, and secondary use of the clinical and genomic information from the research participants.

The information system and the supporting organization was named "RADDAR-J" (RAre Disease DAta Registry of Japan) and the following tasks were carried out:

1. Administering a web-based survey of the rare disease research groups supported by AMED or MHLW
2. Defining the rules and regulations
3. Designing and developing the information infrastructure
4. Establishing a support system for the management of registries

Web-based survey

Modeled on a prior survey in Europe [2], a web-based survey targeting rare disease research groups supported by AMED or MHLW was conducted in order to investigate the current development and management of rare disease registries in Japan, the needs for support, and so on. The survey items were as follows:

- Characteristics of the research project (5 questions)
- Characteristics of the disease registry (25 questions)
- Information system of the registry (24 questions)
- Management and registration scheme (35 questions)
- Collected data (48 questions)
- Management of the data (18 questions)
- Biorepository (16 questions)
- Needs and expectations (2 questions)

Defining the rules and regulations

Rules and regulations necessary for collecting, integrating, sharing, and providing the clinical and genomic information from the research groups included:

- Designing the organization
- Developing the operating policy
- Developing the data-sharing policy

Designing and developing the information infrastructure

The overall design of the information infrastructure necessary for RADDAR-J was created, and the development of the system was started.

Establishing a support system for registry management

A support system for registry management was organized by:

- Establishing a secretariat of RADDAR-J
- Setting up and operating the portal site in both Japanase and English
- Preparing the standard documents for management and operation of the registry
- Holding consultation meetings for research groups about the disease registry

Results

Web-based survey

A total of 303 rare disease research groups supported by AMED or MHLW were surveyed, and 89% (271 groups) answered our web-based questionnaire, which consisted of 173 questions mentioned above. The initial analysis of the answers showed that :

- 74% (200 groups) of the responding groups had some kind of registry.
- 29% (78 groups) were operating some data entry system for registry.
- 18% (49 groups) had a problem in collecting research participants.
- 12% (32 gropus) had a problem in utilizing the collected data effectively.
- 37% (100 groups) were short-staffed (especially with regard to specialist staff).

A part of the survey data was released to the public on our portal site, and all the data obtained from the survey are now under analysis in detail.

Defining the rules and regulations

Designing the organization of RADDAR-J

Design of the organization of RADDAR-J was modeled on an international organization in Europe named "RD-Connect" (https://rd-connect.eu/), which aims to accelerate rare disease research by providing a global platform for database, registries, and biobanks [3]. Based on the result of the web-based survey, the roles of RADDAR-J were set as follows:

- Collecting, managing, and providing the information and data shared from each disease research registry
- Integrating and analyzing the data provided from the disease registries
- Supporting the management of each disease registry research
- Returning the analytic results of the integrated data by RADDAR-J to the original research groups

Considering the diversity of the data types and the importance of the patients' personal information management, it was decided that RADDAR-J should consist of three main departments (Personal Information Management department, Clinical Information Integration department, and Genomic Information Integration department) and a RADDAR-J secretariat, which controls the whole organization. A committee was formed for each department.

Developing the operating policy of RADDAR-J

Detailed operating policies of RADDAR-J, such as the organizational structure, the role of each department, the operation of each committee, the necessary specifications of the standard registry system for reseach groups, the rules for the registry system management and the data management, were developed and documented.

1. Personal Information Management department is mainly in charge of the management of patients' personal information including real names. The department performs a “name-based aggregation” of patient information within one research project group as well as between different research project groups, so that patients are not duplicated within projects and can be tracked between projects.

   Since there is no national identification number available for medical research in Japan, personal information including real names need to be used to identify each patient correctly in order to avoid double registration of a patient in one research project or to find the existence of a patient that is registered in multiple disease research projects. After the “Name-based aggregation” process, patients whose real names, dates of birth, and gender match each other will be extracted as “possibly identical patients”.
2. Clinical Information Integration department is mainly in charge of :
   - supporting research groups in the development and the management of registry.
   - collecting, integrating, and managing clinical data provided by each research group.
   - aggregating and analyzing the integrated data.
3. Genomic Information Integration department is mainly in charge of :
   - collecting and managing genomic information and omics information provided by each research group.
   - collecting some clinical information from Clinical Information Integration department necessary for genomic analysis or omics analysis, and performing an integrated analysis of these data and genomic and/or omics data.
   - supporting research groups in genomic analysis such as providing some disease analysis tools, and providing genomic and/or omics information of control groups available for disease analysis.

Developing the data-sharing policy of RADDAR-J

A data-sharing policy of RADDAR-J was developed based on “Data Sharing Policy for Facilitation of Genomic Medicine” of AMED [4]. Three forms of data-sharing are defined in the policy as follows:

1. Group sharing data

   Data will be shared only between RADDAR-J and the research group, the original source of the data.
2. Controlled-Access Data

Data will be provided to third parties based on review and approval of RADDAR-J if the provision is approved in advance by the original source of the data.

3. Open Data

   Data will be published by RADDAR-J publicly if the publication is approved in advance by the original source of the data.

In order to operate these policies, researchers should obtain written informed consent from patients or use an opt-out consent process only when the research is an academic study and opt-in procedures are impractical, as described in the national ethical guidelines.

The basic data sharing policy of RADDAR-J was decided as group sharing between each research group and RADDAR-J in order to make it easier for each reseach group to obtain agreement with patients on data sharing. Each reseach group develops their own data sharing policy with RADDAR-J and its external seconady users.

Designing and developing the information infrastructure

Based on the organizational structure and the role of each department, a system configuration of RADDAR-J was designed, in which each department holds its own dedicated system and all the systems cooperate with each other as shown in Figure 1.

- Personal Information Management System, used in the Personal Information Management department, stores and manages the patients' basic personal information including real names in encrypted form. In addition, it is able to compare the personal information without decryption for privacy protection, so that it can safely perform "name-based aggregation" of patients as necessary [5].
- In order to standardize the clinical information of each rare disease registry as much as possible, a standard registry system was prepared for each research group to use at a reasonable price, reducing the burden of the system development and management. The system is based on an electronic data capture system that one of our research collaborators had developed as a commercial product. It stores and manages various kinds of patient clinical information in de-identified form and some personal information in encrypted form, which are necessary for the operation of each registry secretariat. International standard codes such as ICD-10 and HPO (Human Phenotype Ontology) were implemented on the standard registry system to facilitate international sharing of information.
- Regarding Clinical Information Integration System that will be used in the Clinical Information Integration department, the specification including the system linkage is currently being considered, and the development will start shortly. The system collects the fixed standard clinical information from each registry system in de-identified and standardized form, and receives the result of "name-based aggregation" from the Personal Information Management System as necessary.
- Genomic Information Integration System, used in the Genomic Information Integration department, stores and manages genomic information, omics information, and some clinical information necessary for genomic analysis in de-identified form. In addition, some simple genetic analysis functions are planned to be implemented in the system. This system is currently under development. The basic functions such as storing or managing genomic information have already been developed, and additional functions such as searching for genetic mutations are under development.

Support system for the management of registries

The official website of RADDAR-J was launched in both Japanese and English (https://raddarj.org/en/). An explanation of the RADDAR-J project and the result of the web-based survey about rare disease registries in Japan are available on the site.

The RADDAR-J secretariat held an explanatory meeting about the RADDAR-J project with rare disease research groups funded by AMED or MHLW, and is conducting individual consultations for research groups that request support for developing their disease registries. For an individual consultation, members of the secretariat have an interview with the reseach group to determine their current situation and demand, and consider how to support them.

Various kinds of standard documents for developing and managing rare disease registries are being developed as shown in Table 1. They will be provided at no charge to reseach groups according to their needs.

Discussion

Background of this research project

According to AMED policy, data obtained from research and development supported by public funds is national intellectual property, and AMED places great importance to the appropriate collection, quality assurance, presevation, utilization and application of data. To that end, AMED has established "Data Sharing Policy for the Realization of Genomic Medicine" [4] and promotes data sharing. Based on the policy, AMED launched a research project for the construction of information infrastructure for rare/intractable diseases, and awarded funding to the current authors' researh group.

RADDAR-J aims to contribute to the acceleration of rare disease research by providing the infrastructure and the organization which enables effective sharing and integration of clinical and genomic information that rare disease research groups collect.

Need for support

Although the data from the web-based survey, which was conducted in advance of designing the organization and the information system of RADDAR-J, are currently under detailed analysis, the survey showed that about three quarters of the responding research groups hold some kind of registry, but that less than half of them operate some data entry system for registry. In addition, slightly more than one-third of the responding research groups are understaffed (especially lacking in specialist staff).

From these results, we concluded that support by RADDAR-J for the information system and the operation of registry would help to advance the progress of rare disease research.

What we have done so far

After the whole picture for RADDAR-J including the necessary systems and regimes were designed, the development of the information system and the supporting organization for the registry systems was prioritized. The rare disease research groups could thus smoothly launch and start using their own registries because this part is, as it were, a gate for the data into RADDAR-J.

In order to secure data provenance, a standard registry system with operational log function and user authentification function, as well as standard documents for organizational operation and procedures are offered by RADDAR-J. Using these, the research groups can manage their registries and the

information appropriately and undergo monitoring when necessary.

Next, an explanatory meeting about the RADDAR-J project was held with rare disease research groups funded by AMED or MHLW, and individual consultations started to be conducted for research groups that request support for developing their disease registries. Being able to exchange frank opinions which can improve future support, these consultations were found to be good opportunities to get to know deeply the actual circumstances of the research groups.

What we are doing

Currently, the information system and the organization for integration, analysis, and secondary use of the patient data collected by the registry system is being developed. Since multiple systems of different origins and by different software manufacturers need to link to each other mainly due to budget, there are many problems to be solved such as the specification of system linkage, the specification of data integration (e.g., patient ID, project ID, data format), the system operations, and so on. Therefore, the detailed specification development has been challenging and time consuming.

There is no national identification number available for medical practice in Japan, and so harmonizing information between registries and clinical record systems is a big challenge for this project. A new system of national identification number for medical practice is recently being designed, which may enable such harmonization in Japan as in the Nordic countries [6].

It can be said that this research project is still in the midst of development and there are numerous issues that remain to be resolved. However, when complete, this infrastructure and organization will greatly fascilitate effective data sharing and promote the progress of rare disease research. International cooperation with some similar organizations in Europe is currently under cosideration.

Conclusions

Data sharing between research groups will play an important role in the field of rare disease research due to the rarity of patients. In this research project (RADDAR-J), an information infrastructure and a supporting organization are being developed for building rare disease registries and sharing patient data, which are expected to greatly contribute to the progression of rare disease research.

Abstract

It is challenging to predict patient's prognosis in oesophageal squamous cell carcinoma (abbreviated to OSCC) or perform early intervention and prevention for this disease. With the development of clinical genomics, genetic heterogeneity in tumors was found to be relevant to OSCC tumorigenesis in precision medicine studies. Over the past decade, global microarray expression profiling has been used to investigate biomarkers for human diseases. In this study, we proposed two computational strategies for identifying RNA biomarkers from microarray expression profiles of OSCC. Firstly, the logistic regression model with a least absolute shrinkage and selection operator (LASSO) regularization was used to analyze RNA expression profiles from OSCC tissues. Secondly, differential expression analysis for lncRNA profiles from both tumor and the corresponding para-cancerous tissues was performed to identify biomarkers related with lymph node metastasis, which might contribute to the early diagnosis and treatment of the disease.

Keywords:

Esophageal Squamous Cell Carcinoma, RNA, Biomarkers

Introduction

Oesophageal cancer is one of the most malignant forms of tumor worldwide regarding its prognosis and mortality, with its incidence expected to increase in the following decade [1]. According to the statistics, esophagus cancer was the eighth most common cancer worldwide with an estimated 456,000 new cases (3.2% of the total), as well as an estimated 400,000 deaths (4.9% of the total) in 2012 [2]. Nevertheless, despite the advances in diagnosis and treatment strategies, therapeutic control of this disease remains limited, with the 5-year survival rate ranging from 15% to 25% [3]. There are two major subtypes of oesophageal cancer, and one of the most common histological subtypes in developing countries, especially in the Asian countries, is the oesophageal squamous cell carcinoma (abbreviated to OSCC) [4; 5].

Generally, OSCC is difficult to diagnose in the early stage, as it has no significant symptoms or signs. However, in patients with early oesophageal cancer who have undergone surgical or minimally invasive endoscopic treatment, the 5-year survival rate can reach > 90%. Lymph node metastasis is a pathognomonic feature of spreading tumors and is widely believed to be one of the most powerful prognostic factors influencing the outcomes of many solid tumors, including oesophageal cancers [6]. Clarifying the molecular mechanisms underlying the development and progression of OSCC and identifying biological markers for screening high-risk populations are therefore of great clinical importance for early diagnosis and treatment.

Studies based on genomic information have confirmed that mutations and aberrant expressions can contribute to the pathogenesis of OSCC [7-9]. For example, Togashi Y *et al*. identified that frequent amplification of ORAOV1 gene in oesophageal cancer can promote the tumorigenesis [10]. High expression of XRCC1 and JWA were found to be correlated with longer median overall survival, and these genes are useful biomarkers in oesophageal cancer [9]. Meanwhile, an increasing number of studies have confirmed that non-coding RNAs also play an important role in tumor biological process, and might be potential biomarkers for tumorigenesis [11-14]. For instance, Hou *et al*. showed non-coding RNAs could be new biomarkers and therapeutic targets for esophageal cancer [15]. Chen and Li *et al*. analyzed the microRNA (abbreviated to miRNA) and long non-coding RNA (abbreviated to lncRNA) expression profiles of 119 paired OSCC samples separately by microarray technology and identified four-miRNA signatures and three-lncRNA signatures that can predict patient survival [16; 17]. Yu *et al.* confirmed that miR-130b plays an oncogenic role in OSCC cells [18]. Actually, lncRNAs might involve in governing critical biological processes in cancer by regulating target genes expression at multiple stages of cancer development. Although various regulatory mechanisms of non-coding RNAs, mRNAs, as well as their interaction mechanisms for disease pathogenesis, have been uncovered. Still, systematic and integrative strategies for analyzing RNA expression profiles are still worth exploring.

On the other hand, previous studies indicated that genome-wide alterations in tumor compared with adjacent tissues may be predictive biomarkers for cancer [19-21]. Thus, identification of the molecular changes associated with cancer risk factors like lymph node metastasis in para-cancerous tissues (adjacent normal tissues) may aid in determining the earliest events of carcinogenesis and informing cancer prevention and treatment strategies.

In this research, we proposed two strategies for identifying RNA biomarkers from microarray expression profiles of OSCC. Followed with a literature search for validating the significance of the proposed biomarkers.

Methods

Strategy_1: Combination Analysis of miRNA, lncRNA and mRNA with Logistic Regression

RNA expression profiles (mRNA, miRNA and lncRNA) for cancer and adjacent normal tissues (para-cancerous tissues) of 119 OSCC patients were obtained from the study by Chen and Li *et al* [16; 17]. Followed with data filtering and normalization to reduce the number of variables. Here we used logistic regression to check whether the combination of different kinds of RNA molecules might be effective prognostic biomarkers for OSCC (Figure 1).

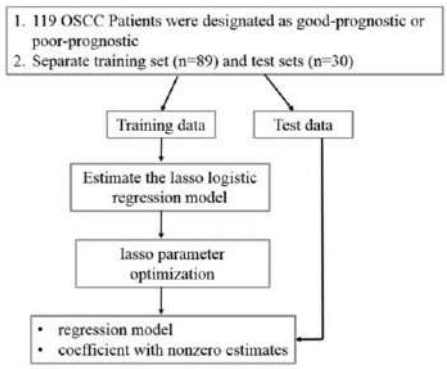

Figure 1. Workflow for strategy 1

- Step 1. Patients were designated as good-prognostic (47 patients) or poor-prognostic (72 patients), based on whether the survival time was longer than 5 years or not (Figure 1). These can be the categorical variable indicating the disease prognosis. Then, split 75% of the 119 OSCC patients selected randomly into training dataset (n=89) and the remaining 25% (n=30) sample into test dataset.
- Step 2. After data filtering (lncRNAs with significant variable expression, differentially expressed between normal and tumor, etc.) and normalization, expression profiles of 286 miRNA, 149 lncRNA and 175mRNA in tumor tissue of OSCC patients were obtained.
- Step 3. Adopt the logistic regression model as follows:
- Logit(P(Y=1|Z))=a+BZ′, Y is the categorical variable with 1 denotes good-prognostic, while 0 denotes poor-prognostic, and Z is the matrix constituted by expression profiles of the mRNA, miRNA and lncRNA selected in Step 2. Here, lasso regularization [22-24], which optimizes the regression output and select features by enforcing sparsity, was used in the regression model to extract RNA biomarkers that can significantly affect the prognosis. It was confirmed to be an efficient algorithm and is suitable for high dimensional problems. We employed the 10-cross validation to optimize the parameter λ that controls the regularization penalty, the one that gives minimum mean cross-validated error was defined as the final penalty parameter.
- Step 4. RNA molecules with nonzero estimates in the final regression model could be the potential biomarkers. Finally, check the efficiency of the classification model composed of the selected RNA biomarkers in the test dataset.

Strategy_2: Extracting RNA Biomarkers from Para-Cancerous Tissues with Differential Expression Analysis

Microarray expression profiles of 8900 human lncRNAs in tumor and adjacent normal tissues of OSCC were obtained [17]. The hypothesis of this strategy is that genetic alterations in normal tissue adjacent to established carcinomas can facilitate tumorigenesis. Here we focused on researching the relationships between lncRNA expression and lymph node metastasis in para-cancerous tissues of OSCC. The workflow of this strategy is shown in Figure 2.

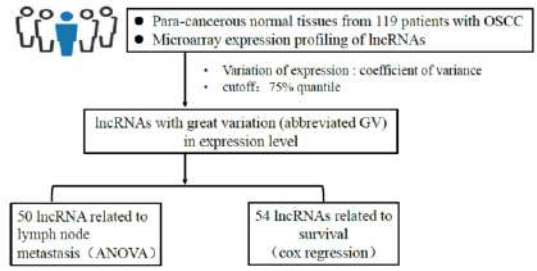

Figure 2. Workflow for strategy 2

- Step 1. Coefficient of variance (abbreviated to CV) was used to measure the specific patterns of expression variation across para-cancerous tissue samples for each lncRNA molecular. For dimensionality reduction, 75% quantile of the CV was used to select lncRNAs with great variation in expression level (abbreviated to GV_lncRNAs).
- Step2. Number of lymph nodes was used to measure the metastasis. Para-cancerous samples from the 119 OSCC patients were designated as subgroup-1 (lymph node: N0) (n=54) or subgroup-2 (lymph node: N1, N2, N3) (n=65), based on the number of lymph nodes (N stage, come from the TNM classification system) of the patients. This can be the categorical variable indicating the disease prognosis [25].
- Step 3. Among the GV_lncRNAs, identify lncRNAs significantly differentiated between para-cancerous tissues of OSCC patients from subgroup-1 and subgroup-2 using ANOVA. Do survival analysis to define lncRNAs whose expression level in para-cancerous tissue was associated with the survival time of patients were defined (Cox regression, $p < 0.05$). These could be potential biomarkers associated with disease prognosis.

Results

Combination of miRNA, lncRNA and mRNA Emerged to be Powerful Biomarkers for OSCC

Followed with the method mentioned in Strategy_1, we defined RNA biomarkers constituted by 10 mRNA, 4 miRNAs and 7 lncRNAs, which achieved high predicting performance (with 20% misclassification error) in our test dataset.

Among the predicted RNA biomarkers, several have been reported to be oesophageal tumour-related items. For instance, DKK1 is the inhibitor of the canonical Wnt signaling pathway, and aberrant expression of this gene was implicated as a novel predictor of poor prognosis in OSCC [26]. WDR66 was reported to be a novel marker for risk stratification and involved in epithelial-mesenchymal transition of esophageal squamous cell carcinoma [27]. Besides, the miRNA biomarker microRNA-1290 and its target gene may play crucial roles in esophageal carcinogenesis and progression and oral squamous cell carcinoma [28].

Expression Level of lncRNA in Para-Cancerous Tissue might Reflect Tumorgenesis

Firstly, variation of expression level for each lncRNA in tumor and para-cancerous tissues showed no significant difference, similar results were observed in those lncRNAs related to lymph node metastasis and survival (Figure 3). Therefore, we

further focused on those lncRNA molecules with great variation in expression level in para-cancerous tissues.

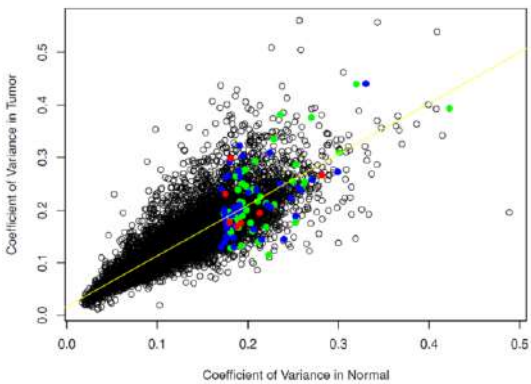

Figure 3. Comparing the variation of expression level for each lncRNA in tumor and para-cancerous tissues. Red dot, lncRNAs whose expression level in normal tissue is associated with patients' survival time and differentially expressed between the para-cancerous tissues of patients from subgroup-1 and subgroup-2; Green dot, lncRNAs whose expression level in para-cancerous tissues is associated with patients' survival; Blue dot, lncRNAs who differentially expressed in normal tissue between patients from subgroup-1 and subgroup-2.

Among the lncRNAs with great variation in expression level, 50 lncRNAs significantly differentially expressed between para-cancerous tissues of patients from subgroup-1 and subgroup-2, as well as 54 lncRNAs whose expression level in para-cancerous tissue associated with the survival time of patients were defined. Resulting in 7 overlapping lncRNAs (linc_XLOC_008811, linc_ENST00000501008.2, linc_ENST00000443445.1, linc_ENST00000504436.1, linc_NR_029392, linc_XLOC_001499, linc_ENST00000582654.1), these could be the potential biomarkers associated with disease prognosis.

For the 50 lncRNAs differentially expressed in para-cancerous tissue of OSCC patients with different lymph nodes metastasis, we divided these molecules into different categories, based on the mean expression level in tumor and para-cancerous tissue. 7 potential lncRNA biomarkers who highly expressed in para-cancerous tissue of patients with lymph node metastasis were identified (Figure 4, Table 1). It is worth noting that the expression level of linc_ENST00000504436.1 is also correlated with the five-year survival rate of patients, indicating that this might be as a potential biomarker for the early diagnosis and prognosis prediction of the disease.

Similarly, we compared the mean expression level of the 54 lncRNAs associated with survival in tumor and para-cancerous tissues and divided these molecules into different categories based on the mean expression level in tumor and para-cancerous tissue. (Figure 5). Expression level of 5 lncRNAs highly expressed in para-cancerous tissue are also associated with tumor prognosis, these molecules are worthy of further research for predicting tumor prognosis.

Table 1. 7 lncRNAs highly expressed in para-cancerous tissue of patients with lymph node metastasis.

lncRNA	N0_ mean	N1_N3 _mean	diff_ mean	CV _N	CV _T	diff_ CV

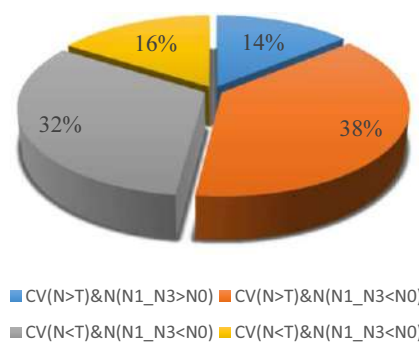

Figure 4. Distribution of 50 lncRNAs based on mean expression level. CV(N>T) represents mean expression level in para-cancerous tissue was higher than in tumor, and vice versa. N(N1_N3>N0) represents mean expression level in para-cancerous tissue of patients designated as N1, N2 or N3 was higher than in normal tissue of those patients designated as N0, and vice versa.

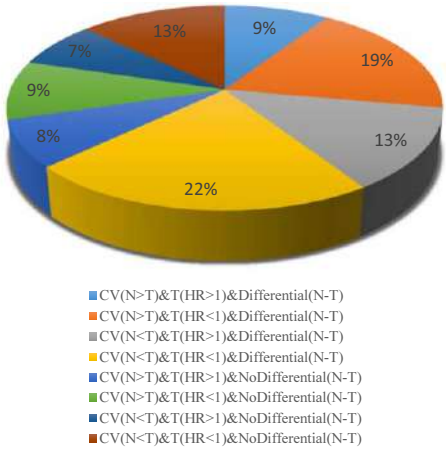

Figure 5. Distribution of 54 lncRNAs based on mean expression level. CV(N>T) represents mean expression level in para-cancerous tissue was higher than in tumor, and vice versa. T(HR>1) represents protective factor, and T(HR>1) represents a risk factor. Differential (N-T) means lncRNA differentially expressed between tumor and para-cancerous tissue, and NoDifferential (N-T) means it is not differentially expressed between tumor and para-cancerous.

Discussion and Conclusions

In this study, we proposed two potential strategies for identifying RNA biomarkers for OSCC. For the integrative analysis strategy, there might be a synergistic effect between mRNAs and non-coding RNAs in tumorigenesis. Generally, based on the extracted biomarkers composed by mRNA, miRNA and lncRNA, patients in test dataset can be classified into good-prognostic and poor-prognostic with low misclassification error. We further searched evidence from published literature and confirmed that several RNA biomarkers have been reported to be oesophageal related risk factors. Actually, selecting prognostic biomarkers from microarray expression profiles is a frequently-used approach, but always limited to dimension of input variables. The lasso approach for logistic regression can limit the number of effective signatures by a proper regularization penalty and extract a minimum number of significant features, and overcome overfitting issues. Application of the lasso approach showed significant power in extracting important prognostic biomarkers for OSCC from high dimensional data.

Nevertheless, further biological effect, as well as the precise regulatory mechanisms between mRNAs and non-coding RNAs in the pathogenesis of oesophageal cancer are essential. Also, due to the sample size limitation, we adopted the cross-validation rather than other independent datasets for penalty parameter optimization, to some extent, might also reduce the model accuracy.

For another strategy, we systematically compared the expression profiles of lncRNA in tumor and adjacent normal tissues from patients with OSCC, to identify potential biomarkers for lymph node metastasis and prognosis prediction. Normal tissue samples are often employed as a control for understanding disease mechanisms, ignoring many of the information that may exist on their own. Actually, exposure to the same biological and physical environment, some genomics mutations occurring in adjacent tissues may also have a certain effect on the development of tumors. Generally, this method can generalized to the analysis of mRNA and miRNA expression profiles. However, the results of informatics research need to be further verified by experimental methods.

Pediatric Asthma Care Assessment for the Emergency Department

Adeola Akinfaderin[a], Kathryn Kovalenko[a], Pamela Newsome[a], Jeritt Thayer[a], Yang Gong[a]

[a] *School of Biomedical Informatics. University of Texas Health Science Center at Houston, Texas, USA*

Abstract

In the United States alone, approximately 6.2 million children have asthma. Managing the care of pediatric patients presenting in the emergency department with asthma requires clinicians to access multiple locations within the electronic health record. This wealth of information makes it vital to develop methods for sifting through the clutter to information that is relevant to the specific task to be completed. Unfortunately, current information displays have not been developed to maximize provider efficiency when integrating information across a number of disparate locations. Using proven data display theories, we aimed to create a consolidated acute pediatric asthma display to aid in the patient's care with the goal of improving the efficiency and consistency by which they are treated - ultimately reducing the length of stay, complications, and morbidity in these patients.

Keywords:
Data Display; Delivery of Health Care; Asthma

Introduction

The amount of information available to the clinician has increased exponentially with the advent of more sophisticated technological tools. Prior to this technology era, the clinician had two sources of information for patient records: the patient's paper chart and the patient. Now, the clinician has access to multiple sources with overwhelming information; the electronic health record (EHR) within their practice, health information exchanges, emergency department (ED) records, and records from other clinicians in the patient's care team, clinical guidelines, and the patient. This wealth of information makes it even more important to develop methods for sifting through the clutter to information that is relevant to the specific task to be completed at a point in time during care delivery.
