Finally, portal and service integration layer components have been implemented as custom solution for demonstration purposes: The “LabHub” in its first iteration is intended as a central platform for user interaction, resource management, data entry, and access to data from past experiments in the EHM context. Aiming for usability, extensibility, and sustainability we utilize the widespread content management system Drupal as a software development framework to create a set of logically independent modules for user interaction and data processing. Service integration functionality is demonstrated by offering an administrative user interface for service and resource registration. Drupal modules in the LabHub context define service types which again are used by other modules as a resource. Instances of services are registered through GUI using internet protocol. This allows for example, to register multiple instances of the SEEK platform, which in turn can be connected to by an arbitrary number of modules that communicate with the SEEK REST API. “Connector” modules that define service types and “consumer” modules that interact with the respective web-service API are implemented for the SEEK and RSpace systems. API and application layer modules for the existing EHM MySQL database are drafted, enabling role-based management of laboratory asset data and access to experimental result data. Using the integration layer functionality, this experiment-specific system communicates with both RSpace and SEEK instances allowing for user-centric documentation of workflow steps in the ELN and FAIR-compliant publication of FoC measurement data in the RDMS component.

At the current stage of the project, access to both the Drupal and SEEK web servers is restricted to the local network. Developmental stage source code of the LabHub prototype is available through a public code repository (http://hdl.handle.net/21.11101/0000-0007-CADE-C).

Discussion

A challenge implicit in the research question is how to find candidate software for implementing an infrastructure satisfying all the diverse requirements of operative and research data processing and managing in a biomedical lab. This is mostly due to the circumstance that no canonical descriptive name for the category of software exists. “ELN” and “LIMS” are labels well-defined and attached to a multitude of open source, service-based, and commercial products. The term “SDMS” is mentioned in articles and per definition comes very close to the here proposed requirements for research lab data management [17] but is neither topical nor actively promoted. Of the discovered software tools that in description satisfied a considerable subset of our requirements, some are no longer available or maintained. The most challenging task for this project is to not follow these projects into a dead end but to aim for sustainability. Remarkably, some software tools initiated in the years 2007-2011 have succeeded due to innovative concepts and future-proof development processes.

Architecture Concept

Inefficiency of user interfaces is a central barrier of adoption of IT systems in the lab [19]. Overcoming usability barriers in practice is the actual challenge and must be made a focal point of infrastructure design and implementation. Four of our declared six main goals emphasize software quality aspects, addressing this need to improve quality of research data handling while not negatively interfering with operative processes [18].

Appropriate models of laboratory information system architecture and the integration of subsystems exist for decades already with similar challenges pronounced as [19]. Despite this understanding of the problems, formulation of solution models, and the obvious progress of technology, seamless integration of data producing and data processing entities is an ongoing effort. The presented analysis updates the modeling with explicit focus on sustainable operation of the technical infrastructure. Strength of the proposed concept is the extensible integration of existing software systems as well as service modules into an architecture accessible through a central portal component. Combination of integration methods [15] serves to integrate the existing systems as components, as demonstrated here with the RSpace instance. This approach allows for re-use of the framework at other laboratories as it is agnostic of whether or not components have been deployed before. "ELN-centric integration" [15] follows a similar reasoning but for adoption of the approach an extensible and modifiable ELN component is required. In comparison, the framework presented here does not require any existing system to function as the central access and integration component but encourages a modular solution.

Considering the broad spectrum of specialized systems discovered in the literature search and the indicated system requirements, only an integrated architecture of multiple systems and services is probable to succeed in the long run. Classic LIMS solutions are reported to expand in functionality and aim towards becoming comprehensive information systems for all laboratory needs [15] but the dynamic nature of method and experiment development at a research lab is not suitably addressed by traditional monolithic systems. Notably, the product STARLIMS is named as an example for an expanding LIMS [15] and is already deployed at UMG service units Biobank and Stem Cell Unit. Investigation of synergistic effects and integration opportunities is planned.

Among RDM projects in medical informatics and biomedicine, the framework discussed here is remarkable for not focusing infrastructure within a collaborative project. Typically, systems are developed and proposed for project-specific use cases on grant-based funding. Here, persistent organizational infrastructure is considered with research projects and the associated data management systems located within the outer system context. Sustainability and extensibility have been exclaimed goals so that the resulting architecture should be more long-lived than project-centric infrastructures. The modularity embedded in the concept is meant to ensure that subsystems can be exchanged and replaced to address changing technical and structural requirements. The more systems are integrated into a complex data management architecture however, the higher becomes the need for capturing data provenance records to prevent data quality from deteriorating [9,20].

LabHub Prototype

The goal dimensions initially declared are addressed by the prototype. Still, the achievements mark only a beginning when assessed against the business goals of enabling research process and improving reporting quality. Most problematic is the question of sustainability. The topic has been at the core of considerations leading to the architecture concept and implementation plan. The prototype created is not inherently sustainable though. Some of the approaches reported in the scientific literature have vanished quickly in spite of support by a professional team of researchers or developers. Re-evaluation of openBIS as a data management system may thus be of interest. Major drawback ascertained in assessment of openBIS for the EHM use case was the user interface design not suited for cross-platform operation. Given the resources to integrate openBIS into a modern, usable, platform-independent front end, reuse of the system's wide spectrum of data management features could be an elegant way to create an integrated platform, as already demonstrated by other projects [21].

Promoting LabHub development to become a data-centric counterpart for efforts to standardize control interfaces for lab automation devices may be considered. We plan cooperation with the Standardization in Lab Automation (SiLA) to advance the automation of EHM generation processes. To our knowledge, no platform for management, control, and scheduling of lab processes using SiLA compatible devices does exist yet, indicating an opportunity to investigate.

Systemic Challenges

Sustainability of a system is less a question of technology than of available resources. Project grants for specialized innovative research data processing systems may be easier to allocate than permanent funding for infrastructures needed for basic operation. Ideally, the operative infrastructure would support FAIR data sharing to promote secondary use of data internally for quality control and meta-analyses, and externally in research projects. Above all, implementing and maintaining a complex integrated system in such a way requires capable personnel. A small dedicated team of software engineers may become an integral asset.

Laboratories and institutes will need to adopt gateway services for inter-organizational collaborative data-driven research projects on (inter-) national scale. Here, the SEEK instance operates as such by allowing FAIR-compatible sharing of data. Projects like the Medical Informatics Initiative in Germany [22] or the European Open Science Cloud (EOSC) [23] promote infrastructural integration and cross-site data exchange. Independent of how the challenge of privacy preserving data sharing will be solved technically, providing internal primary data in FAIR-compliant ways enables integration with the emerging global data infrastructure [4]. Developing and operating a FAIR-compatible infrastructure at an institute or laboratory may prove to be of both scientific and strategic advantage in technological advancement of biomedical research in the coming years.

Conclusions

We describe challenges and requirements that transcend the specific setting of cardiac tissue engineering. The proposed architecture framework promotes extensibility and usability for highly dynamic, constantly evolving operative realities. The topic of innovative research lab data infrastructure is open for collaborative advancements and investigation. FAIR data publication and reporting are explored for the presented use case but are not yet operational and require further investigation and refinement especially with regard to application of semantics. Achieving sustainability of the LabHub software or any integrated infrastructure is a major challenge and requires commitment regarding resources and effort. The development of an integration and control framework for laboratory process automation is promising in terms of scientific and operative potential.

In conclusion, a framework for comprehensive research lab data management is proposed for discussion and possibly adaptation. Our findings are a foundation for diverse subsequent investigation and possibly software development. The core challenges require close cooperation and collaboration of biomedical researchers and computer scientists to pave the way for dynamic and persistent socio-technical information systems connected to a global infrastructure of data.

Abstract

The onset of acute kidney injury (AKI) during an intensive care unit (ICU) admission is associated with increased morbidity and mortality. Developing novel methods to identify early AKI onset is of critical importance in preventing or reducing AKI complications. We built and applied multiple machine learning models to integrate clinical notes and structured physiological measurements and estimate the risk of new AKI onset using the MIMIC-III database. From the clinical notes, we generated clinically meaningful word representations and embeddings. Four supervised learning classifiers and mixed-feature deep learning architecture were used to construct prediction models. The best configurations consistently utilized both structured and unstructured clinical features and yielded competitive AUCs above 0.83. Our work suggests that integrating structured and unstructured clinical features can be effectively applied to assist clinicians in identifying the risk of incident AKI onset in critically-ill patients upon admission to the ICU.

Clinical Decision Support, Natural Language Processing, Acute Kidney Injury.

Introduction

Acute kidney injury (AKI) is commonly seen in adults in the intensive care unit (ICU). AKI is one of the major diagnoses among ICU patients and a leading factor associated with a prolonged hospital stay and subsequent morbidity or early mortality post discharge [1, 2]. Acute renal failure is a complex disorder that presents itself in a variety of settings with clinical manifestations, ranging from a minimal elevation in serum creatinine to anuric renal failure [3]. Unfortunately, the main biomarker of AKI, serum creatinine (SCr), is a late marker of injury, which delays diagnosis and treatment [4]. However, the efficacy of intervention greatly relies on the early identification of AKI [5]. Early recognition is critical in that AKI usually occurs over the course of a few hours to days and is potentially reversible if detected and managed early [5, 6].

In this study, we used the definition of AKI from the Kidney Disease Improving Global Outcomes (KDIGO) [7], in order to standardize the published diagnostic criteria. The diagnostic criteria are defined as an acute increase in the absolute level of serum creatinine of more than 0.3 mg/dl or 50% higher change in serum creatinine (SCr) from baseline within a 48-hour period or decreased glomerular filtration rate (GFR) to less than 0.5 ml/kg/hour for more than six hours [7, 8]. These criteria were based on accumulating evidence that even small alterations in SCr are associated with serious consequences. Therefore, an accurate creatinine forecast may enable prediction of AKI risk. In this study, we focus on predicting AKI using first-day measurements of a multivariate panel of physiologic variables, in order to elucidate early, subclinical deterioration of patient's physiologic baselines that are predictive of AKI.

Many factors including nephrotoxic medications, insufficient effective circulating fluid volume, and intrinsic renal disease can cause or contribute to AKI [9, 10]. In addition, epidemiology studies show multiple comorbidities, including diabetes mellitus, cardiovascular disease, chronic liver disease, cancer, and complex surgery have been associated with the development of AKI [5, 10, 11]. Thus, a comprehensive understanding of ICU patients is essential to predict the development of AKI.

The increasing use of electronic health records (EHRs) allows access a comprehensive and extensive amount clinical data to develop models to predict AKI in ICU [3]. There are several previous studies using EHR data to predict AKI [12-21]. Most studies achieved a modest performance with area under the receiver operation curve (AUC) close to 0.75. However, majority of these studies focus on specific patient population such as the elderly and cardic surgery patients. In addition, many prior studies rely on various static scoring algorithms and/or do not incorporate the temporal progression of the clinical, laboratory information that is shown to be effective for the prediction. Last but not least, some studies incoporate a limited set of predictors that are not inclusive enough to capture changes in clinical care that may impact AKI risk; similarly, some studies rely on non-routine biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL) that are not always tested for general patients. Data-driven predictive modeling for AKI has recently gained traction, but is focused on using either structured EHR data [22] or unstructured clinical notes alone [23]. In summary, these models are not optimally suited for a relatively general patient population and are not set up as adaptive tools to assist the clinical decision-making process.

Our approach, in contrast, involves the careful modeling of a wide array of predictor data including clinical treatments and the temporal aggregation of predictor data. Specifically, we include not only structured data such as laboratory test results, but also unstructured data, the ICU clinical notes (e.g., physician notes and nurse notes) to provide a comprehensive picture of the patients' current pathophysiologic condition and help develop a powerful model to predict AKI.

From a pratical standpoint, our approach focuses on the early prediction of AKI on patients who do not meet AKI criteria on admission to the ICU, thus targeting a population that could

benefit from early intervention which might reverse the development of AKI or minimize its clinical impact. This is especially important since prior studies on automated AKI detection (as opposed to prediction) show limited effectiveness of therapeutic interventions in patients already meeting AKI criteria [24]. We expect the early prediction of AKI in this study to have a wide range of clinical applications.

Methods

Dataset

Data for this study was acquired from Medical Information Mart for Intensive Care III (MIMIC-III). MIMIC-III captures de-identified health information for more than 46,000 patients admitted to the critical care units at Beth Israel Medical Center between 2001 and 2012. We developed a SQL script to extract data of patients for who had a creatinine measured at 72 hours following ICU admission from the MIMIC-III database [25]. Only patients 18 years of age or older were included, and patients with the pre-existing condition of Chronic Kidney Disease (CKD), who have an estimated glomerular filtration rate GFR (eGFR) < 60 mL/min/1.73 m^2 were excluded [26, 27]. Data extracted include patients' age, gender, ethnicity, 72-hour serum creatinine (with only the creatinine value from the first 24 hours used as predictor, the value from the 2nd and 3rd days are used to identify AKI), vital signs and lab values during the first day of ICU admission, whether the patient was mechanically ventilated during the first day of ICU admission, the hourly rate of urine output during the first day of ICU admission, and the clinical notes during the first 24 hours of ICU admission. Only clinical notes from the first 24 hours of the ICU stay are included given the commonly seen lag between the provide-patient encounter and the time the notes were performed.

Based on the criteria from KDIGO [7], AKI is defined as either of the following two conditions being met: (1) greater than or equal to 50% increase from the baseline creatinine value to the current creatinine value and (2) greater than or equal to 0.3 mg/dL change in creatinine from the baseline creatinine to the current creatinine value. Since our study focuses on AKI developed after the ICU admission, patients who got AKI on admission (day 1) were excluded. After this step, the remaining patients' AKI status were determined by comparing day 2 and day 3 maximum creatinine to the day 1 minimum creatinine level (the baseline).

A total of 16,558 ICU stays of 14,469 patients met the inclusion criteria for this study. The dataset was first split into training and test sets by an 7:3 ratio. Then, reassignment was conducted to ensure multiple ICU stays of the same patient stayed in the same set. The AKI prevalence rate overall and in both sets are approximately 17% as shown in Table I below. Table II presents the predictor variables used in this study, along with their statistical characteristics such as mean and standard deviation for continuous variables and count and percentage for categorical or discrete variables.

Table I – AKI Status Distribution Overall and in Training and Test Sets.

Set	All	AKI	Non-AKI	AKI Prevalence
Overall	16,558	2,785	13,773	16.82%
Training	11,558	1,927	9,631	16.67%
Test	5,000	858	4,142	17.16%

Natural language processing of the clinical notes

To better interpret clinical notes, some preprocessing steps were needed. Masked protected health information (PHI) in the notes were removed first. Then, in order to make the information usable in machine learning classifiers, clinical notes were converted to structured features. Our first set of features consists of unigram bag-of-words [1], which identified and normalized lexical variants from the unstructured text content. Those features with document-frequency under 10 were removed to reduce noise. A total of 313 stop words were applied according to NCBI guide. Term frequency-inverse document frequency (tf-idf) weighting adjustment was also applied [28].

Table II - Univariate Characteristics for Predictors of Interest, N= 16,558

Variable	Mean	SD
Age (year)	60.80	16.16
Gender - N, %		
Female	6,735	40.68%
Male	9,823	59.32%
Ethnicity - N, %		
African-American	1,048	6.33%
White	11,981	72.36%
Hispanic	532	3.21%
Other	2,997	18.10%
Heart rate maximum (bpm)	105.43	19.76
Heart rate mean (bpm)	87.10	15.03
Systolic BP minimum (mmHg)	92.45	17.04
Systolic BP mean (mmHg)	119.06	15.85
Diastolic BP minimum (mmHg)	44.60	10.95
Diastolic BP mean (mmHg)	61.33	10.00
Temperature maximum (Celsius)	37.65	0.74
SpO2 minimum (%)	92.20	7.24
SpO2 mean (%)	97.53	1.83
Glucose level maximum (mg/dL)	173.82	72.33
Bicarbonate level minimum (mg/dL)	23.86	4.26
Creatinine level minimum (mg/dL)	0.73	0.20
Creatinine level maximum (mg/dL)	0.80	0.22
Hemoglobin level minimum (g/dL)	10.34	2.07
Platelet count minimum (K/μL)	208.83	113.13
Potassium level maximum (mg/dL)	4.42	0.80
Partial thromboplastin time minimum (s)	32.49	11.49
Partial thromboplastin time maximum (s)	40.39	23.63
International normalized ratio minimum	1.33	0.43
International normalized ratio maximum	1.47	0.68
Prothrombin time minimum (s)	14.48	3.00
Prothrombin time maximum (s)	15.42	4.23
Blood urea nitrogen level maximum (mg/dL)	16.54	8.34
White blood cell count maximum (K/μL)	12.94	8.14
Calcium level minimum (mg/dL)	8.08	0.75
Average urine output (mL)	2,249.40	1419.51
Estimated glomerular filtration rate (eGFR)	110.33	50.20
Mechanical Ventilation - N, %		
No (0)	7,649	46.20%
Yes (1)	8,909	53.80%

Missing data imputation for structured data

There are no missing values among age, gender, and race. Other structured clinical and laboratory data obtained from clinical settings contained missing values, which indicates certain tests were not performed during the patient's ICU stay. For example, the variables having a large proportion of missing values include minimum albumin level (74.1%), maximum bilirubin level (67.2%), maximum lactate level (55.8%), maximum c-reactive protein level (99.0%), maximum asparate aminotransferase level (66.8%), maximum pH level (36.6%), and minimum base excess level (64.8%).

We employed a two-step process to handle missing values. First, we removed the variables with missing values greater

than 20%. We thenfilled in the values for predictors (e.g., labs not performed or recorded) using Multivariate Imputation by Chained Equations (MICE) [29] for those variables with less than 20% missing values. MICE estimates a conditional model for each variable to be imputed, with the other variables as possible predictors [30]. The term chained equation comes from the adoption of a Gibbs sampler, which is an iterative Markov Chain Monte Carlo algorithm for obtaining a sequence of observations that are approximated from a joint probability distribution. As MICE closely tracks the conditional interdependencies among variables, we expect MICE to produce more accurate imputation. Then, as the second step, we used the measured and imputed values for these predictors plus age and gender to predict maximum creatinine results during day 2 and day 3. In this step, we predicted both numerical results for creatinine (linear regression) and whether creatinine increase would be classified as AKI (logistic regression). Although no creatinine results were actually missing from our dataset per the inclusion criteria, we assessed model performance and creatinine predictability by masking creatinine results from a test fold during five-fold cross validation and then compared predicted creatinine results to the masked (measured) values. The masked-measured values were treated as the "ground truth" in assessing model performance. The imputation stage was required because the prediction algorithms used in the second stage of our procedure could not directly accommodate missing data in predictors.

Machine learning classifiers

Logistic regression (LR), random forest (RF), multinomial naïve Bayes (NB), and supported vector machine (SVM) classifiers were implemented in scikit-learn to find the best prediction model. As the class ratio is imbalanced, we set the class_weight parameter to "balanced" for logistic regression, random forest and supported vector machine classifiers to down weight the more popular class. In order to tune parameters and reduce over-fitting and instablity, a grid search with 3-fold cross-validation was performed on the training set. The best parameters for each classifier were then applied to the test set to assess the prediction performance of each model.

Mixed-feature Convolutional Neural Networks

We also explored deep learning models for AKI prediction. We used mixed-feature Convolutional Neural Networks (CNN) to combine word features and structured clinical features. The architecture of mixed-feature CNN model is shown in Figure 1. It used pre-trained word embeddings and structured clinical data as the input. A one-dimensional convolution layer was built on the input embeddings. We used max pooling to select the most important feature with the highest value in the convolutional feature map and then concatenated the max pooling results of word embeddings and structured clinical features. The concatenated hidden features were fed into a fully connected layer, followed by a dropout and ReLU activation layer. Finally, a fully connected layer was fed to a softmax output layer, whose output is the probability distribution over labels (AKI or Non-AKI).

We adopted the following parameter settings for the mixed-feature CNN after further separating 10% from training data as validation set for parameter tuning, the number of convolution filters: 32, the convolution kernel size: 5, the dimension of hidden layer in the fully connected layer: 64, dropout keep probability: 0.8, learning rate: 0.001, batch size: 64. We used weight blancing in mixed-feature CNN training to address the class imbalance issue. In particular, we used the labels of classes to automatically adjust weights inversely proportional to class frequencies using the training data. The weights are then used in calcualting the weighted cross entropy from logits in the softmax layer.

Evaluation

We adopted area under the receiver operating characteristic (AUC) to evaluate the performance of imbalanced binary classifiers. Precision, recall, F-measure of positive AKI status were also calculated for reference.

Results

In this section, we report the evaluation results on the held-out test set using four supervised learning classifiers (LR, RF, NB, SVM) over three different feature configurations (structured feature only, unstructured clinical notes only, and structured features combined with unstructured clinical notes), as well as results by mixed-feature CNN. Table III presents the results from the above model configurations.

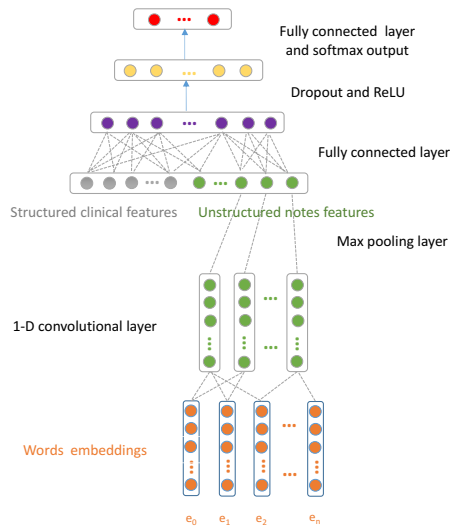

Figure 1. Mixed-feature Convolutional Neural Networks.

We first investigated the combinations of three feature representations and four supervised learning classifiers. The baseline predictor of each representation used Naive Bayes algorithm yielded AUC in the range from 0.65 to 0.75, F-measure from 0.17 to 0.37. In particular, combining structured and unstructured features in NB does not lead to better AUC. Logistic regression with L2-regularization over the mixed features yielded the best F-measure of 0.5423 on AKI status prediction, while calibrated SVM with L1-regularization gave the best AUC of 0.8352. Overall, all classifiers, except for NB as the baseline, yielded a competitive AUC score over 0.79, given that most previous models had modest AUCs around 0.75 (see Related Work section). In addition, the best LR model favored high recall (i.e., sensitivity: 0.7284) over precision (i.e., positive predictive value: 0.4319). This serves well for the clinical application of AKI onset alarm as we want to capture as many future AKI onsets as possible, while tolerating modest false alarms.

For the mixed-feature CNN, using ratio balancing class weights, yielded the best performance of 0.8167 AUC and 0.3559 F-measure. Despite heavy parameter tuning, all configurations of parameters of mixed-feature CNN did not outperform the best non-CNN classifiers. Based on our previous experiments on general domain text corpora [31], CNN-based architectures generally work well for datasets with

short texts, but may not outperform bag-of-word on corpus with long texts such as the AKI clinical note corpus. In addition, due to the fact that training CNN models is usually time-consuming, in our case, well-calibrated non-CNN classifiers seem to be a more suitable choice.

Feature analysis

We further examined important features by ranking coefficients in the L2-regularized logistic regression (best F-measure) over bag-of-words and structured clinical features. Table IV presents top 10 positive structured clinical features that contribute to AKI onset. The maximal creatinine level in day 1 carries a weight almost 10 times higher than the predictor with the second highest weight. The information critical to predict AKI is concentrated in the top three predictors by weight. These predictors are consistent with the known pathophysiology of AKI that older patients have higher incidence of AKI. Mechanical ventilation and coagulopathy (prolonged prothrombin times) are also known risk factors of AKI and also might represent patients with higher severity of illness and/or sepsis. The elevated potassium level likely represents early electrolyte disturbances in the setting of injured kidneys likely to meet AKI definition in the subsequent days. Finally, the elevated creatinine and BUN levels, while not meeting AKI criteria in these patients given the exclusion criteria of the study, likely represents an early elevation indicative of injured kidneys which has not peaked yet.

Table III – Machine Learning Model Results. Str: structured features. Unstr: unstructured features. ALG: algorithm. MCNN: Mixed-feature CNN. Best AUC and F-measure are in bold.

Features	ALG	AUC	Precision	Recall	F-meausre
Str	LR	0.8336	0.4319	0.7284	**0.5423**
+	RF	0.7914	0.6774	0.0490	0.0913
Unstr	NB	0.6728	0.2681	0.6166	0.3737
	SVM	**0.8352**	0.7274	0.2340	0.3541
	MCNN	0.8167	0.7292	0.2354	0.3559
Str	LR	0.8117	0.3782	0.7401	0.5006
	RF	0.8132	0.8125	0.1364	0.2335
	NB	0.6574	0.2560	0.6247	0.3631
	SVM	0.8097	0.7439	0.2133	0.3315
Unstr	LR	0.7735	0.4009	0.6457	0.4946
	RF	0.7582	0.5769	0.0350	0.0659
	NB	0.7495	0.5658	0.1002	0.1703
	SVM	0.7727	0.5306	0.0606	0.1088

Figure 2 presents top 50 positive bag-of-words features with theirs font sizes proportional to their coefficients in the model. For the selected features, in most cases, these features appear to be clinically meaningful. For example, 'lasix' with highest coefficient in bag-of-words is one of the diuretics that can treat fluid retention and edema that might be caused by kidney dysfunction. Also, 'co' and 'ci' in bag-of-words is short for 'cardiac output and cardiac index', which assess whether a patient's heart is pumping enough blood and delivering sufficient oxygen to cells. Patients with abnormal cardiac output and even heart failure often have a higher risk of AKI [36]. The words 'insulin' and 'incisional' indicate diabetes mellitus comorbidity and procedural risks that may predispose AKI onset. Feature examination confirms that clinically meaningful key words in clinical notes can be used to predict AKI onset and the models we built do capture those words.

Discussions, Limitations and Future Work

Due to data accuracy concern, this study only uses the increase in creatinine to determine AKI. Should data that accurately record the decrease of GFR for a prolonged period exist, future studies will include both criteria to better capture AKI.

Table IV – Top physiologic variables that are associated with increased AKI risk by L2-regularized logistic regression.

Physiologic Variable	Weight
Creatinine level maximum (mg/dL)	4.8374
Mechanical Ventilation	0.4578
International normalized ratio maximum	0.2315
Potassium level maximum (mg/dL)	0.0589
Prothrombin time minimum (s)	0.0267
Estimated glomerular filtration rate (eGFR)	0.0199
Age (year)	0.0192
Diastolic BP mean (mmHg)	0.0101
Partial thromboplastin time minimum (s)	0.0095
Blood urea nitrogen level maximum (mg/dL)	0.0063

Figure 2 Ranked top 50 positive features in Bag-of-words with its coefficients as font size in AKI onset prediction by L2-regularized logistic regression.

When working with structured clinical variables, we have used MICE imputation to fill in missing entries [30]. In principle, MICE assumes the missing-at-random pattern, an assumption that almost certainly will not hold in real clinical practice, since clinicians often order tests under certain expectations about the likely results. However, our previous study shows that even when the missing-at-random assumption may not hold, in practice, MICE may still be used as an effective way and baseline for comparing other multiple imputation methods due to its simple implementation [32, 33]. On the other hand, missingness may represent no indication for having the test performed, hence may offer clinical information. Thus, we plan to investigate missingness patterns as additional predictors for AKI prediction in future studies.

When working with clinical notes, we only explored the bag-of-words model in conventional machine learning models and the word embeddings in mixed-feature CNN model. Though this yields promising performance, there are other options for using medical concepts as features such as through NLP pipelines including MetaMap [34], clinical Text Analysis and Knowledge Extraction System (cTAKES) [35]. Further investigation is necessary in order to identify which pipeline is the most suitable tool to generate medical concepts in disease prediction with clinical notes. In addition, we only explored mixed-feature CNN as one deep learning framework. Other deep learning architecture that is suitable for clinical dataset with mixed feature types and long text content are of future interest.

The improved model performance implies the potential clinical application in the near future. However, it requires further study and discussion to determine the model performance that is needed before it could be intergreted in clincal decision-making process.

Conclusions

Our study demonstrates that a supervised learning method that integrates both structured physiologic variables and unstructured clinical notes can be effective in early prediction of AKI onset in the first 72 hours following ICU admission for general adult patient population. We showed that carefully selected physiologic variables and well-represented clinical notes as features can predict new AKI onset with an AUC greater than 0.83, competitive with previous studies focused on specific patient groups or on novel biomarkers. Our work suggests that prospective trials with independent model training and validation cohorts are needed to further evaluate the clinical utility of this approach for identifying at risk patients early in their hospital course and potentially instituting interventions to decrease the likelihood of developing AKI.

Abstract

It is widely anticipated that the use and analysis of health-related big data will enable further understanding and improvements in human health and wellbeing. Here, we propose an innovative infrastructure, which supports secure and privacy-preserving analysis of personal health data from multiple providers with different governance policies. Our objective is to use this infrastructure to explore the relation between Type 2 Diabetes Mellitus status and healthcare costs. Our approach involves the use of distributed machine learning to analyze vertically partitioned data from the Maastricht Study, a prospective population-based cohort study, and data from the official statistics agency of the Netherlands, Statistics Netherlands (Centraal Bureau voor de Statistiek; CBS). This project seeks an optimal solution accounting for scientific, technical, and ethical/legal challenges. We describe these challenges, our progress towards addressing them in a practical use case, and a simulation experiment.

Keywords:

Health Information Systems, Data Science, Machine Learning

Introduction

A growing amount of personal health data are being collected by a variety of entities, such as healthcare providers, insurance companies, and wearable device manufacturers. Use of personal health data such as health status, current and prior medications, lifestyle and behavior offers unprecedented opportunities to augment our understanding of human health and disease. This contributes to improved diagnostic accuracy and efficiency [1,2], and facilitates the transition to preventive [3,4] and precision medicine [5–7]. Moreover, the analysis of health data can help governments pursue effective health policies while minimizing healthcare costs. Such innovation arises from the secondary use of health data for research.

However, a major barrier to research lies in the difficulty of accessing and analyzing health data that are dispersed in both their form (e.g. medical records, consumer activity, and social media), representation (structured, semi-structured, and/or unstructured), and stewardship (who is responsible for data collection and governance?). While many methods to represent and exchange healthcare data have been developed [8], there has been a lack of focus on legal-ethical concerns such as data ownership and data stewardship as well as issues relating to privacy, security, and confidentiality [9]. Such considerations are particularly crucial when use and analysis of health data involve multiple legal entities, different data standards, a lack of detailed provenance, and unclear access authorization procedures.

Another significant challenge lies in the analysis of personal health data from multiple sources. The simplest case is where data are horizontally partitioned, such that data about different sets of individuals are located in different sites. Analyzing these distributed data is relatively well understood and reduces to combining a set of models from each site. A more challenging case is where data are vertically partitioned: different attributes about a particular individual are distributed over a set of data sources. While in the case of horizontally partitioned data analytical results are combined afterwards, this is not possible in the vertically partitioned case since none of the data providers can execute the complete analysis independently of the other providers. This is particularly challenging either when there is a legal impediment to link records across data providers with a unique identifier or when this unique identifier is unavailable. Addressing this challenge effectively requires a great level of technical sophistication to simultaneously address legal and/or privacy constraints.

Instead of centralizing the data for the analysis, one could use distributed learning methods, which operate over vertically partitioned data. In such a scenario, data-processing algorithms are sent to each site, and can only return the results of an analysis rather than any of the original data. One such infrastructure is the Personal Health Train (PHT) [10,11], which sends applications (the trains) containing algorithms to the data sources (the stations). The station can inspect whether the train is allowed to execute the application on (a subset of) the available data. The PHT empowers data subjects with more control (who can access the data?) and transparency (what are the trains requesting?). Hence, the PHT facilitates authorized algorithmic processing in a secure manner at multiple data sites without requiring a transfer of (original) data to a centralized location. Moreover, the PHT implements privacy-by-design in the following ways: 1) it can restrict which data elements are available to an application, 2) it can restrict the results of the analysis to only processed data, rather than original data, and 3) no data party can see the data of other parties in the network.

Here, we describe an implementation of the PHT that uses a Trusted Secure Environment (TSE) to analyze vertically

partitioned data that are prepared in line with the FAIR principles (Findable, Accessible, Interoperable, Reusable) [12]. By describing data using the FAIR principles, the infrastructure becomes ambivalent to certain syntactic data structures (e.g. OHDSI, CDISC-ODM or HL7 v2/v3/FHIR), as the applications, executed at the data source, should be able to interpret different types of data structures. To test the feasibility of this infrastructure, we combine data from two independent data providers to investigate how Type 2 Diabetes Mellitus (T2DM) status affects healthcare cost. The first dataset comes from the Maastricht Study[1], an observational prospective population-based cohort study focusing on the etiology of T2DM, and the second comes from the official statistics office in the Netherlands: Statistics Netherlands[1] (Centraal Bureau voor de Statistiek; CBS). We present preliminary results involving simulated data and discuss the challenges and feasibility of such an infrastructure to be scalable and secure.

Methods

In this section, we describe the development of our proposed infrastructure from a scientific, technical, and legal perspective to support the workflow. Following is the description of our simulation experiment to test the usability of our infrastructure.

Development Workflow

The PHT architecture has been previously used to analyze horizontally partitioned datasets [13–16]. Here, we extend this work to include vertically partitioned data. While several studies discuss exchanging and analyzing vertically partitioned data [17,18], these are largely theoretical and overlook practical challenges, e.g. legal and ethical considerations, incompatible data management standards, scalability of the infrastructure, lack of financial support to sustain such efforts, and the technical requirements of learning from vertically partitioned data. To tackle these challenges, our team has established three interlocking work packages that target: i) the scientific questions in the medical domain; ii) the ethical, legal, and societal issues; and iii) the technical aspect. These packages are highly intertwined to ensure the development of practical solutions.

Scientific Perspective

To develop infrastructure that is useful to scientific researchers, we have identified key research questions that the infrastructure should help answer. Answering these research questions should require the combination of sensitive (non-public) data from multiple providers. To combine data from multiple providers, a substantive set of individuals should be shared by the providers and at least some attributes of these individuals are present in both datasets to enable linking of the data records (and not necessarily by some specific individual identifier).

ELSI Perspective

The Ethical, Legal, and Societal Issues (ELSI) team deals with two types of challenges: i) privacy concerns that arise from the special nature of personal health data[3]; and ii) the legal challenges that arise from working with multiple data providers with each a distinct governance framework. Combining data from multiple parties is a relatively new phenomenon, and often not foreseen when establishing the legal framework when the data are collected. Therefore, one of the major challenges has been to facilitate this study whilst adhering to the original legal framework and defined purpose. In doing so, the ELSI team has examined the reach of the original legal basis (i.e. informed consent) and purpose for which each data provider obtained the personal data, and is further analyzing the legal basis and purpose for which secondary processing can occur. Options that are being considered include but are not limited to the route of compatible processing and the route of scientific research in the public interest. Additionally, there are a number of limitations from the data providers themselves regarding accessing, sharing, and linking data. In addition, for this challenge, a legal framework has to be formulated in order to establish collaborations between the data providers, among themselves and with the research team. Constructing this legal framework and finding the proper legal basis for the researchers' team is a valuable contribution from the ELSI team.

Technical Perspective

Following the PHT architecture[2], we use the concepts of (FAIR data) stations[3], rails (infrastructure) and (applications) trains. The minimal requirement of a FAIR data station is to enable execution of applications, where data providers decide whether to execute the application. These FAIR data stations are based on Semantic Web technologies such as the Resource Description Framework (RDF) [19], to convert the source data[4], and make the converted data FAIR.

Application (train) developers (i.e., researchers) can create the application trains using Docker containers [20], which are lightweight virtual machines. The Docker container carries all required software packages to execute the application on board. These applications can for instance query data available in the data station, perform data cleaning/formatting, and execute machine learning or statistical analysis [15]. Only the results of these (analytical) applications are sent back to the application developers.

To implement the proposed infrastructure, we created three stations. Two FAIR data stations are at the Maastricht Study and at CBS. A third station was configured as a "Trusted Secure Environment" (TSE), containing no data by itself, however, acting as a trusted and independent entity. Additionally, we created two application trains. The first application train extracts the data from two data stations, pseudonymizes the personal identifiers, encrypts the dataset, and sends the data to the TSE station. The second application train decrypts the data and analyzes the data at the TSE. For every execution, both application trains are configured for proper encryption and security measures.

Experiment Design

Prior to feeding our infrastructure with real data, we conducted a simulation experiment with two scenarios where researchers combine data from two independent providers using a TSE station. We monitor time to obtain the analytical results for each scenario. Scenario 1 consists of two providers, A and B, each having the same (small) number of individuals; Scenario 2 consists of providers A and B, but provider B has a much larger set of individuals, including all Provider A's individuals. For these scenarios, we use data from a publicly available dataset which contains attributes that could be interpreted as sex, body mass index (BMI), number of children, smoking status, region, and health insurance reimbursement of participants [21]. Additionally, we generated artificial personal identifiers including date of birth, zip code, house number, and sex for linking purpose [22]. In practice, combining multiple datasets might be prone to record-linking errors. We will discuss this in more detail in the Discussion section. Please find this synthetic

dataset in Figshare[5]. This dataset is vertically split over the two providers: both have artificial personal identifiers (date of birth, zip code, house number, and sex). Only Provider A has BMI, number of children, and smoking status, while only Provider B has living region and health insurance reimbursement. In scenario 1, both providers have 1338 patients. In scenario 2, Provider A still has 1338 patients while Provider B hosts 64,400 patients. Since, Provider A in the second scenario only hosts a small subset of Provider B, a single record of Provider A might match with several records from Provider B. Even though this scenario is often encountered in practice, few solutions are available to address this linking challenge for vertically partitioned data [23].

For our experiment, we developed application trains using Docker 18.03.1. Pseudonymization, encryption, verification, and record linkage were implemented in Python 2.7. The infrastructure was tested with a 2.5GHz PC with 16GB RAM and 500 GB hard disk.

Result

In this section, we detail the contributions of each of the three work packages. Next, we discuss the outcome of the experiment.

Figures 1 and 2 provide an illustration of the infrastructure. In Figure 1, an overview of the operational framework for two providers, A and B, and a trusted secure environment, TSE, is presented. In Figure 2, we present the technical and legal requirements of the FAIR data stations. Researchers request permission to access and process data from the data provider. Once permission is granted, application trains to pseudonymize and encrypt the data are sent and executed in the data stations. Next, the encrypted data are sent to the TSE, followed by the data analysis application (from the researchers).

In the FAIR data stations (Figure 2), personal identifiers are pseudonymized by one-way hashing and salting techniques. One-way hashing turns any format of data into a fixed-length "fingerprint" that cannot be reversed. Salt, as a random string, is appended to data before hashing, to eliminate the risk of malicious decryption. We used Secure Hash Algorithm 2 (SHA-512) as the one-way hashing function and random salts are shared by two data providers to make personal identifiers pseudonymized on both sites. This results in a unique code per record, allowing linking the same records from all data providers. Every time data providers grant researchers permission to process/analyze the data, the personal identifiers get pseudonymized using different salts. The salt needs to be created and agreed upon by all data providers. Additionally, to safeguard secure transfer, processed data are encrypted, prior to sending them to TSE. The same as with the salt, encryption keys are re-generated every time.

The procedure then continues as follows: when the encrypted data are sent to the TSE, a notification is generated by the data stations to confirm the successful execution and departure of the train. After all encrypted data arrive at the TSE station, the researchers trigger analysis at the TSE with a set of keys and an application that includes code for the analysis. There is one private key per data station to decrypt the dataset, and one verification key to test the dataset integrity. The data station can only encrypt using the public key but cannot decrypt. The TSE station maintains the private key to decrypt for this specific data provider. After getting verified and decrypted data from both providers, the data can be linked and merged by pseudonymized personal identifiers. As the salted hashes performed at the data station are unknown to the TSE, it is not able to reverse or decrypt sensitive data such as personal identifiers. Thus, in addition to pseudonymization and encryption, the privacy of information is further protected as no data provider has direct access to the TSE. After executing the analytical algorithms on the merged dataset, the TSE checks whether the results reveal any personal identifiable information. Only the validated results such as figures and/or tables that do not contain any personal identifiable information are returned to the researchers. Finally, all (received and created) data in the TSE are destroyed.

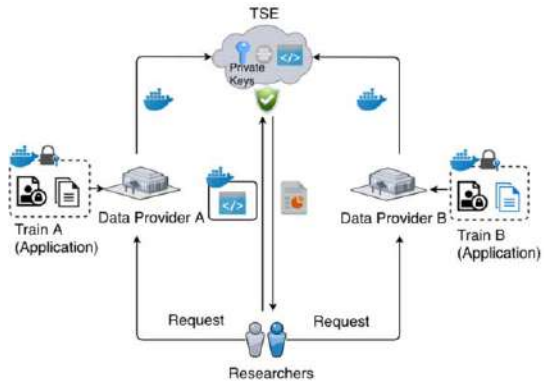

Figure 1 - Conceptual overview of the proposed infrastructure. Data access is regulated by the data provider hosting the stations. If access is granted, the data providers encrypt the data and send these to the TSE. The TSE executes the researchers' application and allows aggregated results to be returned to the researcher.

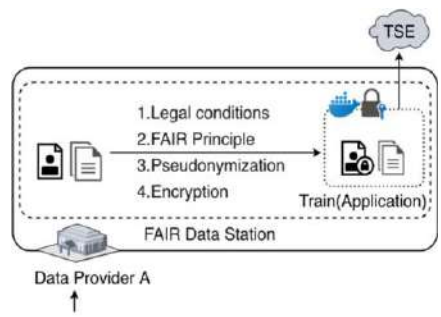

Figure 2 - Overview of data stations and application trains. Within each station, data are prepared, i.e., legal conditions are checked, FAIR principles implemented, personal identifiers pseudonymized, and encrypted. The application train enters the data station with algorithms and leaves with results or processed data.

Simulation Experiment

We used our proposed infrastructure to analyze synthetic data (discussed in the Methods section) that was vertically partitioned to form two datasets, each with a different data provider. Figure 3 shows one such result: a plot of BMI and health insurance reimbursement over one calendar year. While simple, the simulation experiment provides evidence for the feasibility of the infrastructure to execute an analysis, in this case, retrieval of a relation between two attributes in separate datasets in a secure and privacy-preserving manner.

[5] Find our synthetic datasets: https://doi.org/10.6084/m9.figshare.7379810.v2.

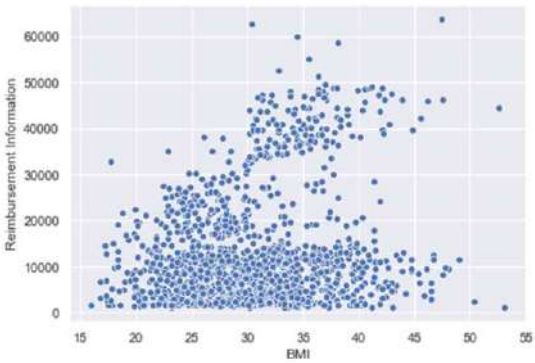

Figure 3. Plot of body mass index (BMI) versus health insurance reimbursement in the past year (dollars) from the analysis of a synthetic and vertically partitioned dataset using the proposed infrastructure.

We conducted an experiment with two scenarios. In the first scenario, where both providers host 1338 individuals, pseudonymization took 0.4 - 0.5 seconds and encryption took 0.1 - 0.2 seconds for each data station. At the TSE, verification and decryption spent merely 0.1 - 0.2 seconds, while record linkage took around 7.2 seconds. For the second scenario, where provider A hosts 1338 individuals and Provider B 64,400 individuals, pseudonymization for Provider B took 7.3 seconds and 2.5 seconds to encrypt. The total time cost at the TSE increased to about 15 seconds. From our experiment, we found that pseudonymization (at data stations) and record linkage (at the TSE) consumed approximately 80% of the running time. Future work will focus on operational performance measures, and among others, the size of provider datasets and number of attributes considered in linking.

Discussion

We have described and demonstrated a distributed learning infrastructure using artificial and vertically partitioned data involving two providers and a trusted secure environment. This is a preliminary, but promising result.

Our long-term goal is to deploy the infrastructure to analyze actual data from two independent organizations - Statistics Netherlands and the Maastricht Study. Thus far, we have requested data for 3451 consenting participants from the Maastricht Study, which is characterized by extensive phenotyping and provides information on the etiology, pathophysiology, complications, and comorbidities of T2DM. All participants are aged between 40 and 75 years and live in the southern part of The Netherlands. We requested those attributes which were complete and consented. Attributes include socio-demographic factors, lifestyle factors, the status of T2DM, physical function, mental functions, BMI, and cardiovascular disease history. From CBS, we requested regional population data of health insurance reimbursement available at Statistics Netherlands. As of November 2018, all application trains have been developed. We are in the stage of approving and building data stations for the Maastricht Study and CBS. A joint controllership agreement between the two organizations is established to enable the TSE. We are preparing analytic algorithms that will 1) answer scientific questions regarding the associations between T2DM status and healthcare costs, and 2) to evaluate the performance and security of our infrastructure.

Applying the infrastructure to real-world situations will present several challenges. Although we have only explored a two-data-provider scenario, we anticipate that it can be extended to more than two providers. While the performance of this system will depend on the size of the data and the algorithms used for encryption, merging, and analysis, we believe that the biggest bottleneck is in creating consortium agreements and deploying the infrastructure in individual facilities. As such, there is a need to further develop a "PHT" deployment kit that enables stakeholders to consider all the issues and options and make informed decisions in the most efficient manner. A second challenge in our implementation lies in the possibility of errors caused by linking vertically partitioned datasets. The accuracy of matching across these will decrease owing to missing data, typographical errors, differences in pseudonymization procedures, and different formats of identifying information. In addition, to match a fraction of records from multiple large datasets, the data providers could limit the size of their data by sending only a selection to TSE. This selection can be discovered and defined by sending exploratory or individual selection algorithms first. For instance, in our case, instead of sending the information of the entire Dutch population to the TSE, only a subset of the Dutch population which meets the criteria of the Maastricht Study sample is sent to the TSE. However, note that this selection might also leak information about the individuals in the data of (one or more) data providers. We intend to explore the impact of such aspects in future studies. A third challenge is how to manage and transport the keys securely among different parties. The TSE requires decryption and verification keys to decrypt the data and run the analysis algorithms. This approach must be agreed on by all parties from both technical and ethical-legal perspectives.

Conclusions

To analyze vertically partitioned data, we extended a Personal Health Train (PHT) infrastructure to send data analysis algorithms to multiple data stations and return only the results instead of the original data to the researchers.

This infrastructure was developed in a coordinated manner across multiple scientific, technical, ethical, legal, and societal aspects involving several units and organizations. This coordination across interests is essential to explore viable solutions for data sharing and reuse, as envisioned by the proponents of the FAIR principles. In particular, the idea of bringing the algorithm to the data, rather than obtaining consent to receive a copy of the data, offers an entirely new paradigm that has not been considered by most organizations. Having a new paradigm will require stakeholders to take the time and effort to thoroughly evaluate this in terms of their legal and technical requirements. However, as our experiment shows, it offers a more scalable and secure solution to analyze vertically partitioned data in a secure and privacy-preserving manner. Additional operational and security enhancements are still needed before the infrastructure is suited to deal with real (sensitive) data. Future work will explore the quality of scientific discovery (accuracy of outcome), the security, scalability, sustainability, and performance of computation. While no solution will be perfect for all situations, we believe that this adaptation of the PHT model will find utility in situations involving sensitive data with a multitude of stakeholders.

Abstract

An attractive feature of non-lattice-based ontology auditing methods is its ability to not only identify potential quality issues, but also automatically generate the corresponding fixes. However, exhaustive manual evaluation of the validity of suggested changes remains a challenge shared with virtually all auditing methods. To address this challenge, we explore machine learning techniques as an aid to systematically evaluate the strength of auto-suggested relational changes in the context of existing knowledge embedded in an ontology. We introduce a hybrid convolutional neural network and multilayer perception (CNN-MLP) classifier using a combination of graph, concept features and concept embeddings. We use lattice subgraphs to generate a curated, loosely-coupled training set of positive and negative instances to train the classifier. Our result shows that machine learning techniques have the potential to alleviate the manual effort required for validating and confirming changes generated by non-lattice-based auditing methods for SNOMED CT.

Keywords:

Non-lattice-based auditing, SNOMED CT, neural networks

Introduction

Non-lattice-based ontology auditing methods are based on the principle of Formal Concept Analysis. They have shown effectiveness in suggesting missing hierarchical relations (or IS-A relations) and concepts in SNOMED CT (SNCT) [1-3] as well as other teminology systems. A non-lattice-based approach consists of the following steps: extracting non-lattice subgraphs with concept pairs voilating the lattice property; detecting defects in the extracted non-lattice subgraphs; suggesting relational changes automatically; and reviewing and validating suggested changes by an ontology curator or a domain expert. Figure 1 shows a non-lattice subgraph in the September 2017 release of SNOMED CT (US edition) [3]. Examination of this subgraph reveals a missing hierarchical relation between nodes 4 and 5: "*Transient neonatal hyperglycemia*" IS-A "*Acute hyperglycemia.*"

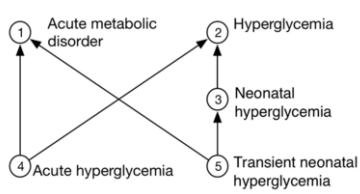

Figure 1 - An example of non-lattice subgraph [3].

However, human review of change remediations requires significant manual effort. The main motivation of this paper is to explore machine learning (ML) techniques as an aid to systematically evaluate the strength of auto-suggested relational changes using existing knowledge embedded in an ontology. Specifically, change predictions resulting from the IS-A relation prediction classifier can be compared with change suggestions using non-lattice subgraphs by assessing their agreement. When such an approach is used to audit the IS-A relations, it can bring benefits in two ways: the agreement between the ML prediction and non-lattice-based prediction can provide independent confirmation of the suggested IS-A changes, while disagreements may point to areas for improvements for both types of approaches. Furthermore, change suggestions generated by ML techniques may provide ranked list of changes based on numeric "strengths." If an ML technique can reach a high level of performance (using e.g. precision and recall measures), it may serve as an independent auditing approach by itself independent of non-lattices.

ML techniques have been widely used in knowledge graphs [4]. To arrive at an optimal subset of features, CNN has been used to automatically learn features [5]. Also pretrained word embeddings [6] have proven to be useful in neural network models for relation extraction. Recent study further improved performance by incorperating additional hand-crafted features [7]. Inspired by this, we propose a hybrid CNN-MLP classifier for IS-A relation prediction by exploring various knowledge in SNCT. Besides of concept embeddings, we analyze lexical and graph structural information in the entire directed acyclic graph (DAG) of SNCT, such as semantic meaning inheriting concept ancestors. Pesquita et al. [8] summerized two main semantic similarity approaches in an ontology graph for comparing concepts: node-based and edge-based. In this work, we aggregate node-based and edge-based similarity approaches as graph level features. Despite concept embeddings can present semantic meaning of concepts, we still handcraft concept level features as task specific features. Non-lattice-based auditing methods suggest IS-A relational changes to correct defects in non-lattice subgraphs and form lattice subgraphs [1-3]. Accordingly, constructing training set from lattice subgraphs equips us with the same objective of non-lattice-based methods.

In this paper, we introduce an ML approach to validate auto-suggested insertion changes from non-lattice-based auditing methods. Combining various knowledge in lattice subgraphs and DAG of SNCT, we implement IS-A relation prediction and auto-insertion change suggestion as two subtasks in the workflow of validation. We apply CNN to explore the concept pair features in concept embeddings and combine the output of CNN with handcrafted graph, concept features via MLP to

predict IS-A relations of concept pairs. Also evaluation metrics for subtasks are provided. Evaluation of our validation method is implemented on a reference set.

Methods

Our method consists of two main steps. In the first step, learning from various knowledge embedded in lattice subgraphs of SNCT, a hybrid CNN-MLP classifier is designed to predict IS-A relations of concept pairs. In the second step, based on the idea of majority voting [10], we validate the given insertion changes with predicted insertion changes generated by the classifier.

Relation Prediction

Figure 2 is an overview of our relation prediction workflow. First, we generate a training set using lattice subgraphs. Second, we pretrain concept embedding and develop graph and concept level features. Finally, we predict IS-A relations of concept pairs with a hybrid CNN-MLP classifier.

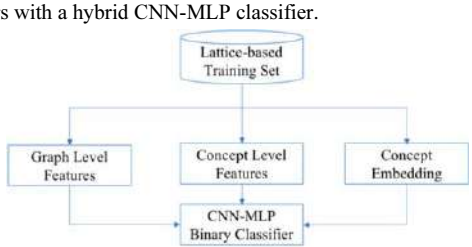

Figure 2-An overview of the IS-A relation prediction workflow

Lattice-based Training Set

A desirable property of the IS-A relationship is that it conforms to the lattice property [9]. This is also a by-product of non-lattice-based auditing methods: non-lattice subgraphs often become lattice-conforming by correcting hierarchical defects (e.g., inserting IS-A relations). Using this as working principle, we construct the training set for our CNN-MLP classifier using relations embedded in lattice subgraphs. Lattice subgraphs also allow us to naturally select a balanced set of positive samples and negative samples. Extracting all lattice subgraphs in SNCT, we construct a lattice-based training set with the following steps.

1. Select a subset of concepts with label length, which is the number of words in a label, no longer than α. We denote this set of concepts as $Con(\alpha)$.
2. Among all lattice subgraphs, choose those with size, which is the number of concepts in a subgraph, no more than β, denoted as $Lattice(\beta)$, and find those that contain any concept in $Con(\alpha)$.
3. Form a positive training set by extracting IS-A edges and their transitive closure from step 2. Form a negative training set by extracting non-edge node pairs in step 2.

Concept Embedding

Learning from current ontologies, the embedding techniques [6] allow us to represent concepts and capture latent semantic properties of concepts. In SNCT, each concept contains an associated human readable label, and concepts occuring in the same relation could describe each other. We take relations represented with labels as sentences to learn word embeddings. After perfoming a few basic text preprocessing steps, such as removing punctuations and digits, converting to lowercase and stemming, we use a skip gram word2vec model [6] to produce word embeddings with 200 dimensions. To generate concept embeddings, a sequence of words in concept labels are transformed to a set of vectors by looking up pretrained word embeddings. The out-of-vocabulory (OOV) word is assigned a vector with zeros. Then the word embeddings are summed into a single embedding as a concept embedding.

Feature Development

The IS-A relation comes with a source concept C_1 and a destination concept C_2. We develop features based on two types of observations. One is that from global graph level of entire IS-A DAG in SNCT, a concept at a lower level inherits semantics from its ancestors and is more specific in terms of the biomedical meaning [11]. The other is that measured from local level of concept pairs, if there are overlaps in noun phrases of C_1 and C_2, the noun phrase in C_1 usually contains more words than C_2 as C_1 becomes more specific. The more overlaping words the two concepts have, the more likely they should form an IS-A relation.

Graph level features. The work of Zhang et al. [11] and Cui et al. [3] provides several heuristics to generate graph level features. Considering concept semantics inherited from its ancestors and path information, we design three graph level features for situations of a concept pair to be in an IS-A relation. All graph level features are explored from the entire active IS-A graph of SNCT.

1. Graph level dissimilarity. The semantic of a concept could be specified through a path to its descendants, that is, a concept inherits all semantics from its ancestors. A pair of concepts, inheriting semantics from different paths, may have some common ancestors. Non common ancestors of C_1 distinguished C_1 from C_2, then the graph-level dissimilarity can be characterized by
$$GraphDissim(C_1,C_2)=1\text{-}CA(C_1,C_2)/A(C_1)$$
where $CA(C_1,C_2)$ is the common ancestor set of C_1 and C_2, and $A(C_1)$ is the ancestor set of C_1.
2. Graph level similarity. The semantic of a concept could be simplified with a concept label. While a given concept inherits semantics from its ancestors, the concept labels of ancestors could be used to enrich the label of the concept. For an IS-A relation (say C_1 IS-A C_2), because C_1 is more specific than C_2, the enriched label of C_2 maybe a part of enriched label of C_1, so we define graph level similarity as
$$GraphSim(C_1,C_2)=CEL(C_1,C_2)/EL(C_2)$$
where $CEL(C_1, C_2)$ is the common enriched label set of C_1 and C_2, and $EL(C_2)$ is the enriched label set of C_2.
3. Path comparison. If C_1 IS-A C_2, we assume that C_2 has a shorter path to the root R than C_1 does. We define a flag feature indicating whether the shortest path from C_2 to R is shorter than that of C_1 to R.

Concept level features. This category of features concerns about properties of labels in concept pairs.

1. Chunk comparison. We observe that if there are overlaps between noun phrases in C_1 and C_2, the noun phrase in C_1 usually has more words than that in C_2. We design two flag features from all the extracted noun phrases in both C_1 and C_2 to indicate word number comparison of noun phrases in C_1 and C_2 separately.
2. Concept level overlap. This feature considers overlaps of pairwise concepts. We define it as:
$$ConceptOLP(C_1,C_2)=W(C_1)\cap W(C_2)/W(C_2)$$
where $W(C_1)\cap W(C_2)$ is the overlapped word set of C_1 and C_2, and $W(C_2)$ is the word set of C_2. High value lesser than one implies that the meaning of C_1 approaches the meaning of C_2.
3. Concept level similarity. This feature concerns about the consine similarity of disjoint words in C_1 and C_2, and

disjoint words are represented with the summation of word embeddings.

Neural Network Classification

We design a hybrid CNN-MLP binary classifier to incorporate concept embedding and handcrafted features (see Figure 3).

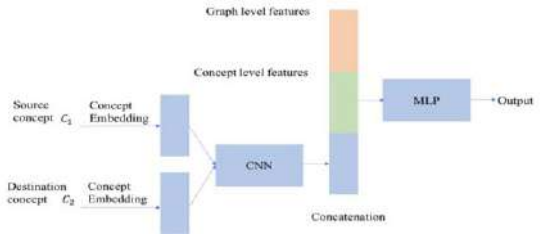

Figure 3 - Architecture of hybrid CNN-MLP binary classifier

We convolute the embeddings of concept pairs with 100 filters of window size 2 to get local features and use ReLU activation function. In order to fomulate a balanced feature vector between embeding features and handcrafted features, we transfer 100 dimension vector into 10 dimension vector by fully connected layer in CNN, which then is concatenated with graph level and concept level features. The concatenated feature vector is fed into a one layer MLP with active function of ReLU for the hidden layer and sigmoid for the output layer. In order to evaluate the performance of features, we feed MLP with different feature combinations, thus the number of neurons of MLP hidden layer is decided by the average of neurons in MLP input and output layers. Time complexity of neural network depends on the architechture, especially the number of neurons, of the network.

Validation of Auto-Suggested Insertion Changes

The objective of our work is using an ML approach to validate auto-suggested insertion changes. The validation workflow involves four stages: test set generation, relation prediction, auto-insertion change suggestion, and majority voting based validation. In stage 1, non-lattice-based auditing method [3] provides a set of non-lattice subgraphs containing auto-suggested insertion changes. IS-A relations and their transitive closure (positive instances), and non-edge concept pairs (negative instances) are extracted from the given non-lattice subgraphs to form a test set. In stage 2, the IS-A relations of extracted positive instances and negative instances are predicted by our hybrid CNN-MLP binary classifier. In stage 3, we retrieve top N predictions ranked by IS-A relation probability outputs. The predicted false positives are the set of auto-suggested insertion changes provided by our classifier. In stage 4, inspired by majority voting [10], we confirm the auto-suggested changes with the agreement between our classifier and the given auditing method. In this way, relational ML techniques alleviate the manual validation effort by confirming and validating changes automatically.

In the validation workflow, our classifier is used in two subtasks: predicting IS-A relation of concept pairs in stage 2, and automatically suggesting insertion changes in non-lattice subgraphs in stage 3. To evaluate performance of subtasks and determine configuration of the classifier for the validation task, we specify a test set, a reference set and evaluation metrics next.

Test Set and Reference Set

To evaluate our method, we use relations in a random sample of 200 non-lattice subgraphs from [3] as a test set, which contains 1,545 IS-A and transitive closure of IS-A edges (positive instances), 3,019 non-edge node pairs (negative instances). A total of 223 insertion changes were auto-suggested for the 200 non-lattice subgraphs [3]. Two domain experts confirmed 185 suggested insertions (a precision of 82.96%), which serve as a reference set for evaluating the performance of this work.

Evaluation of Relation Prediction

To thoroughly analyze the relation prediction part along, e.g., comparing training set parameters (α,β) and different categories of features, we predict 1,545 positive instances and 3,019 negative instances in the test set. For evalution, we report the precision-recall curve.

Evaluation of Auto-Suggested Insertion Changes

Motivated by precision and recall metrics, Zhang et al. introduced insertion recall, insertion precision and insertion G-measure [12] to evaluate an ontology quality assurance (OQA) method against validated changes. They considered an OQA method M as a group of subgraphs. Each xsubgraph may potentially capture missing IS-A relations as edges. A subgraph s is a graph consisting of a set of IS-A relations. E is a reference set of validated missing IS-A relations. Then the insertion recall, precision and G-measure are defined as:

$$R_{insert}=\frac{|\{r\in E/\exists s\in M, r\in s\}|}{|E|}$$

$$P_{insert}=\frac{|\{s\in M/\exists r\in s, r\in E\}|}{|M|}$$

$$G_{insert}=\sqrt{P_{insert}\times R_{insert}}$$

Our classifier outputs probabilities which can be used to rank instances in the test set from most probable IS-A relation to the least. In order to demonstrate the ability to validate auto-suggested changes, we treat our method as an OQA method and take top N predictions as predicted IS-A relations. False positives predicted by our classifier are auto-suggested insertion changes. The reference set contains 185 validated missing IS-A edges and their transitive closure. We use R_{insert}, P_{insert}, G_{insert} [12] to evaluate auto-suggested insertion changes obtained via our method. The higher the G_{insert}, the greater the agreement between our method and domain expert's validation, that is, more likely our method has the ability to alleviate the manual effort required for validating auto-suggested changes.

Results

Dataset and Implementaion

We used the September 2017 version of SNOMED CT (US edition) in this work. We constructed a lattice-based training set [1] by varying label length α and lattice size β. The statistics of training set are shown in Table 1. While relation prediction performance was evaluated with the test set, the reference set was used to evaluate auto-insertion change suggestion. We implemented the model using Keras [13]. Declaring binary cross entropy as the loss function, we ran 10 epochs for all the training examples. Noun phrase chunk detection and preprocessing for learning embeddings were implemented with NLTK [14].

Table 1 - Statistics of Training Set

	# of positives	# of negatives
$\alpha=5,\beta=5$	151,553	243,197
$\alpha=5,\beta=10$	515,954	1,005,074
$\alpha=10,\beta=5$	197,630	319,286
$\alpha=10,\beta=10$	693,776	1,351,872

Relation Prediction

Experiments were performed to evaluate IS-A relation prediction by permuting training set construction parameters and various feature categories. The experiments were performed on a MacBook Pro running MacOS Sierra, with 16 GB RAM and 2.7 GHz Intel Core i7 processor.

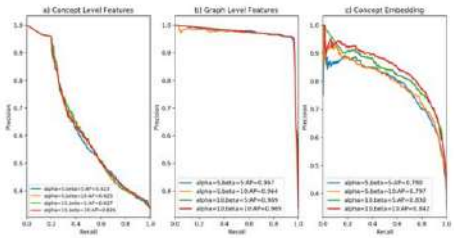

Figure 4 - The performance of relation prediction varying feature categories and training set construction parameters

Comparing Figure 4a), 4b) and 4c), the best prediction performance was produced with graph level features. When recall of IS-A relations was increased, the precision was decreased with concept level features. Though concept embeddings and concept level features both describe sementics of concept pairs, concept embeddings worked better than handcrafted concept level features.

Figure 4a) shows that longer concept label expresses concept level features more effectively, slightly leading to prediction performance improvement. Figure 4b) shows that graph level features are independent with label length α and lattice size β which is coincident with development of graph features, especially while increasing recall. As for the feature category of concept embeddings, prediction performance varied with different settings of training set parameters, which may be explained by Table 2 by OOV word rate over test set while looking up pretrained word embeddings. More OOV words in test set resulted in decrease of relation prediction performance.

Table 2 - Out-of-vocabulary word rate over test set

	$\alpha = 5$ $\beta = 5$	$\alpha = 5$ $\beta = 10$	$\alpha = 10$ $\beta = 5$	$\alpha = 10$ $\beta = 10$
OOV rate	4.4%	3.7%	3.0%	2.6%

Figure 5 shows that combining graph level features, concept level features and concept embeddings as the input of MLP had led to performance improvement. The best average precision was 0.972, achieved with $\alpha=5$, $\beta=5$. Overall, our experiments showed that exploring various features was effective for IS-A relation prediction.

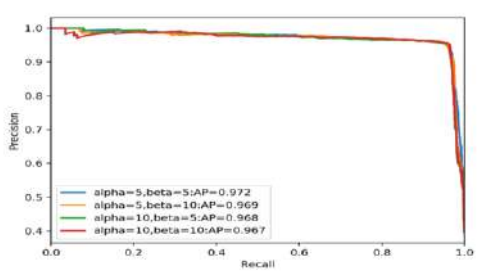

Figure 5-The performance of relation prediction with feature combination varying training set construction parameters

Auto-Suggested Insertion Changes

In this set of experiments, we evaluated our auto-suggested insertion changes for non-lattice subgraphs. A set of 185 validated missing IS-A relations was taken as the reference set. Among top N IS-A relation predictions, we evaluated auto-suggested insertion changes by R_{insert}, P_{insert}, G_{insert} values as defined in the subsection of auto-suggested insertion changes evaluation. Informed by the previous experiments, we configurated this set of experiments with feature combination and setting $\alpha=5$, $\beta=5$.

The test set contained 1,545 positive instances and 3,019 negative instances. Ranked by probability outputs of our classifier, we kept top N predictions as IS-A relations (predicted positive instances). Predicted false positives constituted insertion change suggestions in the non-lattice subgraphs. The top 1,500 predictions contained 129 IS-A relations already identified in the reference set of 185 validated missing IS-A relations. As we retrieve more predicted IS-A relations from the ranked list (i.e., as N increases), we obtain more validated missing IS-A relations. Note that both insertion recall (R_{insert}) and insertion precision (P_{insert}) increase as N increases. We stopped retrieving predictions at N=2,000 in case more irrelevant IS-A relations out of the referece set would be included.

Table 3 - Evaluation of auto-suggested insertion changes at top N predictions

Top N	R_{insert}(%)	P_{insert}(%)	G_{insert}(%)
1500	69.57	59.80	64.50
1600	80.98	69.35	74.94
1700	85.32	72.36	78.57
1800	86.41	72.86	79.35
1900	89.67	75.38	82.22
2000	90.21	75.88	82.74

Compared with the reference set, Table 4 shows examples of auto-suggested insertion changes from top 2,000 predictions in and out of the reference set. For those out of the reference set, they may reveal additional insertation changes needed to make non-lattice subgraphs conforming to the lattice property.

Table 4-Examples of auto-suggested insertion changes compared with the reference set

In the reference set

Source Concept	Destination concept
Thoracic spondylosis	Spondylosis
Sclerema neonatorum	Neonatal dermatosis
Acute empyema of sphenoidal sinus	Sphenoidal sinusitis
Oculocutaneous albinism	Congenital anomaly of eye
Degloving injury of genitalia	Degloving injury of perineum

Out of the reference set

Source concept	Destination concept
Echography scan B-mode for fetal growth rate	Ultrasound scan of fetus
Dilatation of anastomosis of bile duct	Biliary dilatation procedure
Feeding problems in newborn	Feeding problem
Physiological mobilization of the shoulder	Procedure on shoulder region
Carcinoma in situ of lower labial mucosa	Tumor of lower labial mucosa

The evaluation results and examples of auto-suggested insertion changes indicated that our method is effective to predict IS-A relations of concept pairs. Verified by the reference set, our method automatically suggested insertion changes for non-lattice subgraphs.

Validation of Auto-Suggested Insertion Changes

The performances of two subtasks in the workflow of validation, relation prediction and auto-insertion change suggestion, have been demonstrated to be promising by two sets of experiments. Configured with feature combination and $\alpha=5$, $\beta=5$ for the classifier, we evaluated 223 auto-suggested insertion changes in the test set. We compared insertion

changes resulting from our classifier with the given 223 insertion changes, and those changes with agreement were validated. The number of insertion changes validated by our classifier is shown in Table 5. Since 185 insertion changes were validated by domain experts, we also showed the number of expert-validated insertion changes among our classifier's validation. Validated by our method, the auto-suggested insertion change precision improved from 82.96% to 86.46%. We can further alleviate manual effort by narrowing down the number of insertion changes with the improvement of precision.

Table 5 – Validation evaluation at top N predictions compared with the reference set

Top *N*	# of Classifier Validated	# of Expert Validated	Precision (%)
1500	150	129	86.00
1600	174	149	85.63
1700	183	157	85.79
1800	185	159	85.95
1900	191	165	86.39
2000	192	166	86.46

Discussion

In this paper, we introduced a relational ML-based validation approach, CNN-MLP, to alleviate manual effort required for validating change suggestions in ontology auditing work. In addition to validating auto-suggested insertion changes, our experiments indicated that CNN-MLP classifier may be effectively used in tasks of concept pair relation prediction and ontology auditing. As shown in Table 4, five auto-suggested insertion changes were out of the reference set; although they were not used to validate change suggestions, they may provide additonal candidates for change redemiations.

Evaluated with the reference set, the performances of auto-suggested insertion change and auto-suggested insertion change validation look promising. However, note we have not addressed the task of auto-deletion change suggestion and deletion change validation due to the lack of the reference set containing validated deletion changes. Labeled data (or reference set) is required in the framework of supervised ML approach. SNCT is updated by domain experts twice a year, and it may be possible to treat insertion and deletion changes in different versions of SNCT as labeled data for ML based auditing or validation.

Conclusions

We have presented an ML approach to validate insertion changes generated by non-lattice-based auditing methods. In validation workflow, we introduced a hybrid CNN-MLP classifier to predict IS-A relations of concept pairs, and automatically suggest insertion changes for non-lattice subgraphs. Experiments on IS-A relation prediction achieves an average precision of 0.972, and auto-suggested insertion changes achieves F_{insert} of 82.43% with top 2,000 predictions, which indicate the potential of our classifier to validate IS-A insertion changes. Validated with insertion changes resulting from our classifier, the precision of a given set of auto-suggested IS-A insertion changes is improved from 82.96% to 86.46%.

By cumulating SNCT deletion changes as a surrogate reference set for ML approaches [12], our future work will focus on exploring features to predict potentially incorrect IS-A relaitons for validating auto-suggested deletion changes in non-lattice subgraphs.

Detecting Systemic Data Quality Issues in Electronic Health Records

Casey N. Ta[a], Chunhua Weng[a]

[a] *Department of Biomedical Informatics, Columbia University Irving Medical Center, New York, NY, USA*

Abstract

Secondary analysis of electronic health records for clinical research faces significant challenges due to known data quality issues in health data observationally collected for clinical care and the data biases caused by standard healthcare processes. In this manuscript, we contribute methodology for data quality assessment by plotting domain-level (conditions (diagnoses), drugs, and procedures) aggregate statistics and concept-level temporal frequencies (i.e., annual prevalence rates of clinical concepts). We detect common temporal patterns in concept frequencies by normalizing and clustering annual concept frequencies using K-means clustering. We apply these methods to the Columbia University Irving Medical Center Observational Medical Outcomes Partnership database. The resulting domain-aggregate and cluster plots show a variety of patterns. We review the patterns found in the condition domain and investigate the processes that shape them. We find that these patterns suggest data quality issues influenced by system-wide factors that affect individual concept frequencies.

Keywords:

Electronic Health Records; Cluster Analysis; Data Accuracy

Introduction

Secondary reuse of observational health data for research is increasing in importance and popularity as electronic health data become more available and analytic methods become more powerful. However, analysis of electronic health records (EHR) continues to face many social and technical challenges, including data inaccuracy, incompleteness, and biases implicit in the healthcare recording process [1–5]. Since observational clinical data are sourced from disparate systems not designed for research purposes, researchers consuming these data must clearly understand the nuances of their data. Due to the complexity of interactions, ongoing development, and technical challenges of these systems, events that impact data integration can occur without awareness from data managers. Further, experts knowledgeable of the intricacies of the data may not be available to researchers, especially in the context of shared data in collaborative research networks, such as the Observational Health Data Sciences and Informatics (OHDSI) [6].

EHR data quality is receiving increased attention for its effects on secondary analysis for clinical research and population health informatics [7–10]. Temporal trend analysis is a common method of assessing data quality. Kahn's harmonized data quality framework includes temporal plausibility metrics, such as comparing data value density over time against expected values [7]. Hall's database guidelines recommend counting frequency of records and field occurrences over time to identify blocks of missing data or changes in data volume [8]. Brown et al demonstrate visually exploring trends of intrasite and intersite frequency to detect data anomalies [9]. ACHILLES performs temporal analysis of concepts in Observational Medical Outcomes Partnership (OMOP) databases to assess month-to-month stability of counts and flags changes that exceed thresholds [6]. These methods enable detection of data quality issues in individual variables but do not detect systemic issues that may affect multiple variables.

The Columbia University Irving Medical Center (CUIMC) Clinical Data Warehouse (CDW) formatted using the OMOP Common Data Model (CDM) (herein referred to as the OMOP database) contains observational data on nearly 60,000 concepts. Individual analysis of 60,000 concepts would be prohibitively time consuming. Although population prevalence of clinical concepts can change with time, we hypothesize that common patterns of temporal trends in EHRs reveal systemic factors that influence observational data and data quality.

In this manuscript, we present methods of detecting systemic, population-level data quality issues in electronic health records by analyzing domain-level aggregate statistics and identifying common temporal patterns across concepts. We apply these methods to the CUIMC OMOP database and infer and investigate system wide processes that affect the data quality.

Methods

Data Source

This study received institutional review board approval with waiver for obtaining informed consent. The CUIMC CDW contains records from multiple sites and was converted to OMOP CDM v5.1 in March 2018. Diagnoses ("conditions" in OMOP nomenclature), drugs, procedures, and visit types were collected from CUIMC's OMOP database from the *condition_occurrence*, *drug_exposure*, *procedure_occurrence*, and *visit_occurrence* tables, respectively. We analyze conditions, drugs, and procedures to provide multiple views of patient data and visit types to indicate clinical service capacity.

Conceptual Framework

Figure 1 shows our conceptual framework for analysis. There are four entities: patients, concepts, domains, and time. Patient health is characterized in the OMOP database by individual concepts, which are categorized by domains (e.g., conditions, drugs, and procedures). For each concept, we count the number of patients in each year and plot the counts over time. Data captured in EHRs are affected by population health status, health service capacity, medical coding protocols, and operation of clinical databases. These parameters change over time, as reflected in the counts and frequency of concepts.

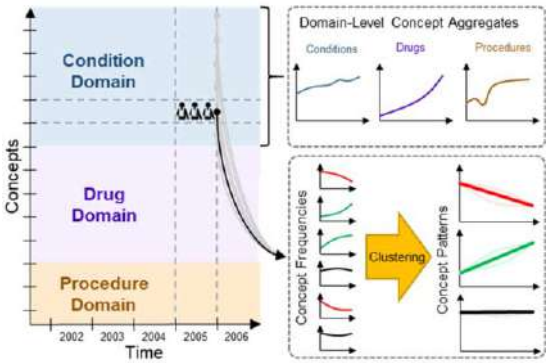

Figure 1– Conceptual framework for analysis.

Concept Prevalence

We assume that population health is consistent with only minor changes annually and gradual changes over many years [11]. Correspondingly, we assume the annual frequency of most clinical concepts to be relatively stable over time if the health system is stable. Observed fluctuations in concept frequencies may have causes intrinsic to the concept (e.g., outbreaks or new interventions) or extrinsic to the concept (e.g., expansion of clinical services). We measured yearly counts and frequencies of concepts from the OMOP database. We defined counts as the number of unique patients with the concept per calendar year. We defined frequency as the count divided by number of patients in that year. We estimated the number of patients per year from the number of unique patient identifiers associated with at least one condition, drug, or procedure per year.

Domain-Level Concept Aggregates

Given a stable healthcare system, we hypothesize the domain-level aggregated metrics are highly stable over time. Fluctuations in these metrics may reflect changes to healthcare services or the EHR recording process. To identify global trends in each domain, we analyzed the yearly patient count and yearly aggregated statistics across concepts in condition, drug, and procedure domains using the domain of each concept as defined in the OMOP standard vocabulary to aggregate concepts. We analyzed four aggregated statistics across each domain per year: 1) the total patient counts across concepts; 2) the count-per-capita (total patient count divided by number of patients), indicating the average number of conditions, drugs, or procedures per patient; 3) the number of unique concepts; and 4) the mean frequency across concepts.

Clustering of Concept Patterns

Analyzing thousands of individual concept frequencies would be overwhelming and difficult to differentiate between changes in the population prevalence versus changes affecting the recorded prevalence in EHRs. To identify common behavior patterns with similar trends among concepts, we performed K-means clustering [12] within each domain. Each concept's annual frequencies were normalized to unit magnitude and treated as vectors. We used concept frequency instead of count to normalize against population changes. We normalized frequencies to unit magnitude to match trends with similar proportional changes. Annual frequencies from calendar years 1985 to 2017 were included; we excluded 2018 since data was not yet available for the entire year. We excluded concepts with maximum frequency below 0.01% of the population to reduce noise from infrequent concepts. We performed K-means clustering on the normalized frequency vectors. We manually selected K by clustering each domain with different levels of K (4, 6, 8, 10, 12, 15, 20, and 25) and selecting the smallest K before intracluster variance ceased to improve substantially.

Post-hoc Analyses

To determine if the clustered concept patterns reveal systemic factors (e.g., changes in health service capacity or medical coding protocols) that affect concept frequency in the database, we manually reviewed the domain- and concept-level patterns, arriving at hypotheses on the causes of several patterns. We performed post-hoc analyses to validate these hypotheses.

Results

As of March 2018, the CUIMC OMOP database contains EHR records on 5,368,414 patients, covering 59,583 concepts, including 18,399 conditions, 18,691 drugs, and 22,787 procedures spanning October 1985 to March 2018.

Domain-Level Concept Aggregates

Figure 2 shows plots of the domain-level count-per-capita and total counts of a) conditions, b) drugs, c) procedures, and d) people per year. Patient counts are relatively flat between 1986-2001, except for a slight depression from 1992-1995, and grows steadily from 2001-2010 and rapidly after 2010, with a spike in 2014. The condition domain total count and count-per-capita increase nearly linearly over time. The condition count-per-capita is slightly unstable before 2000 but steadily increases after 2000, peaking in 2015 and dropping in 2016-2017. The total count of conditions spikes in 2014. Drug data is nearly non-existent before 2001 but steadily increases until it peaks in 2013. The drug count-per-capita drops substantially in 2014 and fluctuates through 2017. The procedure domain is the most unstable. Procedures display notable growth in 1989, a large spike in 1996-1997, rapid increase from 2001-2005 and steady

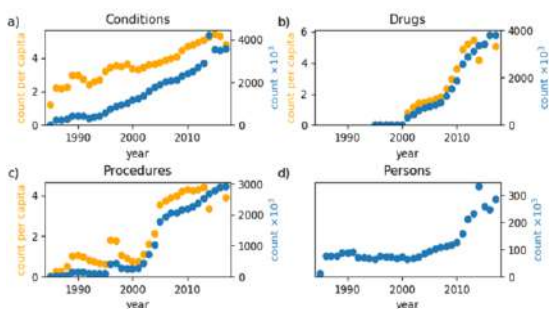

Figure 2– Total count (blue) and count-per-capita (orange) of a) conditions, b) drugs, c) procedures and d) people per year.

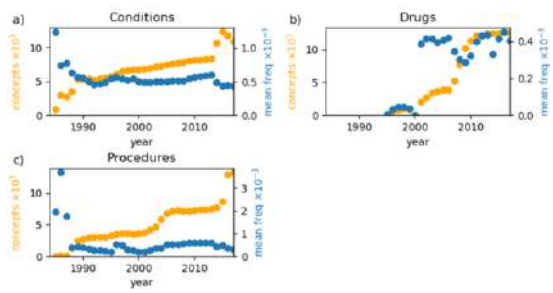

Figure 3– Count of unique concepts (orange) and the mean frequency of concepts (blue) per year for a) conditions, b) drugs, and c) procedures.

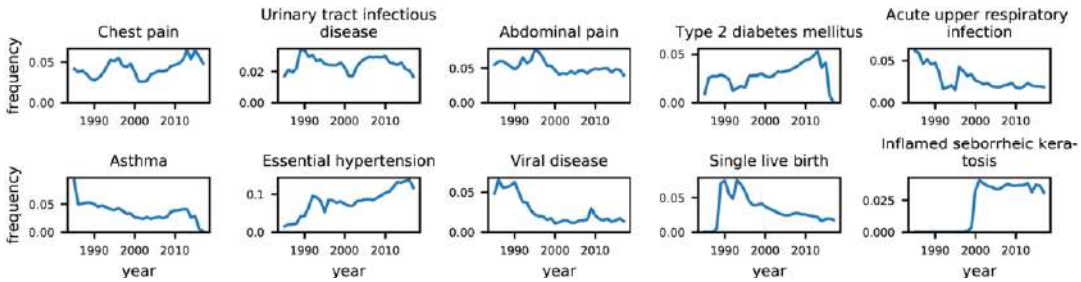

Figure 4– Example annual concept trends for the ten most prevalent conditions.

increase thereafter. Similar to drug count-per-capita, procedure count-per-capita drops in 2014 and fluctuates through 2017.

Figure 3 shows the annual number of distinct concepts and the mean frequency of patients across concepts for each domain. The condition domain stably grows from 1989-2013 but fluctuates thereafter. The drug domain is relatively stable from 2001-2006 but fluctuates thereafter. In the procedure domain, the number of concepts stably grows from 1989 to 2001, grows quickly to 2005, slowly grows through 2014, and quickly grows again. The mean frequency of procedure concepts has similar periods of behavior with an additional sharp increase in 1996.

Concept-Level Analyses

Due to space limitations, we primarily present and discuss the results for concept-level analyses in the condition domain and exclude drug and procedure results. Figure 4 plots annual frequencies for the ten conditions with the highest total counts across all years, showing multiple remarkable behaviors. Type 2 diabetes mellitus and asthma both begin to drop in 2014 and are nearly zero by 2017. Type 2 diabetes mellitus and acute upper respiratory infection both exhibit abrupt depressions from 1992-1995. Inflamed seborrheic keratosis is nearly zero until 1999 but rapidly increases and plateaus after 2001. Chest pain and abdominal pain both increase in frequency from roughly 1990-1995 and decrease from 1995-2000.

K-means clustering was performed for conditions (K=20). Figure 5 shows plots of cluster centroids (i.e., the temporal pattern) for condition concepts. The clusters are sorted in descending order of the number of concepts belonging to each cluster. The two largest condition clusters have nearly zero frequency until a rapid increase in 2014. Clusters 4, 5, 6, 11, 12, and 19 drop in frequency starting around 2014. Cluster 12 is the only cluster with constant frequency over a large time period but only contains 3.47% of condition concepts. Clusters 3 and 16 increase almost linearly with time. Other clusters display patterns that are more dynamic. Clusters 7, 8, 10, 13, 14, 17, and 18 exhibit peaks at different times. Condition cluster 11 decreases from 1989-1999 and then increases until 2014.

Post-hoc Analyses of Trends

To demonstrate that the above methods reveal systemic data quality issues, we manually reviewed the domain- and concept-level patterns, hypothesized the causes of several patterns, and performed post-hoc analyses to test these hypotheses.

Condition clusters 0 and 1 behave like step functions with a rapid increase in 2014 while many other clusters begin to decrease around the same time. The number of condition concepts (Fig. 2a) also suddenly increases in 2014. We hypothesized that these patterns were caused when the health systems converted from using one medical coding system to another, e.g., from ICD9CM to ICD10CM. To investigate this, we analyzed the composition of medical coding systems (i.e., OMOP source vocabularies) contributing to these clusters. Table 1 shows the source vocabulary composition of condition clusters 0 and 1 compared against the aggregate of all other trends. Condition clusters 0 and 1 are composed of 93.9% and 92.0% ICD10CM source concepts, respectively. The remaining clusters are composed of 83.2% ICD9CM concepts.

The domain-level count of condition concepts displays an abrupt depression from 1992-1995 (Fig. 1a). Condition clusters 9, 15, and 19 also display similar depressions from 1992-1995, but this behavior is not noticeable in other clusters. Since the behavior was isolated to a few trends, we hypothesized that this depression was caused by changes affecting specific service types (e.g., temporary loss of data or reduction of services) which cover the conditions in these clusters.

To investigate whether changes in health services occurred, we analyzed the number of patient visits per year stratified by visit type (e.g., inpatient, outpatient, etc.) from the OMOP *visit-occurrence* table. Figure 6 shows plots of the annual counts for the 10 most frequent visit types, which account for 97.3% of

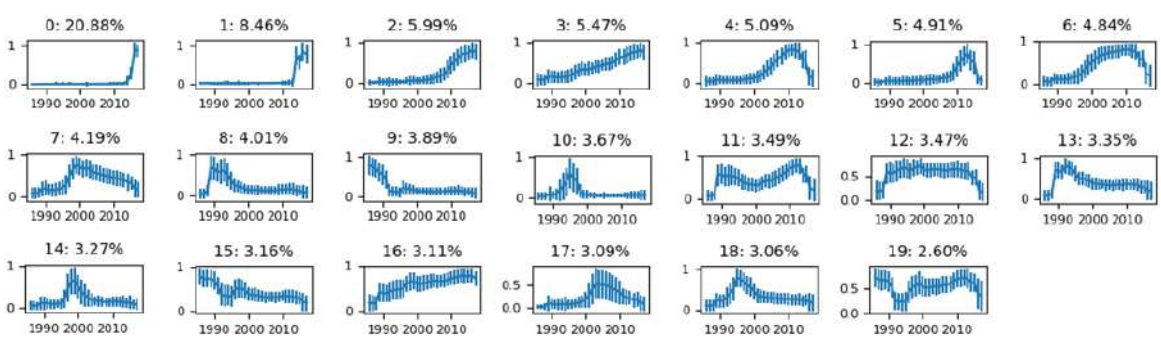

Figure 5– K-means clusters for conditions. Plots show cluster centroids (the cluster trend over time) with standard deviation across concepts as error bars (intracluster vaiance). Subplot titles show cluster labels and the percent of concepts belonging to each cluster.

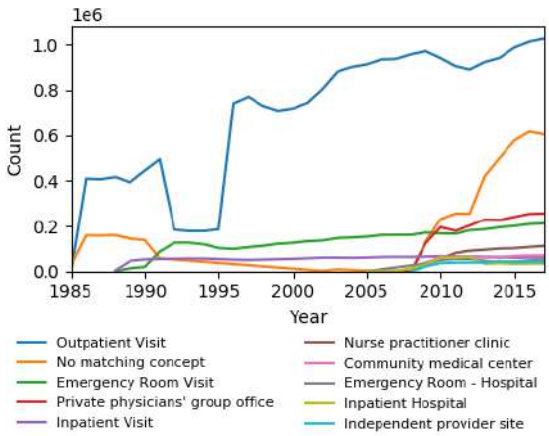

Figure 6– Annual number of visits for the 10 most common visit concepts.

Table 1– Source vocabulary composition of condition clusters.

Vocabulary ID	Cluster 0	Cluster 1	Remaining clusters
SNOMED	0.2%	1.6%	0.0%
ICD10CM	93.9%	92.0%	16.8%
ICD9CM	6.0%	6.4%	83.2%

visits. We excluded 17 less frequent visit types, including cardiology clinic, general surgery clinic, community clinic, etc., from the figure for visual clarity. Outpatient visit is the most frequent type and exhibits a large depression from 1992-1995. The other visit types do not display similar depressions. Inpatient visits appear in 1989 and are very stable throughout the years. Emergency room visits appear in 1989 with unstable growth until 1995 and stable growth thereafter. 11.7% of visits did not have a specified visit type (No matching concept).

Discussion

Concept Prevalence

Reviewing plots of annual frequencies of individual concepts, we found that the large majority of concepts exhibited a variety of unstable behaviors. Figure 1 shows a sample of plots, including the ten most prevalent conditions. We show the most frequent conditions because we assumed they would generally behave more stable than less frequent conditions. If frequencies of clinical terms in the EHR are representative of general population prevalence, then the behavior of terms in the EHR should reflect the behavior of the clinical concepts in the population. We should expect relative stability from the conditions in Figure 1, but from this small sample, it is immediately apparent that concepts exhibit a wide variety of behaviors in the EHR. Most of these fluctuations are too dramatic to be reflective of real health changes in the population. For example, Type 2 diabetes mellitus and asthma fall to nearly 0% frequency in 2015 while inflamed seborrheic keratosis was nearly 0% until 1999 but plateaus from 2000 onward. These patterns suggest underlying changes in the usage of medical coding systems (e.g., changing from ICD9CM to ICD10CM). Type 2 diabetes mellitus and acute upper respiratory infection both have abruptly depressed frequencies from 1992-1995. Chest pain and abdominal pain have similarly shaped growth and decline patterns in the 1990s.

Domain-Level Analysis

The domain-level aggregate plots show high-level changes observable in the EHR. Figure 1 shows the annual number of patients, total patient count across concepts, and the count of concepts per capita for each domain. Some of the patterns observed in individual concepts also exist at the domain-level. From 1992-1995, the number of patients abruptly drops relative to surrounding years, corresponding to decreased condition counts. This suggests that the dips in type 2 diabetes mellitus and acute upper respiratory infection were caused by system level events, potentially affecting many conditions. Drug counts were practically non-existent before 2001 and almost linearly increased after 2001, indicating that drug data was not available before 2001. Changes in the annual number of unique concepts and the mean patient frequency across concepts (Fig. 2) may suggest changes in the usage of medical coding systems. The increased number of concepts in the condition domain from 2014-2015, in the drug domain from 2007-2011, and in the procedure domain from 2002-2005 and 2015-2017 all suggest that changes occurred in the medical coding system.

Concept-Level Analysis

As discussed above, many concept frequency curves display fluctuations too dramatic to be caused by changes in population prevalence. We applied K-means clustering to find groups of concepts that have similar behavioral patterns. Clusters contain hundreds to thousands of concepts, so their average frequency curves are minimally influenced by true changes in individual concepts' population prevalences. These cluster patterns may suggest changes in the medical system that influence the clinical recording process, including service capacity changes (e.g., expansion of medical system) or events that affect patient data records (e.g., deployment of new clinical databases). In Figure 5, various patterns among condition concepts can be easily identified along with the proportion of concepts that follow the pattern. A small number of concepts remain stable and constant over time (e.g., condition cluster 12, 3.47% of conditions), and the stability only lasts for a period (1989-2013). The majority of concepts are stable only during certain time windows, and these windows vary by cluster.

Several clusters have sharp increases that correspond with decreases in other clusters. Clusters 0 and 1 increase while clusters 4, 5, 6, 11, 12, and 19 drop around 2014. We hypothesized that these patterns were caused by changes in the medical coding systems in 2014. To test this hypothesis, we analyzed the composition of source vocabularies among these clusters to determine if these clusters are primarily represented by different vocabularies (Table 1). Indeed, clusters 0 and 1 are composed of over 90% ICD10CM concepts, while all other clusters are cumulatively composed of 83.2% ICD9CM concepts, supporting the hypothesis above. Similar patterns were observed in the procedure domain associated with changes from ICD9Proc to ICD10PCS in 2016 (data not shown).

Condition clusters 9, 15, and 19 exhibit a marked drop in frequency between 1992-1995, corresponding with dips in domain-level counts (Fig. 2a). Since this behavior was not observed among most other clusters, we hypothesized that this depression was isolated to specific sites or services. To test this, we analyzed annual visit type occurrences (Fig. 5). Outpatient visits display a similar depression between 1992-1995 while the other visit types behave stably during this time, suggesting that clusters 9, 15, and 19 are primarily composed of conditions observed in outpatient settings. Inpatient visit and emergency room visit types both begin in 1989, corresponding with the opening of the Milstein Hospital Building of Presbyterian

Hospital. A flurry of other visit types, including private physicians' group office, nurse practitioner clinic, and community medical center, begin to appear in 2009, suggesting that the network of clinical data sources connected to the clinical data warehouse was expanding to more sites.

Limitations

There are a number of limitations to our methods. While clustering the annual concept frequencies reveals patterns of behavior among the concepts, the clusters on their own do not provide meaningful insight for the causes of these patterns. For some patterns, we were able to generate hypotheses and corroborate the causes by investigating other information sources (e.g., visit types and source vocabularies) to reveal systemic forces behind these patterns. However, many patterns are unexplained, and we cannot infer causality for the hypothesized causes of patterns as we did not apply statistical analyses. Even without causal explanations, these methods still allow researchers to identify time frames of data instability to exclude from their analyses or interpret with caution. These methods do not produce quantitative, scalar, and invariant results, which are desired characteristics of data quality metrics to allow comparison of data quality statistics across data sets and time [13]. The domain- and concept-level analyses were performed at annual intervals, which may be too coarse to detect short data aberrations. However, the method should perform well with shorter intervals.

The selected number of clusters for K-means clustering was arbitrary. The choice of K influences the resulting clusters and, thus, the interpretation of results. We attempted to use the elbow method [14] to guide our choice, but the intercluster sum of squared differences had broad-shouldered changes over K in all domains (data not shown). This indicates the presence of many small clusters or many concepts may not follow common patterns, thus, there may not exist an optimal choice for K.

We determined the annual number of patients based on observations in the condition, drug, and procedure tables and subsequently used this patient count in calculating concept frequencies of those conditions, drugs, and procedures. This introduces bias into the calculation of concept frequency. Ideally, the patient population should be identified externally from the variables undergoing analysis. The OMOP CDM contains *observation_periods* which should identify the start and end dates when the patient was observed in the database. However, in our database, 66.6% of patients have missing start dates, which may indicate an error in the extract-transform-load process, which converts data from the clinical data warehouse to the OMOP CDM. Also, we assume that each patient has a single unique identifier. This may not be true if patients have duplicate registrations within the CDW.

Developing this analysis on an OMOP database confers both advantages and disadvantages. By analyzing the transformed database, we lose some ability to investigate data provenance and sources of data quality issues. However, developing this analysis on a widely adopted CDM allows other institutions to immediately benefit and learn from these results. Although other data models will not be able to replicate this analysis directly, the methods are simple to implement in other systems.

Conclusions

We contribute methods for analyzing EHR data quality aspects (e.g., temporal plausibility, consistency, etc.) for secondary analysis using domain-level aggregate statistics and clustering the annual concept frequency trends to find common temporal patterns across concepts. These patterns may indicate EHR data quality issues caused by operational or system-wide factors that affect multiple concepts simultaneously.

[a]The State University of New York at Albany, Albany, NY, USA, [b]George Mason University, Fairfax, VA, USA

Abstract

Prescription information and adverse drug reactions (ADR) are two components of detailed medication instructions that can benefit many aspects of clinical research. Automatic extraction of this information from free-text narratives via Information Extraction (IE) can open it up to downstream uses. IE is commonly tackled by supervised Natural Language Processing (NLP) systems which rely on annotated training data. However, training data generation is manual, time-consuming, and labor-intensive. It is desirable to develop automatic methods for augmenting manually labeled data. We propose pseudo-data generation as one such automatic method. Pseudo-data are synthetic data generated by combining elements of existing labeled data. We propose and evaluate two sets of pseudo-data generation methods: knowledge-driven methods based on gazetteers and data-driven methods based on deep learning. We use the resulting pseudo-data to improve medication and ADR extraction. Data-driven pseudo-data are suitable for concept categories with high semantic regularities and short textual spans. Knowledge-driven pseudo-data are effective for concept categories with longer textual spans, assuming the knowledge base offers good coverage of these concepts. Combining the knowledge- and data-driven pseudo-data achieves significant performance improvement on medication names and ADRs over baselines limited to the use of available labeled data.

Keywords:

Natural Language Processing, Machine Learning, Information Storage and Retrieval

Introduction

Electronic health records (EHR) contain significant amounts of medical information. However, most of this information is presented in unstructured narrative free-text and remain unavailable to computerized systems that rely on structured representations for access and retrieval [1,2]. This unavailable information includes medication and prescription information, which is often described in narrative portions of electronic health records (EHRs) [3] and can complement the information represented in prescriptions themselves [4].

Natural language processing (NLP) methods such as information extraction (IE) can open up this information to downstream uses [2,3], such as comparative effectiveness [5] cohort selection [6,7], medication reconciliation [8], and pharmacovigilance and pharmacogenomics [9]. Extraction of medication information from narratives enhances patient safety by making this more complete medication information available to use for clinical decision support [8]. Extraction of ADRs supports goals highlighted by the U.S. Food and Drug Administration (FDA) [10] for comparing the ADRs present in labels from different manufacturers for the same drug, and for performing post-marketing safety analysis by identifying new ADRs not currently present in the labels [11].

Over the last few decades, there have been many efforts for extracting information from clinical narratives [4,11]. An important factor in the development of these systems is the availability of sufficient training data [12]. However, preparation of training data is time-consuming and labor-intensive; as a result, such data sets are scarce. Even when such data are available, some concept types in the data tend to be sparsely-represented [13]. NLP systems either relatively underperform on concept categories that are more sparse or they complement their supervised machine-learning models with hand-build rules [14,15]. An alternative to these approaches requires augmenting labeled data with pseudo-data. Pseudo-data are synthetic data that are derived from samples in labeled data, e.g., by combining elements of existing samples. Despite its promise for IE, to the best of our knowledge, pseudo-data generation has received limited attention in the clinical domain. Instead, researchers have focused on modifying the architectures of their systems to improve recognition of concepts, potentially over-fitting their systems to the data and to the task [4]. We aim to address this gap in the literature.

Our proposed approach develops and compares knowledge- and data-driven pseudo-data generation methods for IE from narratives of EHRs [4] and from drug labels [11]. We use the resulting pseudo-data to enhance NLP methods for extracting medication and ADR information. Despite focus on medication names and ADRs, we also study concepts that relate to medications and ADRs. Our IE methods extract concepts in a sentence; therefore, improving identification of a key concept in a sentence can have a spillover effect and help extraction of the rest of the concepts in the sentence, even when those concepts themselves are not directly enhanced with pseudo-data. We, therefore, report results on the following set of concept types: medication names, dosages, frequencies, modes, durations, and reasons; ADRs, animal species, drug classes, factors, negated phrases, and severities. Our results show that pseudo-data helps improve performance on medication names and ADRs over methods that are limited to the use of available labeled data.

Related Work

Extraction of ADR and medication information is commonly solved using rules and/or machine learning classifiers. Rule-based systems have proven to be useful [4,14] for this purpose but come with limitations on performance, scalability, and generalizability [16]. They suffer particularly on concept types that show much syntactic variation [13]. In response to these limitations of rule-based systems, most high-performing

methods utilize machine learning classifiers [13,15-17]. The primary challenge facing these systems is data sparsity [13]. As a result, machine learning solutions often require support from rules [16] and have given promising results. The current state of the art in medication extraction is one such hybrid system that combines a machine learning classifier with post-processing rules and achieves 89.6% F-measure on medication names in narrative EHRs [15]. In comparison, the current state of the art in ADR extraction is a machine learning system that achieves 82% F-measure [17] on ADRs. Given their reliance on labeled data, performance on both tasks can be improved by more data. Given the high cost of generating manual gold standard data, we explore an automatic method, pseudo-data generation, for augmenting available labeled data. To assess generalizability, we incorporate pseudo-data into two tasks tackled on two different kinds of corpora: medication extraction from EHRs and ADR extraction from drug labels.

Pseudo-data generation is a common way of resolving imbalanced datasets. Despite its potential benefit for addressing data sparsity, pseudo-data generation remains relatively unexplored in the clinical domain. Outside of the clinical domain, Chawla et al. [18] proposed an oversampling method, called synthetic minority over-sampling technique (SMOTE), that generates pseudo-samples for minority classes by joining existing samples with their nearest neighbors in terms of feature vectors. SMOTE takes the size of the largest class as a parameter to produce a fully balanced training set for all classes. Within the clinical domain, pseudo-data generation has been tackled only in very few studies: e.g., Keretna et al. [19] formulated an extended segment representation technique to improve biomedical IE, with emphasis on ambiguous named entities.

In our study, we evaluate the efficacy of pseudo-data in clinical IE on medications and ADRs. We propose two methods for pseudo-data generation. The first method utilizes a combination of random duplication and external gazetteers. Being one of the simplest oversampling methods, random duplication on its own is rarely effective [18]. Literature [20] fails to show significant improvement on minority class recognition when data sizes of the minority class are increased through repetition of existing data. We expect that this finding results from lack of any "new" information. Therefore, we incorporate information from external gazetteers and generate new samples from them so that we can address the sparsity of unique samples. The second method takes advantage of word embeddings. Pennington et al. [21] have shown that semantically similar words cluster together in the word embedding space. Given this, we generate pseudo-data by replacing tokens (from clinically-relevant concepts) in the existing training data with their nearest neighbors in terms of embeddings. After generating pseudo-data, we use them to enrich our training data. We hypothesize that pseudo-data can help improve IE performance.

Data

We base our studies on two established NLP data sets for medication and ADR extraction. Our first corpus consists of 991 discharge summaries from Partners Healthcare and was the basis for the 2009 i2b2 Medication Challenge [4] which focused on the extraction of medication and prescription information from narratives of EHRs. This dataset contains 145 annotated summaries and 846 unannotated summaries in the training set. The test set contains 252 annotated summaries. Our second data set consists of 2,309 drug labels from the FDA and were the basis for the 2017 TAC ADR Challenge [11], which focused on the extraction of ADRs, related drug classes, ADR severities, and other information from narratives. This dataset contains 101 annotated labels and 2,208 unannotated labels in the training set. The test set contains 99 annotated labels. In our study, we build systems based on the training data. We then run an end-to-end system against the test set. See **Table 1** for the per-category statistics for each dataset.

Table 1 - Number of records, tokens, and phrase-level concepts per category (training and test set)

2009 i2b2 Medication Challenge

(L) indicates labeled data. (U) indicates unlabeled data.

Methods

We study pseudo-data generation on two types of concepts, medication names and ADRs, which lie at the heart of any prescription and ADR extraction task. Given our focus on pseudo-data generation, we first introduce a baseline IE system that can extract these concepts from labeled data. We then present two pseudo-data generation methods and measure the contribution of pseudo-data to the gold standard data and to extraction performance.

Creating a Baseline IE System

Our baseline IE system [16] uses conditional random fields (CRFs) [22] trained with: (1) Normalized tokens: lower-cased tokens with punctuation or special characters removed. We replace all numbers with a generic placeholder (e.g., 300 ml → DDD ml, 3rd degree → D degree). (2) Part-of-speech (POS) tags. (3) Temporal properties: A set of seven binary features that indicate whether a token represents a signal for temporal expressions such as time, temporal period, and temporal reference. (4) Real-valued word embeddings trained on the unannotated portions of our datasets, as indicated by prior work [23]. When including these features into the training process, we use window size of ±2 around the target word. This window size is selected as the optimal parameter from cross-validation experiments which checked window sizes from ± 1 to ± 5 in our previous study [16].

We evaluated this system on both ADR and medication extraction using only gold standard labeled data (see **Table 2** for results [16]). We then enhanced it with pseudo-data as follows: we collected sentences from the annotated training data that contained at least one ADR or medication name. We generated pseudo-data based on these sentences using two different methods: Knowledge-driven and data-driven.

Generating Knowledge-Driven Pseudo-data

This method takes advantage of external gazetteers. Using ADR extraction as an example for describing the methodology, we select and access a database (i.e., Vigibase from VigiAccess.org) that can serve as a lookup table for ADRs [23]. In our study, most ADR concepts found in drug labels use normalized terms and controlled vocabularies (i.e., the FDA

publishes regulations governing the content and format of ADR information [10]). With the help of Vigibase, we manually create a gazetteer that contains 18,310 ADRs commonly found in the drug labels. We then randomly select one sentence from the ones previously collected from our gold standard and replace the ADR in that sentence with a different one from the gazetteer. If we have more instances in the gazetteer than the total number of sentences that contains ADRs in the gold standard, then we continue this step until all instances in the gazetteer are injected to the sentences in the gold standard, creating at least one pseudo-data sentence per original that contains an ADR. For example, the original sentence "the most common adverse reactions (>=20%), regardless of causality, were stomatitis, infections, and asthenia" becomes "the most common adverse reactions (>=20%), regardless of causality, were dizziness, pyrexia, and fatigue". We use the same method for pseudo-data generation for medication names, creating a gazetteer from Drugs.com which contains 5,394 commonly used medication names.

Generating Data-Driven Pseudo-data

This method takes advantage of patterns observed in the data. In particular, we study similarity of concepts using word embeddings. We utilize word embeddings trained on MIMIC-III (a large database of about 2 million clinical notes for about 46 thousand patients [24]). For each sentence containing an ADR/medication, we replace each token within the concept with the top three closest tokens represented by word embeddings (i.e., replacing each ADR/medication token with its first, second, and third nearest neighbor, respectively) to create pseudo-concepts. For multi-token concepts, we create multiple pseudo-concepts by combinatorically putting together the nearest neighbors of each of their constituent tokens. We measure word-to-word distances using Euclidean distance, as suggested by the literature [21] as a proxy for semantic similarity. This measure of similarity between tokens is a likelihood rather than a certainty; however, it has been widely-accepted and used in NLP with reliable results [21]. The purpose of the data-driven pseudo-data is to enrich the training data with more tokens that resemble ADRs/medication names [25-27]. We do not aim to replace each word with its synonym. Rather, we aim to replace each concept with a concept that is semantically similar or related [25-27], and is of the same type, i.e., replace a drug with a drug in order to improve learning contexts in which drugs occur.

Unlike knowledge-driven pseudo-data that is guaranteed to contain pseudo-concepts of the correct type, concepts that are related in the word embedding space may not all be concepts of the same type. In order to identify and utilize the most useful pseudo-concepts from data-driven pseudo-data, we use confidence thresholds and filter examples with lower confidence. For this, we start with training a supervised model using labeled data. We apply this model to predict concepts on the data-driven pseudo-data. We obtain confidence rates for each of the predicted labels and utilize sentences from pseudo-data that contain at least one ADR concept (or medication concept) that scores higher than the confidence threshold. We repeat this process until no ADRs/medications in the pseudo-data are introduced to the labeled data.

The literature suggests picking a confidence threshold of 0.90 or 0.95 [28] for filtering. In these cases, the system only utilizes high-confidence concepts from the pseudo-data. Such high thresholds would minimize noise that can come from incorrect pseudo-concepts. However, setting a high confidence threshold also potentially excludes some correctly predicted pseudo-concepts from the training model. Given sufficient samples of training data, the optimal threshold can be tuned via cross-validation. In our case, we observe that a threshold of 0.85 would filter out some potentially useful pseudo-concepts. Therefore, we set the threshold to 0.8 in order to be conservative without being overzealous. **Figure 1** shows some example pseudo-concepts.

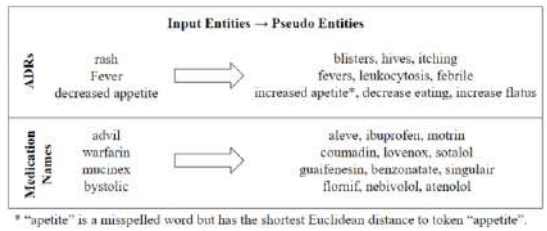

Figure 1 - Examples of data-driven pseudo-concepts

Generating Hybrid Pseudo-Data

Knowledge- and data-driven methods can generate different pseudo-data. Therefore, as a final step, we combine these two datasets to create a hybrid pseudo-dataset. **Figure 2** shows the workflow we designed to generate the hybrid pseudo-data.

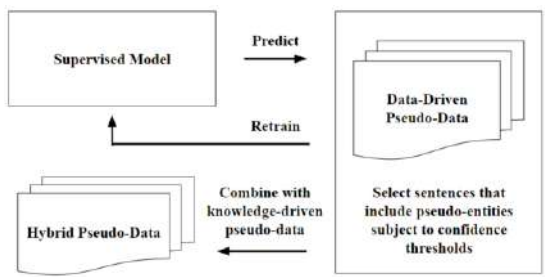

Figure 2 - Generating hybrid pseudo-data

Results and Discussion

We tune the parameters of our models with five-fold cross-validation on the training set. Then we train our IE system on the complete training set and evaluate on the test set for each task. Feature sets and window sizes remain identical to those described in Baseline IE System section.

Table 2 shows phrase-level F1-measure with and without pseudo-data on the test set for both IE tasks. When extracting ADRs and medication names, with respect to the baseline using no pseudo-data, the model performs significantly better when enhanced with either knowledge-driven or data-driven pseudo-data. The performance gain also spills over to other concept categories, with significant performance improvement on the severity class.

In medication name extraction, the model with data-driven pseudo-data performs significantly better than the model with knowledge-driven pseudo-data. However, there is no significant advantage of data-driven pseudo-data in ADR extraction when compared to knowledge-driven pseudo-data. Manual analysis of the system output and pseudo-data showed that medication names are mostly single token nouns in the MIMIC III vector set. As a result, these concepts can be used interchangeably without breaking the surrounding context and can benefit IE performance. In contrast, in spite of 53.60% of the ADRs being single-token concepts in the test set, many of

them have longer textual spans. Given that our data-driven methods utilize word embeddings at the token level, even after filtering through confidence thresholds, these pseudo-concepts may not benefit IE.

Our results and manual analyses suggest that data-driven pseudo-data are suitable for concept categories with short textual spans, whereas the knowledge-driven pseudo-data are effective for concept categories with longer textual spans, assuming that the gazetteer offers a good coverage of the concept types in focus. Hybrid pseudo-data puts the strengths of the two together and shows statistically-significant performance improvement on the extraction of both ADRs and medication names. The biggest gains come from improved performance on concepts that appear only once in the data. For example, on the ADR extraction task, 10.92% of ADR concepts fall under this category. Furthermore, 53.95% of these ADRs appear in the VigiAccess gazetteer. We also checked the ADRs that were not extracted by the model with knowledge-driven pseudo-data but by the model with hybrid pseudo-data. The model with hybrid pseudo-data performed particularly well on ADRs that are modified by adjectives or prepositional phrases. For instance, unlike the model with hybrid pseudo-data, the knowledge-driven model failed to recognize "peripheral sensory neuropathy" and "residual neuropathy" when "sensory" and "residual" are modifying the ADR term ("peripheral neuropathy").

Table 2 - Phrase-level F1-measure with and without pseudo-data on the test set for both IE tasks

Pseudo-Dataset	ADR	Animal	Drug	Factor	Negation	Severity
No	0.727	**0.738**	**0.398**	**0.540**	**0.308**	0.502
Gazetteer	0.744	**0.756**	**0.408**	**0.537**	**0.315**	0.546
Optimal Euclidean	0.745	**0.737**	0.349	0.488	**0.313**	0.515
Optimal Hybrid	**0.765**†	**0.737**	**0.381**	**0.538**	**0.308**	**0.559**†
Pseudo-Dataset	**Medication**	**Dosage**	**Mode**	**Frequency**	**Duration**	**Reason**
No	0.888	**0.926**	**0.936**	**0.941**	**0.558**	**0.426**

Optimal Euclidean	0.899	**0.926**	**0.935**	**0.940**	**0.559**	**0.436**
Optimal Hybrid	**0.907**†	**0.929**	**0.942**	**0.940**	**0.561**	**0.432**

* Bold indicates the highest score in each categor. Numbers followed by † indicate statistical significance with respect to other results in the same column. We use a Z-score of 1.96 ($\alpha = 0.05$).

The model with hybrid pseudo-data also shows statistically significant gains on severity. However, it fails to show any performance gains against the baseline (differences are not statistically significant) on the rest of the minority classes. These concept categories have limited training samples therefore the classifier faces difficulties when generalizing patterns. For example, there are only 44 samples (5 unique samples) for Animal class in the training data. Therefore, the model fails to recognize other animal entities in the test data (e.g., "cynomolgus", "minipig", "ferret").

Error Analysis and Limitation

We analyzed the system's output to pinpoint incorrect predictions with respect to the gold standard. In medication extraction, we found the model still cannot distinguish some generic medication names (e.g., "his medication", "other antibiotics", "this medication", "trial drug"). We found 70 instances related to "medication(s)", 53 instances related to "antibiotic(s)", and 14 instances related to "home" in the remaining errors. Also, the system cannot recognize some ambiguous medication names. For example, the extraction of "No Doz" and "One A Day" is problematic because the first one starts with a negated token, whereas the second one looks like a medication frequency. In ADR extraction, generic ADRs are also a common theme in erroneous predictions (e.g., "gi adverse reactions", "autoimmune disorders", "interstitial lung disease"). Furthermore, some ADR concepts contain (or are surrounded by) multiple generic concepts and are syntactically complex, (e.g., "irreversible vision damage with vision damage from SABRIL", "structure infections with moderate/severe pre-existing renal impairment", "drug reaction with eosinophilia and systemic symptoms"). What is more, some concepts contain negated tokens and mislead the system. For example, the model failed to extract "negative thoughts" and "non-melanoma skin cancer" due to the included negation signals, "negative" and "non".

Other errors arise because of misleading lexical context. For example, "alcoholic beverage" and "vomiting" are both predicted as medication names when appearing respectively in "she took 600 ml alcoholic beverage for the day" and "vomiting x 5 hours". Similarly, the system does not recognize animal concept "rodent" in "rodent models inhibition of IL-12/IL-23p40" because it is presented with a protein product. Finally, our system still misses concepts that have longer textual spans or lack temporal signals (e.g., "disruption of the body ability to reduce core body temperature", "progression of pre chronic myelomonocytic leukemia with nras mutation", "after your cardiac catheterization", "possibly lifelong").

In addition, our method faces its biggest challenges when differentiating certain concepts that look like ADRs but are not caused by a reaction to a drug (and are therefore not ADRs). These include: (1) Concepts that look like ADRs but actually refer to the medical problems of patients. For example, in "fever and persistent constipation upon admission", where the underlined concepts are not ADRs. This is the most prominent type of challenge. (2) Hypothetical or negated ADRs that do not actually occur. For example, "evaluate if neuropathy is suspected" and "if muscle signs and symptoms persist".

Our future work will focus on these challenges and explore more comprehensive knowledge-bases, such as the Unified Medical Language System (UMLS) [29] as well as phrase-level [30] or sentence-level embeddings [31] that can generate more reliable pseudo-data for the training models.

Conclusion

In this paper, we evaluated the contribution of pseudo-data to clinical IE, using ADR and medication extraction as test bed applications. We developed two methods for generating pseudo-data. The first method is knowledge-driven and uses gazetteers that contain clinically-relevant concepts, whereas the second method is data-driven and takes advantage of word embeddings. We found that the data-driven method is suitable for concept categories with short textual spans, whereas the knowledge-driven methods are effective for concept categories with longer textual spans, assuming the gazetteers offer good coverage of the concepts within each category. Hybrid pseudo-data takes advantage of strengths of both, improving performance on the extraction of two important concept categories in clinical IE: ADRs and medication names.

Abstract

NimbleMiner is a word embedding-based, language-agnostic natural language processing system for clinical text classification. Previously, NimbleMiner was applied in English and this study applied NimbleMiner on a large sample of inpatient clinical notes in Hebrew to identify instances of diabetes mellitus. The study data included 521,278 clinical notes (one admission and one discharge note per patient) for 268,664 hospital admissions to medical-surgical units of a large hospital in Israel. NimbleMiner achieved overall good performance (F-score =.94) when tested on a gold standard human annotated dataset of 800 clinical notes. We found 15% more patients with diabetes mentioned in the clinical notes compared with diagnoses data. Our findings about underreporting of diabetes in the coded diagnoses data highlight the urgent need for tools and algorithms that will help busy providers identify a range of useful information, like having a diabetes.

Keywords:
Natural language processing, Text classification, Diabetes.

Introduction

With the wide international adoption of electronic health records and other information technology in healthcare, there is an exponential growth in health data. It is estimated that as much as 50 to 80% of all healthcare data are captured as unstructured, mostly free text narrative data. Examples of health narrative data include daily inpatient progress notes that are completed by physicians and nurses, primary care clinics follow-up notes, radiology notes, surgical notes, etc. [1].

With large potential benefits that are projected from using these data, these exponentially growing narrative information sources pose several significant challenges. Busy clinicians are now required to go through an increasing number of narrative notes about a patient to understand their medical history and diagnose their conditions correctly [2]. Health researchers are dealing with an increasing number of clinical notes they need to review in order to identify important aspects of care and patient characteristics [2].

Some of these challenges can be solved through natural language processing (NLP) with a variety of techniques aimed at extracting meaning from narrative data [1]. NLP can be broadly divided into linguistic approaches and statistically based approaches. Linguistic NLP systems tend to use complex language characteristics, for example large vocabularies of pre-defined terms and expressions, to identify a concept of interest in clinical texts. For example, past studies extracted wound characteristics from outpatient notes [3] and identified patients with poor treatment adherence in inpatient notes [4] using pre-build vocabularies of clinical terms for these domains. Statistically-based NLP approaches - sometimes also called text classification- are often based on probabilistic estimations of a presence of a specific phenomenon in the clinical texts. For example, text classification was used to classify clinical notes in terms of information completeness and adequacy [5] or to identify depression and depression symptoms among patients [6].

Although significant advancements in clinical NLP were made over the last decades, most of the published NLP studies and existing NLP systems focus on processing information in English. In general, a vast majority of languages around the world are considered low-resource languages in terms of NLP [7]. More tools and approaches are urgently needed to overcome the resource barrier so advances in NLP can deliver more widespread benefits to health providers, researchers and patients [8].

This paper presents a novel open-source NLP system called NimbleMiner. NimbleMiner was previously tested in text classification tasks in English. For example, we successfully applied NimbleMiner to identify fall-related information in clinical notes, while achieving higher system performance in significantly less time compared to a previous rule-based systems [9]. By design, NimbleMiner implements a language-agnostic NLP approach and we estimated that our system can be applied to languages other than English. To evaluate this assumption, this study applied NimbleMiner to process clinical narratives in Hebrew.

Similar to many other languages, Hebrew has very scarce resources to implement NLP [8]. In healthcare, we found only one published effort that reported building Hebrew NLP healthcare pipeline in early 2010 [10] and since then, no other reports were identified. The aim of this study was to apply NimbleMiner on a large sample of inpatient clinical notes in Hebrew to identify instances of diabetes mellitus (both insulin dependent type I diabetes and insulin resistant type II diabetes). We worked with clinicians in the largest hospital in Israel (Sheba Medical Center) to develop the NLP pipeline and evaluate its performance.

Methods

Our methods are summarized in Figure 1. We first manually reviewed a random sample of admission and discharge narrative notes for 400 patients, identified diabetes cases, and created a gold standard of human annotated notes with the help of clinical experts. We then trained and tested our NLP system—called NimbleMiner—and classification algorithms. Finally, we assessed our automated approach by comparing system-generated classification against the gold standard. We also compared diabetes cases extracted from narrative data versus coded diagnoses for pateints included in the gold standard.

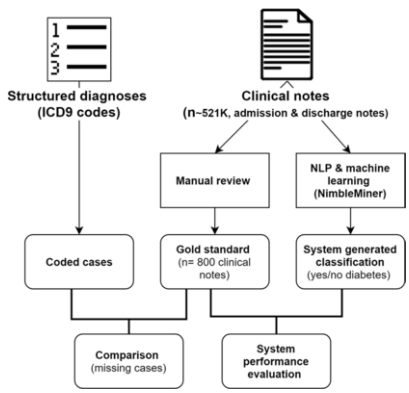

Figure 1– *Study Methods Overview*

Dataset

We extracted a large sample of clinical notes of all the patients admitted to the Sheba Medical Center over two years 2016-17. Sheba Medical Center located in the Tel Aviv District, is the largest hospital in Israel with about 1,700 beds, over 1,400 physicians, and 2,600 nurses. Only patients admitted to medical-surgical units were included in this study. We excluded any pediatric patients or women who were admitted for pregnancy/delivery reasons. Over the study time period, there were 268,664 admissions for 127,851 unique patients. Patients' average age was 65.1.

In this project, we used a subset of admission and discharge narrative clinical notes for all the patients in the sample. There were 521,278 clinical notes (one admission and one discharge note per patient's admission) after excluding missing data. Admission notes consisted of narrative description of patient's state at the hospital admission, including previous medical history, patient's diagnoses, medications, reason for admission, patient's signs and symptoms, relevant social history, etc. Discharge notes included information similar to the admission note, with addition of hospital treatment course and discharge recommendations. On average, clinical notes had roughly 2,000 characters, with admission notes being slightly longer than discharge summaries (about 200 charters longer on average). It is important to note that the written Hebrew alphabet does not include vowels, thus writing is more concise compared to other languages. This study received an Institutional Review Board approval from the University of Haifa, Israel.

Domain Definitions

We used clinical literature [11] and our team's expertise to define the domain of interest. In this project, we focused on identifying clinical notes where diabetes is very likely to be described. To accomplish that, we defined several categories of terms that will suggest high likelihood of diabetes presence, as follows:

- **Diagnosis of diabetes**: any mention of patient's having diabetes in the text (e.g., terms like "diabetes mellitus", abbreviations like "DM", etc.).
- **Mention of one or more diabetic medications** in the text: including – Insulin derivatives (e.g., Lantus, Apidra, Novorapid, Actrapid), Insulin pump, Glucomin, Glucophage, Methformin, Januet, Jardiance, Sulfanyl urea, Gluben, Forxiga, DPP4, Januvia, GLP1, Victoza, Trajenta, etc.).
- **Indication of hemoglobin A1c** >6.5% or **fasting glucose levels** > 125 mg/dL in the text.
- **Diabetes complications** in the text (e.g., diabetic foot, diabetic neuropathy, diabetic retinopathy, etc.).

NLP System Description

NimbleMiner is an open source NLP system developed by our team [9]. User manual and download options can be accessed at: http://github.com/mtopaz/NimbleMiner. Other research or clinical teams can use the system under the GNU General Public License v3.0. NimbleMiner includes several methodological stages of clinical note processing that are briefly described below and presented in Figure 2.

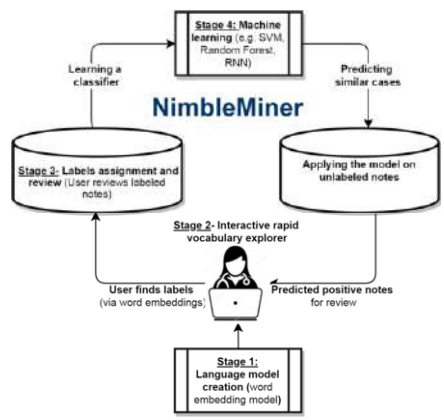

Figure 2– *NimbleMiner System Process Stages*

Stage 1- Language model creation: The user selects a large corpus of clinical notes and defines language model characteristics. We use a word embedding model (specifically skip-gram model) for language model generation and users can change model settings based on their preferences. **Stage 2- Interactive rapid vocabulary explorer**: The user enters a query term of interest, and the system returns a list of similar terms it identified as relevant. The list of suggested similar terms is based on the cosine term similarity metric extracted from the word embedding model. The user selects and saves the relevant terms by clicking on them. Negated or other irrelevant terms and expressions that are not selected by the user are saved by the system for further tasks, such as negation detection. Figure 3 describes the steps of the vocabulary explorer stage. **Stage 3- Labels assignment and review**: The system uses the stage 2 discovered similar terms to assign labels to clinical notes (while excluding notes with negations and other irrelevant terms). Assigning a positive label means that a concept of interest is present in the clinical note. When needed, the user reviews and updates lists of similar terms and negated similar terms. The user reviews the clinical notes with assigned labels for accuracy. This weakly supervised rapid labeling approach

is based on a positive labels learning framework validated in previous research [12,13]. **Stage 4- Machine learning:** The user choses a machine learning algorithm to be applied to create a predictive model (e.g., Support vector machines, recurrent neural network, random forest). The model is then applied to predict which clinical notes might have the concept of interest. The user reviews the predicted notes and can go through stages 2-4 again to add new labels.

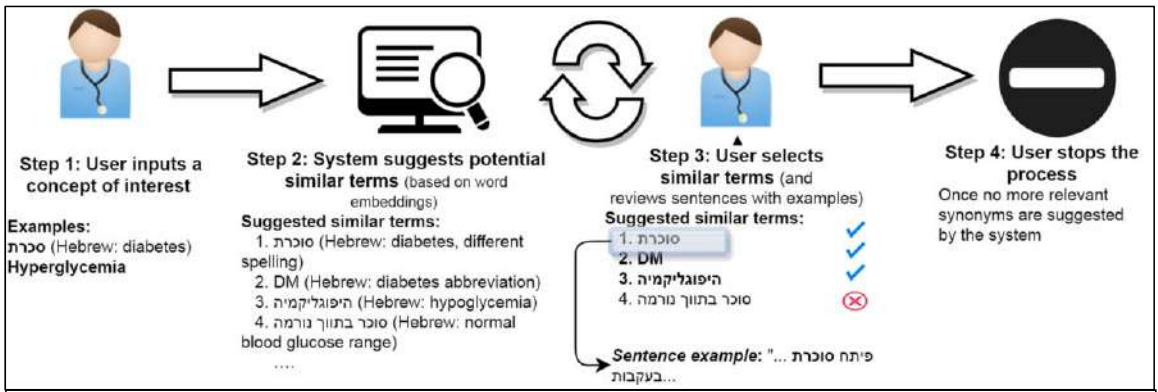

Figure 3– *NimbleMiner Stage 2 -Interactive Rapid Vocabulary Explorer Process Overview*

Legend*: Interactive rapid vocabulary explorer: The user enters a query term of interest (step 1), and the system returns a list of similar terms it identified as relevant (step 2). The list of suggested similar terms is based on the cosine term similarity metric extracted from the word embedding model. The user selects and saves the relevant terms while negated or other irrelevant terms that were not selected by the user are also saved in the system for further tasks (step 3). The system iteratively identifies new potential similar terms and presents them to the user for review (steps 2-3) and the process continues until there no new similar terms to suggest (step 4)*

NLP System Settings

Narrative data were pre-processed by removing punctuation and lowercasing all English words (Hebrew letters do not have upper case). All numeric symbols were kept in the text. Additionally, we converted frequently co-occurring words in the clinical notes into phrases with lengths of up to four words (4-grams) [14]. This is a common process in NLP where sets of co-occurring words are combined into phrases. For example, "pt has diabetes" might be a common 3-gram. We used a phrase2vec algorithm with default settings to implement this in NimbleMiner.

NimbleMiner has a user interface that is implemented in R statistical package. We used a skip-gram model implementation called word2vec and phrase2vec to create a word embedding model in R [14]. Parameters of the word embedding model were held constant based suggestions in other studies of word embedding [15]. Specifically, we used a model with window width size = 10, vector dimension = 100, minimum word count = 5, negative sample size = 5, and sub-sampling = 1e-3. We used all the available clinical documents (~ 521K clinical notes) to train the model.

For each similar term entered by the user, the system presented 50 potentially similar terms based on the cosine term similarity. Our previous experiments [9] showed that the random forest algorithm outperforms other approaches (e.g., J48 Decision trees, Support Vector Machines), hence we used this algorithm in the machine learning stage of this study. Random Forest algorithm was used with default settings (number of iterations = 100, minimum number of instances = 1, minimum variance for split = 1e-3, depth = unlimited).

To identify negation terms for medical domain in Hebrew, we started from translating a commonly used vocabulary of negation terms in English, called NegEx [16]. Next, we used our clinical and Hebrew linguistic knowledge to identify additional negation terms. We then used NimbleMiner's vocabulary explorer to identify other potential negations and variations in negations spelling. Our final list of medical negations in Hebrew includes 118 terms, which might appear before or/and after a diabetes term (e.g., "שולל"- denies or "ללא"- has no). n-grams (irrelevant terms not selected by the user) were used to detect family and past history contexts.

NLP Implementation

Similar terms were explored by a team of 2 nurses and 2 physicians who used NimbleMiner. First, two nurses and one physician used NimbleMiner to identify and review potentially relevant terms independently (NimbleMiner stage 2) and then the lists of terms were combined into one list. Another physician then reviewed the combined list and finalized any disagreements or additional terms that appeared in one list but not in the other.

System Evaluation- Gold Standard Creation

We extracted a random sample of admission and discharge notes for 400 patients in our database (800 clinical notes total). Each note was reviewed by 3 clinicians on our team (2 nurses and 1 doctors) for presence of diabetes. Clinicians were asked to use their clinical judgment and indicate if each specific note has a mention of diabetes. There was moderate inter-rater agreement (Cohen's Kappa inter-rater agreement = .69). A senior internal medicine physician then reviewed each of the cases and adjudicated whether diabetes was present or absent in cases of disagreement. This corpus of documents was not used for algorithm training but only as a gold standard for algorithms evaluation.

We applied our NLP algorithms on the gold standard dataset to predict presence of diabetes in each of the documents. We calculated precision (defined as the number of true positives out of the total number of predicted positives), recall (defined as the number of true positives out of actual number of positives) and F-score (F1, weighted harmonic mean of the precision and recall) to evaluate and compare the performance of our algorithms.

Comparison with Structured Diagnosis Data

In this project, we only had access to coded diagnoses of patients included in the gold standard set. Based on expert judgment, we labeled each note as either positive or negative for presence of diabetes based on information identified in the clinical notes. We then compared our results (per hospital admission and discharge) with structured data on patient diagnoses. Diagnoses data included primary diagnosis at admission, a list of secondary diagnoses, and discharge diagnoses (that might be different from admission diagnoses because they were updated during hospitalization). All diagnoses data were stored as International Calcification of Diseases version 9 (ICD 9) codes [17] and we used all codes from category 250.XX (diabetes mellitus) and V58.67 (Long term, current insulin use).

Results

Overall, 1,427 terms and expressions were discovered for diabetes using NimbleMiner. There was a moderate inter-rater agreement (Cohen's Kappa inter-rater agreement = .69) on the relevant terms between the three clinicians. Another physician reviewed all the terms, forming the final terms corpus. Table 1 presents the number of terms identified for each diabetes category. Since the system is using cosine similarity as a measure of term relatedness, our approach identified terms in Hebrew, English, misspellings in both languages, abbreviations and other lexical variants specific to Hebrew (for example specific Hebrew suffixes indicative of male or female).

Table 1– Categories and Examples of Diabetes Expressions

Domain	Number of terms	Examples
Diagnosis of diabetes	928	"dm 2", "סכרת type 2" (diabetes type 2), "ברקע גבולית סכרת" (diabetic background)
Diabetic medications	358	"באינסולין מטופלת" (uses insulin), "lantus במינון", "ב glucophage"
Hemoglobin A1c >6.5% or fasting glucose levels > 125 mg/dL	49	"hba1c>6.5", "מעל סוכר 180" (blood sugar above 180)
Diabetes complications	92	"diabetic foot", "נפרופתיה סוכרתית" (diabetic nephropathy)
Total	**1,427**	

NLP System Performance Evaluation

We first evaluated NimbleMiner's performance using just the labeling process (see NimbleMiner stage 3, weakly supervised labeling) and then compared these results with random forest algorithm performance. Table 2 shows that NimbleMiner's labeling alone showed better results than further machine learning or codes alone.

Table 2– Codes and NLP performance on the gold standard

	Diagnoses codes	NimbleMiner labeling	Random forest
Precision	.78	**.91**	.87
Recall	.85	**.96**	.86
F-score	.82	**.94**	.87

Comparison with Structured Diagnosis Data

Overall, we found 176 patients with diabetes in the coded diagnoses data while our experts found 159 patients with diabetes based on clinical notes review (800 clinical notes included in the gold standard). This difference is explained by the fact that diabetes for these patients (n=17) was coded, but was not mentioned in the text. On the other hand, we found that our experts identified an additional 15% (n= 26) more patients with diabetes described in the text compared to the diagnoses data.

Discussion

This study is one of the first to implement NLP in medical domain in Hebrew. In general, NimbleMiner's approach proved useful for clinical narratives in Hebrew. First, our team of clinicians have successfully interacted with NimbleMiner to identify a large vocabulary of terms and expressions describing diabetes in clinical notes. This list included misspellings, expressions in both Hebrew and English, specific Hebrew lexical variants, etc. Compiling such a vocabulary is often a challenge in NLP projects and it is usually conducted thorough literature review, reading large amounts of clinical notes, etc. [8]. Our approach enables clinicians to identify a comprehensive vocabulary of terms specific to their domain within a short period of time, while being assisted by machine learning components.

This comprehensive vocabulary of terms is then applied to label clinical notes. During labeling, negated terms are removed from positively labeled cases. We also remove irrelevant terms that were reviewed by the user during the vocabulary exploration process (stage 2). For example, similar terms related to presence of diabetes, like "dm 2" or are sometimes included in a larger irrelevant term, like "family history of dm 2", "son has dm 2", or "screened for dm2". These irrelevant terms are excluded, which helps our system to conduct high quality labeling. Our results support the current literature suggesting that machine learning with human-in-the-loop is an effective approach in healthcare.[18,19] Human experts can interact with machine learning to reduce NLP task complexity and improve machine learning speed.

Machine learning is then performed using the set of positively labeled clinical notes and similar in size sample of notes labeled as "unknown" to train the algorithm. In this project, our labeling approach outperformed random forest algorithm. One possible explanation is that for domains with relatively straightforward words and expressions, like presence of a diagnosed disease, rule-based approaches like ours work better than machine learning. On the other hand, machine learning can work better for domains where more ambiguity is present. Further research is needed to validate these claims. Other studies of NLP in the diabetes domain in English achieved similar NLP system performance.[20,21]

Importantly, our results indicate that about 15% of patients with diabetes mentioned in the clinical notes, did not have a diabetes-related diagnoses in the coded data. This is a serious concern for various reasons. First, not having a diabetes diagnosis might affect patient safety. For example, diabetic patients might be given a contra-indicated medication or provided with an inappropriate diet. Additionally, there are several significant implications for the organization in terms of reimbursement for patient care. When diagnoses are underreported to the health services payer—whether it is an insurance or ministry of health—medical institutions can potentially receive less reimbursement for the care they

provided. Third, underreported major diagnoses—like diabetes—pose significant limitations for any research that is conducted with clinical data.

Limitations: This study has several important limitations. First, we have only experimented with one data mining algorithm and more work is needed to examine more algorithms, such as Support Vector Machines. In addition, the use of NimbleMiner might be restricted to classifying documents based on phrases with high positive predictive value, such as diabetes terms and expressions, and further work is needed to explore the generalizability of our approach.

Conclusions

Our pioneering results indicate the feasibility of an NLP approach that can span across different languages, like English and Hebrew. Our finding about underreporting of diabetes in the coded diagnoses data highlight the urgent need in tools and algorithms that will help busy providers identify a range of useful information, like having diabetes. Identifying this information can also help health organizations receive optimal reimbursement for their services while health researchers will glean a more accurate picture of the patient population for research.

Abstract

Surgical procedures carry the risk of postoperative infectious complications, which can be severe, expensive, and morbid. A growing body of evidence indicates that high-resolution intraoperative data can be predictive of these complications. However, these studies are often contradictory in their findings as well as difficult to replicate, suggesting that these predictive models may be capturing institutional artifacts. In this work, data and models from two independent institutions, Mayo Clinic and University of Minnesota-affiliated Fairview Health Services, were directly compared using a common set of definitions for the variables and outcomes. We built perioperative risk models for seven infectious post-surgical complications at each site to assess the value of intraoperative variables. Models were internally validated. We found that including intraoperative variables significantly improved the models' predictive performance at both sites for five out of seven complications. We also found that significant intraoperative variables were similar between the two sites for four of the seven complications. Our results suggest that intraoperative variables can be related to the underlying physiology for some infectious complications.

Keywords:

Postoperative complications, Machine learning.

Introduction

Surgical procedures carry the risk of postoperative infectious complications, which can be severe, expensive, and can put patients' lives at risk [1-5]. With the ubiquity of decision support tools integrated into electronic health record (EHR) systems, perioperative decision support capabilities represent a promising direction for reducing postoperative risk or tailoring care including interventions aimed at individualized anticipation and management of the complication risk.

Initial surgical planning is primarily based on a preoperative assessment. While clearly essential, this assessment is insufficient to capture dynamic risks or changes in patient status, which may occur in the operating room. Preoperative assessment is, by definition, based on preoperative data and the planned procedure. Surgeries can deviate from the original plan for a variety of reasons or may involve unexpected physiologic changes such as bleeding, rendering the original risk estimates less valid. While the original estimates reflect the general risk of the patient and the planned surgery, they reflect neither new findings, changes in patient status, nor an altered course of surgery.

A growing body of published literature indicates that high-resolution intraoperative data can be predictive of complications [6-9]. However, the findings in these studies often contradict each other, are difficult to replicate at other sites, and are often based on very limited use of intraoperative data. For example, several studies have reported intraoperative hypothermia increases the risk of post-surgical infectious complications [6-8]. On the contrary, other studies found that there were no differences in the minimum, maximum, or ending temperatures between patients with surgical site infection (SSI) and those without – potentially due to an institutional effect: better temperature control at certain institutions. While temperature was unassociated with the surgical site infection, other intraoperative factors, most prominently blood loss, showed a significant association [9]. Besides institutional differences in clinical practice, differences in findings may also arise due to differing analytical approaches. Studies differ in the way they aggregate intraoperative variables: some studies use moments and extrema (minimum and maximum), while others use the ending measurement (the last measurement or the average of the last few measurements). Finally, differences in findings can also stem from discrepancies in definitions of the variables and outcomes.

Several high-quality registries form the backbone of surgical quality improvement research aimed at understanding and reducing postoperative complications. The National Surgical Quality Improvement Project (NSQIP) registry [10, 11] uses high-quality manually curated data [1, 12] and stands out as the gold-standard for surgical quality improvement and surgical outcomes research. NSQIP offers standardized definitions for exposure/risk variables and outcomes, helping to ensure consistency across studies. Unfortunately, it lacks detailed information regarding intraoperative risk factors, including physiologic data, laboratory data, medications, or other treatments, limiting its use for our purpose.

We conducted this study at two independent sites, Mayo Clinic and University of Minnesota-affiliated Fairview Health Services. These are two large Midwestern academic health systems with tertiary centers providing a wide range of surgical services. Both sites are members of the NSQIP registry; so, we were able to use outcome data from NSQIP patients at each site, serving as a high quality gold-standard. We used preoperative and intraoperative EHR data collected from the

clinical data repositories of the respective sites and standardized the data elements across the two sites to facilitate direct comparison of the models.

The study aims to answer the following questions: (i) In the context of perioperative decision support, does the use of intraoperative data improve the performance of 30-day postoperative risk models? (ii) Do significant intraoperative variables in the risk models pertain to the same physiological concepts across the two sites? We proceed with the assumption that when significant intraoperative variables differ despite having been defined identically, the models may capture institutional differences; when the significant variables coincide, they are more likely to relate to the physiological processes underlying the postoperative complications.

Methods

Setting and cohort definition. We consider two independent Midwestern health care systems: Mayo Clinic (MC) and Fairview Health Services (FHS). We include all patients from MC and FHS between 2010 and 2017 who are part of the NSQIP sample. For these patients we collected all available information about their NSQIP index surgery and a 30-day history before the index surgery from the respective institutions' EHR repositories. The NSQIP registry collects complications within a 30-day postoperative window. If a patient had another surgery in the 30-day postoperative window, we used the index surgery and measured the 30-day postoperative window for the outcome from the index surgery. For each complication, patients with the same pre-existing complication at the time of surgery were excluded.

Independent variables. We primarily rely on known risk factors of infection [13-15]. Independent variables were divided into three groups: demographic, preoperative, and high-resolution intraoperative. We limit ourselves to basic demographic information, such as age, sex, and body mass index (BMI) that are generally available. Preoperative variables are historic diagnoses including the problem list, procedures, and medications, as well as the preoperative indication for surgery. We use laboratory results and vitals to establish a preoperative baseline. Data from the preoperative assessment were preferentially used; if the data is not available, we use measurements from no more than 30-days before surgery. Diagnosis codes are rolled up into complications using the Clinical Classification Software [16].

Aggregating intraoperative variables. The intraoperative variables include orders, medications, and high-resolution vitals and labs. The stream of high-resolution variables needs to be divided based on the three stages of anesthesia. During the first (approximately) 15 minutes, called the *induction* phase, the vitals drop and deviate heavily from the normal. The last 15 minutes is called the *emergence* phase, where vitals are expected to return to close to normal but also involves significant changes as the patient is transitioned from anesthesia—often with full ventilation—to no anesthesia. The operation takes place between these two phases, in the so-called *maintenance* phase, where the vitals are expected to remain stable, although different from the preoperative baseline. In this work, we focus on the maintenance phase and use the mean value of labs and vitals during this phase.

Outcomes. We consider seven infectious outcomes: sepsis, septic shock, urinary tract infection (UTI), pneumonia (PNA) and the three kinds of SSI (superficial, deep tissue, and organ space SSI). We extract the outcome information from the NSQIP registry.

Modeling. Each outcome was modeled independently using logistic regression. For each outcome, two models are constructed. The "*pre*" model only uses demographics and preoperative data (30-day history of complications, baseline labs and vitals), while the "*pre+intra*" model uses aggregated intraoperative measurements on top of the preoperative and demographic data.

All models are logistic regression models. Missing labs and vitals were imputed using the middle of the normal range for the measurement. This assumes that the measurement is missing because it was deemed unnecessary to measure. The initially high number of independent variables was reduced by causal variable screening [19]. We used the PC-Simple algorithm [20] with a maximal condition set size of three [21]. This algorithm discards all variables that are independent of the outcome given at most three other variables. The rationale is that these variables do not affect the outcome directly, they only affect the outcome through other variables. Subsequent backwards elimination was applied to the remaining set of independent variables with a significance level of .05. The R statistical computing environment was used for all modeling. The PC-Simple algorithm is available in the pcalg R package [20].

Evaluation. Consistent with the intended use in perioperative decision support, we evaluated the models based on their predictive performance using concordance as the metric. Concordance is the probability that between two randomly selected patients, among which one has the complication in question while the other does not, the one with the complication has the higher predicted risk. Concordance is equivalent to the commonly reported area under the receiver-operating-characteristic curve (AUC).

Internal validation and effect of the intraoperative variables. Bootstrap estimation with 200 replications was used to estimate the concordance of the models. For each complication, two models were built on the same bootstrap replication: one with and one without the intraoperative variables. We measured the effect of the intraoperative variables as the mean difference in concordance between the models with and without intraoperative variables across the 200 bootstrap replications. The statistical significance of the difference was determined through a paired t-test.

External comparison. If the intraoperative variables capture a valid physiological phenomenon, then the variables selected at the two sites relate to the same quantity. We manually examined the models with the intraoperative data across the two sites to determine whether the selected variables coincide or at least relate to the same physiological concept. For example, oxygen saturation and ventilator settings relate to the same physiological concept (oxygen in the blood). When the selected variables relate to different concepts, there is a risk that the model simply captures an institutional artifact.

Results

Cohort Description

Table 1 contains a description of the analytic cohort at the two health systems. It contains demographic information, outcomes, history of the outcomes, history of relevant complications, and baseline (preoperative or at most 30 days before the index surgery when preoperative measurement is unavailable) lab results and vitals. Due to the high number of lab results and vital signs, we only report those that were significant in at least one of the models. Categorical variables are reported as count and percentage in parenthesis; continuous variables are reported as median and interquartile range in parenthesis.

Table 1 – Cohort Description.

	Mayo Clinic	Fairview
Number of patients	38,045	9,044
Demographics		
Age	61 (49, 71)	55 (40, 66)
Gender (male)	18,769 (48.7%)	4053 (45%)
Outcomes		
SSI Superficial	586 (1.5%)	107 (1.2%)
SSI Deep Tissue	186 (0.5%)	45 (0.5%)
SSI Organ Space	417 (1.1%)	119 (1.3%)

PH	7.38 (7.32, 7.42)	7.38 (7.32, 7.42)
CO_2	40.5 (36.5, 43.5)	25.5 (24.0, 27.5)
Ca	4.71 (4.55, 4.92)	4.59 (4.30, 4.78)
K	4.15 (3.90, 4.50)	3.9 (3.7, 4.2)
Na	138 (137.8, 138.4)	139 (137, 141)

(1) Abbreviations: UTI: urinary tract infection; PNA: pneumonia; SSI: surgical site infection; COPD: chronic obstructive pulmonary disease; BMI: body mass index; BUN: blood urea nitrogen; RBC: red blood cell [count]; WBC: white blood cell [count]; MCV: mean corpuscular volume; RDW: red blood cell distribution width; Ca: calcium ion concentration; K: potassium ion concentration; Na: sodium ion concentration. (2) Only variables that were significant in at least one model are presented.

Model performance and effect of the intraoperative variables

Table 2 presents the predictive performance of the models for each of the outcomes. For each outcome, the table contains three rows: the first one shows the performance as measured by AUC of the "pre" model (that uses only demographics and preoperative data), the second one shows the performance of the "pre+intra" model, which uses the intraoperative data in addition to the demographics and preoperative data, and the third row shows the difference in performance between the "pre" and "pre+intra" models. For the "pre" and "pre+intra" models, the standard deviation of the performance (obtained from 200 bootstraps) is shown in parenthesis; for the difference, the p-value of the paired t-test is shown in the parenthesis using the scientific notation (e.g. 2e-8 is $2*10^{-8}$). All differences are statistically significant at 0.05 confidence level, but superficial and deep tissue SSI are not significant on FHS side after Bonferroni correction.

Table 2 – AUC performance of the "pre", the "pre+intra" models, and the difference in performance.

Outcome	Model	Mayo Clinic	Fairview
PNA	Pre	.877 (±.021)	.693 (±.044)
	Pre+intra	.881 (±.022)	.734 (±.044)
	Difference	***.004 (1e-8)***	***.041 (1e-16)***
Sepsis	Pre	.736 (±.024)	.695 (±.045)
	Pre+intra	.755 (±.021)	.711 (±.046)
	Difference	***.019 (1e-16)***	***.016 (8e-13)***
Septic Shock	Pre	.827 (±.031)	.715(±.078)

External Comparison of the Significant Variables

Table 4 displays the number of bootstrap iterations in which the variable was selected for each complication at each site. We only list variables that were selected in at least 100 of the 200 bootstrap iterations for at least one outcome at one site.

Table 3 offers a summary of the information in Table 4. It lists the most important intraoperative variables that are common between the two sites for each outcome.

Table 3 – Selected variables

	Significant intraoperative variables	
Outcome	**Mayo Clinic**	**Fairview**
PNA	antibiotic use, lactate, CO_2, FIO2	Lactate, MCV, pulse, SpO_2
Sepsis	Glucose, isoflurane expired, PEEP, pulse	PO2, RBC, pulse, hematocrit
Septic Shock	Antibiotic use, glucose, WBC, pulse, PEEP	Lactate, FIO2
SSI Superficial	CVP, PEEP, pulse	PEEP
SSI Deep Tissue	Antibiotic use, steroid use, PEEP	PO2
SSI Organ Space	Antibiotic use, bicarb, Ca, glucose, CVP, isoflurane expired	Hemoglobin, PH arterial, PO2, pulse
UTI	Antibiotic use, steroid use	Ca, PO2, CVP, PEEP

Abbreviations: FIO2: Fraction of Inspired Oxygen; PEEP: Positive End Expiratory Pressure; PO2: Partial pressure of oxygen; WBC: white blood cell [count]; CVP: central venous pressure; Ca: calcium ion in the blood; MCV: mean corpuscular volume; SpO_2: blood oxygen saturation; RBC: red blood cell [count].

Discussion

We view EHR-integrated perioperative clinical decision support as a key avenue towards reducing postoperative complications or towards better anticipating and managing them. Central to such systems are accurate risk models with the ability to produce risk estimates on demand based on contemporaneous data, including intraoperative data. In this work, we sought to answer the following two questions: (i) Do intraoperative data elements improve our ability to predict postoperative complications? and (ii) Are these models specific to institutions or do they describe possible physiological phenomena that are institution-independently predictive of postoperative complications?

Regarding the first question, we found that the inclusion of intraoperative variables led to statistically significant improvements in the risk models' predictive ability for five of the seven infectious complications at both sites. These complications were pneumonia, sepsis, septic shock, organ space SSI, and urinary tract infection. At the Mayo Clinic site, the inclusion of the intraoperative variables led to statistically significant (albeit not necessarily clinically relevant) improvements for all complications, likely due to the much larger sample size.

The lack of statistically significant improvement for the other two SSI types, superficial and deep tissue, is unsurprising. These diagnoses have more ambiguity and our previous work on detecting SSI retrospectively also suggests that predicting superficial and deep tissue SSI is difficult [17, 18].

Regarding the second question, we found that some of the intraoperative variables overlap across the two sites for all four of the complications in which intraoperative variables improved the predictive performance. In the cases of pneumonia, sepsis, and organ-space SSI, some of the variables (lactate, pulse) matched exactly, while others referred to a shared concept. For example, FIO2 and SpO2 are related to the sufficiency of oxygen in the bloodstream: the first one is the ventilator setting (to supply the oxygen into the bloodstream) while the second one is the direct measurement of oxygen saturation. For sepsis, partial pressure from oxygen and PEEP have an analogous relationship; and for organ space SSI, bicarbonate and PH both measure the acidity of blood. The fact that many of the significant variables are common across the two sites suggests that these variables can be related to the physiological process(es) underlying the outcomes.

Conclusion

Intraoperative variables were found to statistically significantly improve the performance of 30-day post-operative risk models for five of the seven infectious complications at both sites. There was considerable overlap in the significant intraoperative variables across the two sites and the overlapping variables were related to lactate, acidity, and blood oxygen.

Abstract

In trauma care and trauma care research there exists an implementation gap regarding a consistent controlled vocabulary to describe organizational aspects of trauma centers and trauma systems. This paper describes the development and evaluation of a controlled vocabulary for trauma care organizations. We give a detailed description of the involvement of domain experts in the domain analysis workflow and the authoring of definitions and additional term descriptions. Finally, the paper details the evaluation methodology to assess the initial version of the controlled vocabulary. The results of the evaluation show that our development process yields terms most of which find approval from domain experts not involved in the development. In addition, our evaluation tools resulted in valuable domain expert input to optimize the controlled vocabulary.

Keywords:

Trauma Centers; Vocabulary, Controlled; Biomedical Ontologies

Introduction

Since the 1970s, the American College of Surgeons (ACS) has worked to establish and refine criteria that set the standards for trauma centers. Due to the inherent difficulty in obtaining reliable outcome data, these standards have focused largely on measures of structure and process. The most recent standards were published in *Resources to Optimal Care of the Injured Patient (2014)* [1]. In 2008, the ACS established the Trauma Quality Improvement Program (TQIP) to enable trauma centers to measure and compare their risk-adjusted patient outcomes to similar organizations [2,3]. Though the TQIP program continues to grow, at this time the relationship between structure and process measures and clinical outcomes remains elusive. Further, beyond the standards themselves, the ways in which the particular attributes of trauma centers, and at a larger scale, of regional trauma systems, contribute to optimal patient outcomes have not yet been identified or measured.

While the trauma center standards have paved the way for a consistent and reusable terminology, there still exists an implementation gap in providing and using a well-structured controlled vocabulary to describe the structure of trauma centers and trauma systems. Having such a resource will facilitate transferring knowledge and experience from one trauma center or trauma system to another. In addition, controlled vocabulary also will facilitate comparison of organizational structures and procedures both nationally and internationally.

CAFÉ (Comparative Assessment Framework for Environments of Trauma Care) is an NIH-funded project that aims to collect detailed information on the particular organizational attributes of trauma systems and trauma centers. Ultimately, the goal is to link that data to clinical outcome data to identify those organizational attributes of trauma centers and trauma systems that are of high impact on patient outcomes. The project creates a web-based service that allows an interested individual to enter data about their trauma center or trauma system and to conduct an anonymous self-assessment of the organizational structures of their trauma center or trauma system. The first step to enable such a comparison is to provide a common controlled vocabulary covering all relevant aspects of trauma center and trauma system management. Preliminary CAFÉ project work that leveraged natural language processing to create lists of relevant terms from published abstracts pertinent to the domain was described in a previous publication [4]. In this paper we report the workflow of creating the initial version of the vocabulary in close collaboration. In addition, we describe our evaluation methodology, describe the results of the evaluation, and draw conclusions on whether the development methodology of the controlled vocabulary has been successful. For the purpose of the CAFÉ project, the controlled vocabulary needs to exist as a Web Ontology Language (OWL2) to be used with other semantic web technologies. The general outline of the project plan was published elsewhere [4].

Methods

The first step necessary for developing the CAFÉ system was the domain analysis of organizational structures of trauma centers and trauma systems. A domain analysis for the purpose of developing a controlled vocabulary consists of identifying the relevant terms to represent the domain of interest and providing definitions for those terms. For the CAFÉ project, that meant collecting relevant terms to represent and analyze the organizational structure of trauma centers and trauma systems. Since our aim is to create an ontology that follows the OBO Foundry principles, it was prudent to use the OBO

Foundry suggested form of definition, the *genus-differentia* (http://www.obofoundry.org/principles/fp-006-textual-definitions.html) form. In the OBO Foundry community, definitions of that form are frequently provided using the IAO:definition annotation property (http://purl.obolibrary.org/obo/IAO_0000115). In addition to the *genus-differentia definition* being an OBO Foundry requirement, these definitions are also particularly useful when creating a taxonomy for the controlled vocabulary since these definitions always refer to the parent term of the term being defined.

Earlier work on OBO Foundry ontologies has informed the project leads for ontology development that domain experts and potential users often find the *genus-differentia definition* a poor representation of how they view the domain and communicate about its phenomena. Hence, we decided to follow the advice of Hogan et al. [5] to provide definitions that are easily accessible for domain experts using an annotation property different from the IAO:definition. To allow that, we created the OOSTT user-centered description annotation property (http://purl.obolibrary.org/obo/OOSTT_00000030).

In addition, we also created the annotation property "CAFE application label" for cases where the label that was created to follow naming conventions in ontology development would be a suboptimal label to display to the user of the system (http://purl.obolibrary.org/obo/OOSTT_00000043).

The effect of this consideration on our domain analysis is that we are collecting one RDFS:label, one IAO:definition and, in cases where the *genus-differentia definition* is deemed hard to parse for domain experts, one OOSTT user-centered description.

After the CAFÉ project was funded by the National Institute of General Medical Science (NIGMS) in spring 2015 (R01GM111324), a weekly (later bi-weekly) expert call was started to identify relevant terms to assess the organizational structure of trauma centers and trauma systems and, in future work, its relationship to patient safety and outcomes. The committee consisted of two trauma surgeons, both bearing roles in the American College of Surgeons (ACS) Committee on Trauma (COT); two representatives of the COT with experience in trauma center verification and trauma system consultation; two researchers with experience in analyzing data on trauma care, including data from trauma centers and trauma systems; and one expert in organization analysis. To accomplish the domain analysis part of the project, a multi-step process was created during which the members of our expert group reviewed material from the ACS COT and added material based on their experience to identify the relevant terms and provide user-centered descriptions for those. The goal of this process was the implementation of our controlled vocabulary in the OWL language.

Step 1: *Domain set of terms.* In the first step, the expert group agreed on a set of terms necessary to cover the domain of organizational structures of trauma centers and trauma systems. This step used the American College of Surgeons' *Resources for Optimal Care of the Injured Patient, Sixth Edition* from 2014 as a starting point [1]. The experience of the domain experts regarding the practical implementation of trauma center verification, trauma system consultation, and quality improvement on trauma, in general, informed the final decision on which terms to include.

Step 2: *Preliminary descriptions provided.* Once the initial set of terms was agreed upon by the domain expert group, preliminary descriptions of each term were provided by the domain experts. The goal was to capture a description that the domain experts were able to agree upon regardless of whether the description met the requirements of an OBO Foundry definition.

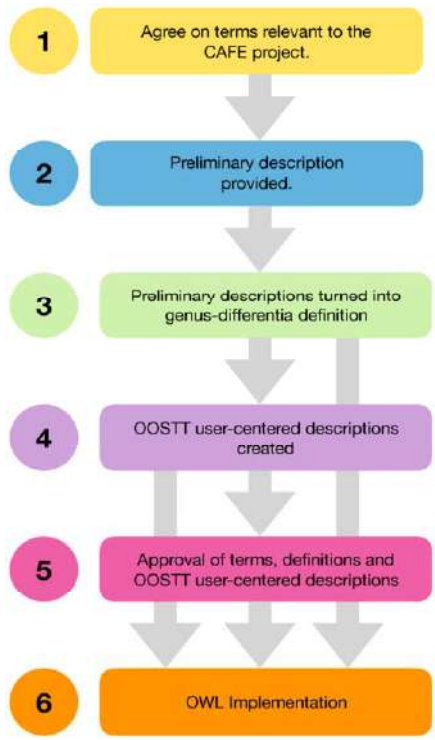

Figure 1 – Development workflow of the controlled vocabulary on organizational structures of trauma centers and trauma systems.

Step 3: *Preliminary descriptions turned into genus-differentia definitions.* Based on the descriptions, the CAFÉ OWL implementation team suggested *genus-differentia definitions*. In doing so, the OWL implementation teams thought about definitions and descriptions in a set-theoretical way. We assumed that for each definition/description there is a set of entities for which that definition/description is true. In creating a *genus-differentia definition* for a description it is crucial that the former is true for the same set of entities as the latter. In other words, that the p *genus-differentia definition* has the same extension as the initial description authored by the domain experts. In many cases, this process involved iterative communication between the domain experts and the ontology developers to a) achieve a clear understanding of the intended meaning and b) ensure congruency between the preliminary description and the *genus-differentia definition*.

Step 4: *OOSTT user-centered description created.* Based on whether the domain experts felt that the *genus-differentia definition* was useful for the target audience or not, OOSTT user-centered definitions were created where usefulness for the target audience was in doubt. To the extent the delimitation of the CAFÉ domain expert group agreed that the *genus-differentia definitions* are useful to the target audience was one of the parameters that we plan to assess with our evaluation approach. For the terms that have both a OOSTT user-centered description and a *genus-differentia definition* the same kind of congruency as described in Step 3 was required.

Step 5: *Approval of terms, definitions and OOSTT user-centered descriptions by domain experts.* Our aim was to submit all final terms, their definitions, and their OOSTT user-centered descriptions to another round of expert approval. While this strategy worked for many terms, restrictions created by our timeline limited another approval round for all terms.

Step 6: *OWL implementation.* Finally, all terms were included in the OWL file step-by-step during the rollout of the OOSTT ontology, which started in 2015 and was described in more detail in a previous publication [4]

To help determine the quality and acceptance by our target audience of the terms and definitions created, we conducted a survey with feedback. A new surveying tool was created for the task. Our goal for this new tool was to show a small number of random terms and definitions to members of our target audience while minimizing inconvenience to them. This tool also needed to ensure a balanced number of reviews for each term and easily allow us to load the up-to-date version of the 216 terms and definitions. The term survey tool (https://github.com/cafe-trauma/term_survey) was built over two days in Python using the Django Framework. To ensure current terms and definitions could easily be loaded, the tool was built with the functionality to parse an OWL file for OWL classes from which the RDFS:label would be used for the "term" and the URI of an annotation would be passed to query for the "definition". As mentioned above, we used a custom annotation property for "User Centered Definitions." After the terms and definitions were loaded, an administrator set a welcome message, a logo, and a number of terms for each respondent to review (Figure 2).

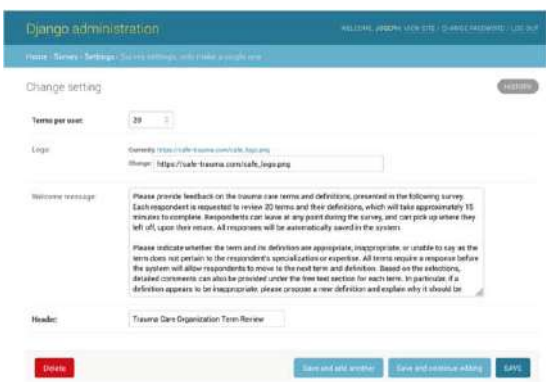

Figure 2 - Term Tool Configuration

At this point the survey was ready. To distribute it to respondents we emailed a link to the landing page of the survey, where the respondent was greeted by the welcome message and could begin reviewing terms (Figure 3). We distributed the survey to 75 members of the ACS COT. The terms for each respondent to review were not preselected. Each time a respondent attempted to review a new term the tool would query for the current list of terms with the lowest number of reviews and return a random term from this list, ensuring an equal coverage of reviews for our terms. On the term review page, a respondent was presented with a term, its definition, radio buttons to indicate the acceptability of a definition, and space to provide feedback (Figure 4). After clicking to move to the next term, a respondent's feedback was immediately saved to the server and a new randomly selected term was presented. The term review page also had a progress bar to indicate the number of terms remaining for review. After giving their initial feedback, a cookie was created in the respondent's browser that tied them to their session of terms in case they closed the browser before finishing. Since we saved feedback after each term we still had feedback even if the respondent did not finish the requested number of term reviews. After reviewing the assigned 20 terms and definitions, the respondent was shown a summary screen with all of their feedback and given the choice to edit any of their feedback or to clear their session and review more terms if so inclined (Figure 5).

Figure 5 – Survey Completion Summary

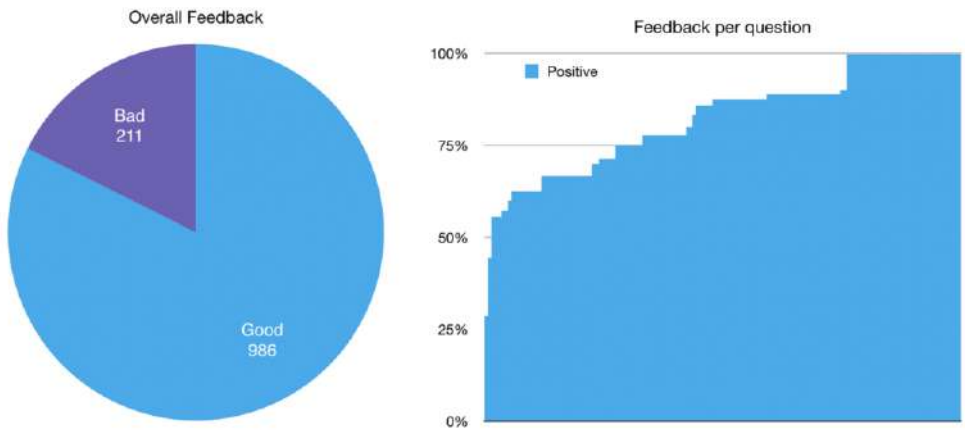

Figure 6 - Survey Feedback

Results

Using our newly built survey tool, we received a large amount of good feedback about our terms. The survey was distributed to 75 people in the trauma care domain. We received at least one term review from 74 people. In total, our 142 terms and definitions received 1,197 reviews. That response rate allowed us to have, on average, eight different people review each term and definition. Of the 1,197 individual reviews 986 of them considered the term and definition suitable (Figure 6). The reviewers largely agreed with each other when reviewing the same terms both positively and negatively. Our highest rated terms, such as "trauma program leadership," "hospital governing body role," and "trauma program" received uniformly good feedback, while the lowest rated terms, "trauma nursing evaluator obligee role," "trauma quality improvement and patient safety program lead role," and "emergency medical services provider association" were negatively reviewed by multiple people. Overall, 103 or 72% of our total terms received positive feedback from over 75% of reviewers (Figure 6).

The responses and comments were provided to the ontology developers who reviewed the comments and aimed to correct the issues pointed out by the domain experts. For the lowest rated terms, this included a complete revision of the definition, as in the case of "emergency medical services provider association," which was updated based on reviewer feedback[1]. The most reported problem with "trauma quality improvement and patient safety program lead role" was that the label was singular, while the definition implied plural. The definition was changed to better reflect the label[2]. The label "trauma nursing evaluator obligee role" was critized for the use of uncommon language, namely "obligee role." Since that class did not have a CAFÉ application label, we added the CAFÉ application label "trauma nursing evaluator"[3].

Table 1 – Highest rated terms in our controlled vocabulary and their initial definition/OOSTT user-centered description.

Term label	OOSTT user-centered description or definition
trauma program leadership	The individuals who provide oversight, direction, coordination, and management for the facility's trauma program.
hospital governing body role	A group of individuals appointed to a hospital's board of directors who provide governance, direction, and oversight of the overall operation of a hospital.
trauma program	The organizational unit of a healthcare facility that is designated to provide and coordinate care for injured patients.

Table 2 – Lowest rated terms in our controlled vocabulary and their initial definition/OOSTT user-centered description.

Term label	OOSTT user-centered description or definition
trauma nursing evaluator obligee role	The individual with authority and responsibility for evaluating the nursing care provided to trauma patients.
trauma quality improvement and patient safety program lead role	The role of an authorized group of healthcare providers that ensures trauma quality improvement and patient safety within the trauma program.
emergency medical services provider association	An association of EMS agencies that any agency may join voluntarily to share information or collaborate on issues of state or national importance.

Discussion

The results presented in this paper provide insight into two main areas: a) domain analysis and definition authoring in a clinical domain and b) providing a novel resource for trauma care and trauma research to facilitate comparison between trauma centers and trauma systems by creating a controlled vocabulary.

The current evaluation of the initial version of the domain analysis yielded primarily positive results. Not only did participants rate most terms as "good," they also provided insightful and highly actionable comments to make the terms and definitions more useful or correct. The curators of the controlled vocabulary have already incorporated multiple improvements based on reviewer comments and are currently working to finalize that process. At this point in time, the survey has only been distributed to trauma care experts affiliated with the American College of Surgeons. We are planning to distribute the survey to clinical staff in trauma management in order to gather their input on these terms.

Larger, international evaluations of the vocabulary are planned for 2019. Distributing the survey to experts from diverse healthcare systems will provide interesting insights into which terms are useful and which definitions are shared across healthcare systems.

While efforts to improve terminologies to advance trauma care and trauma research are not uncommon [6,7,8], literature searches conducted on PubMed reveal an astonishing lack of effort to create terminologies or controlled vocabularies relevant to trauma care in general and its organization. Oliver and Walter [9] point out the problems arising from the lack of a common terminology in trauma research related to preventable death. Searching PubMed for ["trauma system" terminology], ["trauma center" terminology], ["trauma system" vocabulary], ["trauma center" vocabulary], yields 38 distinct papers, only one of which specifically deals with the problem of providing a terminology/vocabulary for organizational structures in trauma systems and trauma centers. Notably, that paper is also the output of the CAFÉ project [4]. So, while there is an established field of work on terminologies and classifications for specific types of trauma and a corpus of research on outcome measures, there is not much effort to provide a unified language to describe the organizational structure of trauma centers and trauma systems.

Table 3 – Number of publications retrieved from PubMed using a set of queries related to trauma systems, trauma centers and terminology/vocabulary.

Query	Number of retrieved publications
["trauma system" terminology]	2
["trauma center" terminology]	34
["trauma system" vocabulary]	1
["trauma center" vocabulary]	1

Conclusions

While some of the terms still required additional refinement, a vast majority of the terms was deemed "good" by a large group of domain experts working in collaboration with the American College of Surgeons. Based on these results we conclude that our methodologies for domain analysis and creation of definition and user-centered descriptions have successfully created an initial version of a controlled vocabulary for the ACS community and the trauma care community in the U.S.

We also believe that the number of targeted and useful comments we received from the domain experts participating in our survey highlights the fact that dividing review tasks into small portions and distributing them over a larger number of participants is a valuable approach to encourage expert feedback.

Normalizing Dietary Supplement Product Names Using the RxNorm Model

Abstract

The use of dietary supplements (DSs) is increasing in the U.S. As such, it is crucial for consumers, clinicians, and researchers to be able to find information about DS products. However, labeling regulations allow great variability in DS product names, which makes searching for this information difficult. Following the RxNorm drug name normalization model, we developed a rule-based natural language processing system to normalize DS product names using pattern templates. We evaluated the system on product names extracted from the Dietary Supplement Label Database. Our system generated 136 unique templates and obtained a coverage of 72%, a 32% increase over the existing RxNorm model. Manual review showed that our system achieved a normalization accuracy of 0.86. We found that the normalization of DS product names is feasible, but more work is required to improve the generalizability of the system.

Keywords:

Dietary supplements; RxNorm; Natural Language Processing

Introduction

Dietary supplements (DSs) are defined as "products taken by mouth that contain a dietary ingredient that includes vitamins, minerals, amino acids, and herbs/botanicals, as well as other substances that can be used to supplement the diet" [1]. They comprise one of the fastest growing categories of complementary and alternative medicines [2]. According to the National Health and Nutrition Examination Survey (NHANES), the age adjusted consumption of DSs has steadily increased, both in male (28% to 44%) and female (38% to 53%) populations [3], especially among adults aged ≥60 years where 70% have reported using one or more DS [4]. Increasing usage of DSs has led to substantial market growth resulting in wide availability of dietary supplement products.

The regulations covering DSs are much less stringent than those covering commonly consumed foods and clinical drugs [1], even though DS adverse events and DS-drug interactions are common [5, 6] and potentially severe [7]. DS products and dietary ingredients are regulated by the U.S. Food and Drug Administration (FDA) under the Dietary Supplements Health and Education Act (DSHEA). As part of this, the FDA developed guidelines to help ensure that DSs sold in the United States (produced both domestically and abroad) are properly labeled. However, according to the FDA, "those guidance documents only represent the agency's current perspective and should be viewed only as recommendations, unless specific regulatory or statutory requirements are cited" [8, 9]. Thus, it is not required to obtain approval of a label in order to import or distribute a DS, and failing to comply with the guidelines does not entail any legally enforceable consequences.

To make matters worse, DS product names express ingredient and brand information in a large variety of ways. Product names often include additional components such as ingredient qualifiers (e.g. "leaf", "dried", "extract"), dose information (e.g. "capsules", "10mg"), and flavors. This, along with loose labeling guidelines, have resulted in DS product names that lack a consistent structure, which hinders critical tasks such as cross-platform communicability and the reuse of DS knowledge.

The situation is very different for clinical drugs. In addition to stricter regulations regarding drug naming, the U.S. National Library of Medicine develops RxNorm, a normalized naming system for generic and branded drugs [10]. It supports semantic interoperability between sixteen drug terminologies and pharmacy knowledge bases. RxNorm normalizes drug names using a set of 15 term types corresponding to drug entities [11]. Term types are codes which indicate the level of specificity of a given drug name or qualifier. For example, the drug name "Fluoxetine" is assigned the term type *IN* (ingredient) and the qualifier "Oral solution" is assigned *DF* (dose form). Some RxNorm term types are the combination of two or more atomic term types. For example, the *IN* and *DF* term types combine into *SCDF* (Semantic Clinical Drug Form), such as in "Fluoxetine Oral Solution".

As a means of normalizing drug names, RxNorm plays an essential role in decision support, quality assurance, healthcare research, reimbursement, and mandatory reporting [12]. Similarly, normalizing DS product names is an important step. By providing a reliable way to refer to DS products, it would facilitate DS pharmacovigilance and knowledge discovery such as in [13, 14]. However, Y. Wang et al. showed that existing normalization resources such as RxNorm and UMLS cover only a fraction of DS terms, indicating a need for DS-specific resources [15]. Sharma and Sarkar developed such a resource to extract DS mentions from adverse event reports and clinical notes, but their system is restricted to ingredients and do not consider related concepts such as dose form or strength, which are crucial in the RxNorm model [16, 17]. A recent study by L. Wang et al. showed promising results applying and extending the RxNorm model to Chinese clinical drugs [18]. In a similar vein, this study evaluates the feasibility of applying an RxNorm-like normalization approach to DS product names. We developed a rule-based natural language processing (NLP) system which is able to find various components of the product names and assign them to term types, which can be used for normalization. Our system leverages three existing terminologies to develop the NLP patterns: The Therapeutic Goods Administration (TGA) [19], RxNorm, and iDISK - an integrated knowledge base of DSs and related terms [20]. We evaluated the generalizability of the system by reporting its coverage and accuracy on a set of product names extracted from the Dietary Supplement Label Database (DSLD) [21].

Methods

This study is comprised of three phases: data extraction and preprocessing, NLP pattern development, and evaluation. Figure 1 illustrates the overall process and each phase is detailed below.

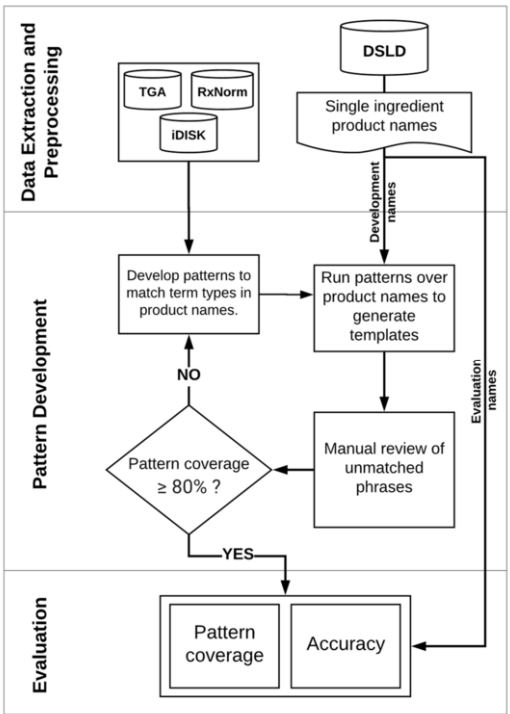

Figure 1– The study design.

Data Extraction and Preprocessing

We extracted 12,383 product names from DSLD using a web scraper. We restricted the extracted names to those listed as containing a single dietary ingredient in order to reduce the amount of variability in the product names. This set of names was then split into a development set (9,906, 80% of the original data) and evaluation set (2,477, 20% of the original data). In order to ensure both sets were representative of the full data set, the split was stratified on the LanguaL (http://www.langual.org) product type assigned to the DS product by DSLD.

NLP System Development

The development set of product names was used to build the NLP system. This system was built using an iterative process comprised of four stages:

1. We developed a set of term types corresponding to components of the product names, detailed in Table 1. We also developed regular expression patterns to match these term types in the product names. These patterns used keyword lists obtained from TGA and RxNorm to match components such as dosages and dose forms, plant preparations (e.g. dried leaf), etc, as detailed in Table 1. We used the ingredient name thesaurus from the iDISK knowledge base to match ingredient names as well as a regular expression for certain vitamins. Where necessary, we manually augmented these keywords lists with lexical variants such as abbreviations and plural forms (e.g. "cap" and "capsules" in addition to "capsule"). Brand names were matched using a combination of a rule based method and manually curated list of brand names extracted from the development set. We removed common stop words from the product names in addition to defining a stop word term type (*STOP*) in order to designate which words should not be included in the normalized product names.

Table 1– Term types used in the product name normalization system.

Term Type (Abbreviation)	Description	Example	Pattern Source
Animal Source (ANM)	The part of an animal from which the ingredient is derived.	Bone Marrow	TGA
Brand Name (BN)	Manufacturer's name.	GNC	Annotation, rules
Certification (CERT)	Official certifications claimed by the product.	USP certified	TGA
Claim or Use (USE)	A description of the purported use of a dietary supplement.	Sleep aid	Annotation
Dose Form (DF)	The phsyical from of the product.	Capsule	TGA, RxNorm
Dose Form Group (DFG)	A grouping of dose forms related by route of administration.	Topical	TGA, RxNorm
Flavor (FLV)	The flavor of a supplement.	Strawberry	Annotation
Ingredient (IN)	Name of the dietary supplement ingredient.	Gingko Biloba	iDISK, rules
Plant Source (PLNT)	The part of a plant from which the ingredient is derived.	Leaf	TGA
Demographic or Population (POP)	The group of persons for whom the product is intended.	Children's	TGA
Preparation (PREP)	A descriptor of how an ingredient is prepared.	Dried	TGA
Stop Word (STOP)	Uninformative words that are to be excluded from the normalized form.	With, Natural	Annotation
Strength (STR)	The quantity of the ingredient in a product.	100 mg	TGA
Time of Use (TIM)	When the product is intended to be used.	Night time	TGA

2. For each name in the development set, we searched for each pattern in turn. Thus the output of this step is an ordered list of term type codes each corresponding to a matched span in the product name string. The ordering of this list matches as closely as possible the RxNorm term types. For example, running the patterns on the product name "Herb Pharm Elderberry" returns the list of matched term types *BN IN*, where *BN* (brand name) matches "Herb Pharm" and *IN* (ingredient) matches "Elderberry". We call each unique list of term types a template. Note that the *STOP* term type is not included in the final templates. Templates correspond to the higher-level RxNorm term types such as *SCDF*. Ambiguous contexts were handled either by the regular expressions themselves (e.g. "mg" for milligrams must be preceded by a number to avoid confusion with magnesium), or by the order in which the

patterns were searched. Regarding the latter case, brand names were search first, followed by ingredients, as these have the most potential for overlap with other term types.

3. We computed the coverage of the patterns on the development set. This included the number of fully matched (i.e. all parts of the name were matched to one or more patterns), partially matched (i.e. some substring of the name was matched), and unmatched product names. Our target full-match coverage on the development set was 80%. If our system did not reach this target, we reviewed the partially matched and unmatched names (step 4 below) and proceeded with the next round of development. If it met or exceeded 80% we moved on to evaluation.
4. At each iteration of the pattern development cycle while the full-match coverage was below 80%, Two health informaticians (RR and AB) manually reviewed 20% of the partially matched and unmatched product names. The results of this review were used to modify existing patterns and create new patterns to improve the coverage of the system.

Evaluation

Evaluation proceeded after our pattern matching system obtained the target 80% full-match coverage on the development set. At this point we ran the pattern matching system on the 2,477 held out evaluation product names and computed the coverage on the evaluation set. Each fully matched product name corresponds to a template which is output by our system. For each template that is also present in RxNorm, we report the frequency with which it occurred in the development and evaluation sets.

Additionally, we evaluated the accuracy of our system on the evaluation set in two ways:

1. We measured the accuracy of the term type patterns on the evaluation set. Each *matched span - term type* pair in each product name in the evaluation set was annotated according to its correctness. We assigned a 1 if the words within the span belonged to the corresponding term type, or a 0 otherwise. We then computed the accuracy for each term type using these annotations.
2. We measured the accuracy over the product names in the evaluation set. This was computed by averaging the accuracies of the product names, where the accuracy of a given product name *n* is the mean of the labels assigned to each token in the name in step 1, computed by

$$accuracy(n) = \frac{1}{|T(n)|} \sum_{t \in T(n)} \ell(t)$$

Where $T(n)$ is a function that returns the tokens in the product name n and $\ell(t)$ is a function that returns the label (1 or 0) for token t.

In the case of partially matched or unmatched product names, each unmatched token is implicitly assigned a 0. This allows us to compute the accuracy of partially matched and unmatched product names and thus an accuracy value for the entire evaluation set.

Results

Running the pattern matching system over the development set produced 129 unique templates using all 13 term types after removing *STOP*. Running the system on the evaluation set produced 62 unique templates, 7 of which were not seen in the development set, for a total of 136 templates. The *TIME* term type was not present in any full matches on the evaluation set.

The 5 most frequent templates across the development and evaluation sets are shown in Table 2.

8 of the 129 development templates and 5 of the 62 evaluation templates matched existing RxNorm term types. The frequencies of these templates in the development and evaluation sets are given in Table 3. In both the development and evaluation sets the *BN IN STR* template (*SBDC* in RxNorm) accounted for about one third (33%) of the fully matched product names. The most frequent of these templates are also the first, third, and fourth most frequent templates overall in both the development and evaluation sets, shown in Table 2. Note that the second most frequent template, *BN IN*, does not have a corresponding RxNorm term type.

Table 2– The 5 most common templates and their product name coverage across the development and evaluation sets along with examples for each.

Frequency ranked templates	Example product name
BN IN STR (32.0%)	Bronson Laboratories Vitamin E 200 IU
BN IN (21.3%)	NutraBio Melatonin
BN IN DF (3.4%)	TERRAVITA Potassium Citrate Powder
BN IN STR DF (3.0%)	Optimum Nutrition Tribulus 625 MG Caps
BN IN PLNT (1.9%)	Nature's Answer Hawthorn Berry

Table 3– Frequencies of templates generated on the development and evaluation sets that match RxNorm term types, computed using the fully matched product names. We do not include the following RxNorm term types: Precise Ingredient (PIN), Multiple Ingredients (MIN), Generic Pack (GPCK), Brand Name Pack (BPCK) as they are not applicable to this study.

RxNorm Term Type	Corresponding Template	Dev Frequency	Eval Frequency
Ingredient (IN)	IN	1 (0.01%)	1 (0.04%)
Semantic Clinical Drug Component (SCDC)	IN STR	1 (0.01%)	0
Semantic Clinical Drug Form (SCDF)	IN DF	2 (0.02%)	0
Semantic Clinical Dose Form Group (SCDG)	IN DFG	0	0
Semantic Clinical Drug (SCD)	IN STR DF	3 (0.03%)	0
Brand Name (BN)	BN	209 (2.11%)	10 (0.40%)
Semantic Branded Drug Component (SBDC)	BN IN STR	3353 (33.85%)	812 (32.78%)
Semantic Branded Drug Form (SBDF)	BN IN DF	370 (3.74%)	80 (3.23%)
Semantic Branded Dose Form Group (SBDG)	BN DFG	0	0
Semantic Branded Drug (SBD)	BN IN STR DF	325 (3.28%)	85 (3.43%)
Total		**4264 (43.04%)**	**988 (39.89%)**

The coverage of the final NLP system on the evaluation set, after obtaining 80% full match coverage on the development set, was 71.9% full match, 27.6% partial match, and 0.5%

unmatched. Thus only 11 (0.5%) evaluation product names were completely unmatched by our system. Compared to the coverage of RxNorm term types (39.89%), our system improves full-match coverage by 32% on the evaluation set.

Table 4 shows the average accuracy of the pattern matching system on the evaluation product names. The average of the fully matched names is 0.30 greater than the partially matched names. This is expected due to the fact that each unmatched token in the partially matched names is treated as incorrect. Still, because the majority of the names in the evaluation set were fully matched, the average accuracy (0.86) is closer to the fully matched accuracy.

Table 4– Overall accuracy on the evaluation set, reported for all evaluation names, only those which were fully matched, and only those that were partially matched.

Match Type	Accuracy
Full + Partial + None	0.86
Full match only	0.95
Partial match only	0.65

The accuracy of each term type, computed over the fully matched and partially matched evaluation set names, is given in Table 4. We report both the average accuracy of each term type over all the evaluation names (given by the bars) as well as the accuracy on the fully matched and partially matches names separately (given by the triangles and Xs, respectively).

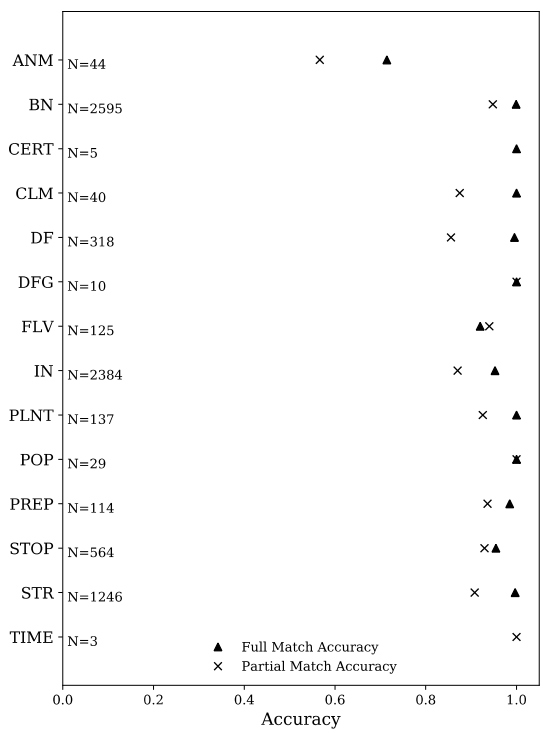

Figure 2– Accuracy of each term type on the evaluation set. The bars indicate the average accuracy of the term types over the full and partially matched product names in the evaluation set. The points indicate the accuracy on the fully and partial matched names, respectively.

A number of term types achieved a perfect 1.00 accuracy, and the most common term types, *BN* and *IN*, achieved accuracies above 0.90. *ANM* (animal source) obtained the lowest accuracy, with 0.61.

Discussion

As shown in Table 3, only about 40% of DS product names fit existing RxNorm term types. This suggests that RxNorm is not well suited to the space of DS products. Table 2 and Table 3 show that brand names (*BN*) play a significant role in DS product labeling, with most or all of the most frequent templates containing *BN*. Indeed, further investigation revealed that 91% of the patterns generated on the development and evaluation sets contain *BN.* This is not surprising, given the different ways in which drugs and DS products are marketed. Drugs are carefully prescribed and regulated, with brand name and generic drugs being for the most part interchangeable, meaning that the *IN* term type is most useful for clinicians, patients, and regulators. On the other hand, there are many competing DS products containing similar ingredients so DS manufacturers emphasize product branding to appeal to consumers.

Nevertheless, the accuracy of our system indicates promising potential for normalizing DS product names. Even when treating unmatched words as misses, our system was able to achieve an accuracy of 0.86 on the evaluation set, which improves to 0.95 on fully-matched product names only (Table 4).

On the other hand, the generalizability of our system is limited by its coverage. Our system was only able to fully match 71.9% of the evaluation set names, a difference of 8% from the development set coverage (80%). Still, a majority of the remaining names were partially matched (27.6%) and our system was unable to find a match for only 11 (0.5%) of the evaluation names.

Reviewing examples of unmatched words in the development and evaluation sets revealed that many were unseen brand names. For example, our system missed the brand name “Cellucor COR-Performance” because it did not occur in the development set. In the future, the use of machine learning methods could improve the coverage and accuracy of the system on brand names, which are too numerous and varied to be manually curated. Many other unmatched words were uninformative buzzwords such as “High Intensity Training Program”. We found that most errors for the *IN* term type were due to the inclusion of phrases that belong to *PLNT* or *PREP*, such as in “Peppermint *Leaf”* and “Green Tea *Extract”*. These occurred because our system searched the *IN* patterns before *PREP* and *PLNT* and the iDISK ingredient thesaurus often includes these phrases in ingredient names. Also, many brand names contain implicit information regarding claims or ingredients which our system could not match. For example, “PomGuard” in “Jarrow Formulas PomGuard” suggests the inclusion of pomegranate as in ingredient.

This study has the following limitations: First, we only include single ingredient products from DSLD. Single ingredient products comprise 22% of all product names extracted from DSLD, so the generalizability of our method to multi-ingredinet products remains to be investigated in future work. Second, because of the above limitation, we assume the presence of at most one ingredient in each product name. Still, some product names listed as single ingredient in DSLD contain more than one ingredient mention, e.g. “Physician's Preference *Royal Garlic* with *Hawthorn* and *Cayenne*”. It would be straightforward to modify our system to search for multiple ingredient mentions, which would increase coverage. Third, our system has limited ability to disambiguate context.

Therefore, only one meaning was chosen for any polysemous keywords, e.g. keywords that occurred in more than one TGA list. Important future work would be to employ more advanced NLP and machine learning methods to disambiguate context in product names. This could vastly improve the accuracy of term types such as ANM, which contains keywords (e.g. “Heart” and “Liver”) that are often confused with claims or uses.

Conclusions

In this study we developed and evaluated an NLP system to apply an RxNorm-like normalization approach to dietary supplement product names. As has been done for drugs, normalization is important to facilitate interoperability and the search for information about DSs. We found that the existing RxNorm drug normalization templates do not generalize to dietary supplements and that it is necessary to extend the RxNorm model to sufficiently cover DS product names. The normalization system outlined here obtains a substantial increase (32%) in coverage on DS product names over RxNorm as well as an accuracy of 0.86. Nevertheless, there is great variability in supplement product names and more work is required to improve the performance of our system.

Abstract

Suicidal ideation is a risk factor for self-harm, completed suicide and can be indicative of mental health issues. Adolescents are a particularly vulnerable group, but few studies have examined suicidal behaviour prevalence in large cohorts. Electronic Health Records (EHRs) are a rich source of secondary health care data that could be used to estimate prevalence. Most EHR documentation related to suicide risk is written in free text, thus requiring Natural Language Processing (NLP) approaches. We adapted and evaluated a simple lexicon- and rule-based NLP approach to identify suicidal adolescents from a large EHR database. We developed a comprehensive manually annotated EHR reference standard and assessed NLP performance at both document and patient level on data from 200 patients (~5000 documents). We achieved promising results (>80% f1 score at both document and patient level). Simple NLP approaches can be successfully used to identify patients who exhibit suicidal risk behaviour, and our proposed approach could be useful for other populations and settings.

Keywords:

Natural Language Processing; Suicide; Electronic Health Records

Introduction

Suicidal ideation (SI) occurs in approximately 10% of adolescents in the general population [1,2]. It is a risk factor for self-harm and completed suicide, and is associated with a number of mental disorders. Amongst young people attending Child and Adolescent Mental Health Services (CAMHS), who are often receiving therapeutic support for mental health disorders, the prevalence is higher. SI is an important risk indicator that is used in clinical practice by CAMHS professionals. It is asked about in routine clinical assessments, particularly in situations where patients report low mood, anxiety, emotional regulation difficulties, trauma or distress following difficult life experiences.

Information about suicide risk including suicidal thoughts can be documented in structured risk assessment forms [3], or in free-text in Electronic Health Records (EHRs). Whilst admissions to general hospitals following suicide attempts would be routinely recorded with structured diagnostic codes, routine assessments of suicidal behaviour risk in clinical practice are predominantly recorded as free-text [4–6]. To capture and extract suicide-related information from text within EHRs, Natural Language Processing (NLP) approaches are essential. Common to many NLP solutions for extracting particular pieces of information from EHR text are: to 1) identify concepts of relevance (e.g. the term *suicide*) and 2) classify contextual attributes that semantically alter the meaning of the identified mention. Negation detection is particularly important for clinical constructs that are routinely documented as part of clinical assessments (e.g. *denies suicidal ideation*). Current state-of-the-art NLP methodologies that model such problems in the clinical domain rely on machine learning approaches or symbolic approaches (or a combination of both) [7,8].

However, extracting *patient*-level risks or classifications from (a collection of) documents presents some challenges. Each patient EHR might contain several documents, and each document might contain several relevant (and irrelevant) mentions of clinically important information. Particularly for complex clinical constructs such as suicidality, generating sufficiently large and high-quality datasets that could be used to develop machine-learning based models is costly due to the time and human effort required for manual data annotation. Inferring patient-level labels from individual mentions can be done by post-processing identified mentions using currently available clinical evidence, as was done in a recent study for asserting asthma status [9], or by other heuristic approaches.

Haerian et al. (2012) found that NLP approaches combined with ICD-9 codes had higher precision/positive predictive value (PPV) than using ICD-9 codes alone when evaluated on data from the New York Presbyterian Hospital/Columbia University Medical Center [4]. Similarly, Anderson et al. (2015) found that only 3% of patients who had an indication of suicidal ideation written in text had a corresponding ICD-9 code in a study performed on a large distributed health network of primary care organizations [5]. In a study to identify suicidal behaviour amongst pregnant women, similar findings are reported: using diagnostic codes alone reduced sensitivity considerably [10]. Rule- and machine-learning based approaches to extract suicide ideation and suicide attempt mentions from psychiatric EHR text have been developed with promising results [6], but were evaluated on the mention level, not the patient level.

We have previously developed a step-wise rule-based NLP approach that 1) identifies suicide-related mentions and filters out negated instances using lexicons (for concepts as well as negation terms) and rules based on syntactic information (constituency-based parse tree of sentences), 2) determines a document-level label based on heuristics (counting the number of positive and negative instances and assigning a document-level label based on a majority rule), and 3) determines a patient-level label based on document labels (patient positive for suicidal behaviour = the patient had one (or more) documents labelled as positive for suicidality). This approach was evaluated on a cohort of adolescents diagnosed with autism

spectrum disorder (ASD), resulting in precision, recall, and f1 scores all > 0.85 at the document and patient level [11].

In the study presented here, we extend this approach. We had two main aims: 1) to generate a manually annotated reference standard of an adolescent cohort that was inclusive of all mental health conditions and 2) to apply and modify an existing NLP approach for mention-level extraction of specified clinical constructs [12] that only relied on target (relevant clinical concepts) and modifier (terms that alter the contextual meaning of the target, e.g. negation) lexicons and a sentence tokenizer; thus, minimizing the need for time-costly pre-processing steps such as syntactic parsing, and test its performance on the new cohort. Our focus was on finding *asserted* suicidality risk, filtering out negated cases. Further, we applied previously published target and modifier lexicons (in this case, negation terms), to assess their applicability on a new clinical use-case and dataset. Finally, we developed and evaluated these lexicons at both document and patient level. To our knowledge, this is the first study that focuses on a general adolescent patient cohort and that systematically analyses the applicability of published lexical resources on the problem of retrieving asserted suicide risk from EHR text.

The capacity to extract data on suicidality from free-text EHRs has many implications: it provides an estimate of the prevalence of this problem in a clinical CAMHS population; it generates a cohort of high-risk patients in which to study risk factors for self-harm and suicide; and it contributes to an emerging field of research using text from routinely collected health data and data-driven methods to help understand suicide risk at scale.

Methods

Data Source and Clinical Cohort

We used data from the Clinical Records Interactive Search (CRIS) database [13,14], which contains anonymized EHRs from the South London and Maudsley (SLaM) NHS Foundation Trust and has ethical approval for research use (Oxford REC C, reference 08/H0606/71+5) under an extensive governance model. The full cohort consisted of all patients aged 11-17 and in contact with CAMHS in SLaM between April 1st 2009 and March 31st 2016. All documents for these patients in this time period were extracted (documents include event notes, correspondence letters, and free-text sections from different types of semi-structured assessments), yielding a total of 1,601,422 documents (derived from 23,455 patients)[1]. No structured data was included, and access to patient outcomes was not covered by the ethical approval for this project.

Reference Standard Development

EHR Corpus

All documents for a sample of 200 patients were extracted for manual review. This subset was split into a training set (100 patients, 2883 documents), and a test set (100 patients, 2602 documents). The sample was randomly extracted from the patients who had a number of EHR documents within the 1st and 3rd quartiles (12,146 patients, 342,037 documents in total, cut-off points: minimum of 10, maximum of 61 per patient).

Annotation

A review of similar studies was performed to guide the definition of suicide-related information, and suicidal behaviour. In summary, any mentions that indicated the desire to kill oneself, end one's life, or wanting to be dead/to die (including having tried to kill oneself) were included. Mentions related to self-harm without suicidal intent or no explicit mention of suicidal intent were excluded. No assumptions on implicit information about intent (e.g. overdoses) were made and were thus not annotated. All documents for each patient were manually reviewed and annotated by a child psychiatrist (SE) for a document-level label (non-relevant, suicidal, non-suicidal, or uncertain). Each document labelled as suicidal, non-suicidal or uncertain was also annotated with mention-level annotations (positive, negated, uncertain or unrelated). The definition of a mention-level annotation was deliberately not constrained to specific textual units (e.g. word or paragraph), instead, any text segment that was indicative of the mention-level labels could be marked by the annotator to allow for expressivity and clinically relevant segments. Guidelines were iteratively developed to refine inclusion and exclusion criteria for each label. A small subset (100 documents, randomly extracted with a 2:1 ratio of not positive:positive) was annotated by a second clinical annotator (TS) to measure inter-annotator agreement (IAA). We used the Extensible Human Oracle Suite of Tools (eHost)[2] annotation tool.

Document- and Patient-Level Label Heuristics

Because the purpose of the clinical use-case for which this approach was developed was to generate a cohort of patients who had *ever* exhibited suicidal tendencies, priority was placed on detecting *affirmed* suicide-related information. Thus, if there was *at least one* affirmed mention of suicidality in a document, the document label was set to suicidal. Similarly, a patient-level label of suicidal was set if there was at least one document labelled as positive for suicidality (Figure 1).

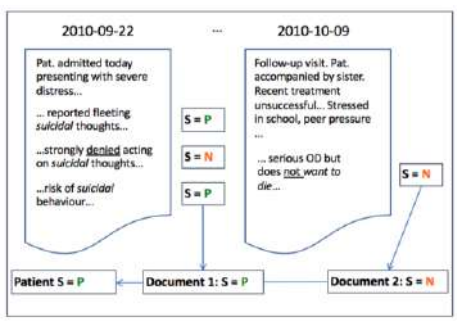

Figure 1 - Example illustrating document and patient-level label heuristics. A patient may have several EHR documents. This example illustrates two fictitious documents from two fictitious dates, where there are multiple suicide-related mentions in the first document (left), 2 positive (P) for suicidality (S) and one negated (N), which leads to a positive document-level label, and only one mention in the second document (right) which is negated, leading to a negated document-level label. Because one document was labelled as positive, the patient-level label is positive (Patient S = P)

Natural Language Processing Approach

We extended our previous approach by relying solely on pyConTextNLP [12] (version 0.6.0.0) that only requires a sentence tokenizer for pre-processing, and on two lexicons: one that defines relevant concepts/mentions (*target terms*, e.g. *suicidal*) and one that defines modifiers (e.g. negations) and so-called termination terms. Termination terms define if the scope of a target modifier should be triggered within a sentence. For instance, in a sentence like *'The patient **denies** wanting to die **but** has had suicidal thoughts.'*, the scope of the negation term

[1] As of 12 April 2018

[2] http://blulab.chpc.utah.edu/content/ehost-extensible-human-oracle-suite-tools

'denies' covers *'wanting to die'* and not '*suicidal'* due to the termination term ***but*** pyConTextNLP allows for matching with character-based regular expressions. We used spaCy[3] (version 2.0.9) for sentence tokenization. The work was performed in a Python 2.7.6 environment. The development and analysis of target and modifier term lexicons was the main focus, and was done in two main phases. For target terms, we reviewed previous similar studies [6,11,15] and experimented empirically with these to identify a good coverage lexicon. As a baseline, we used a minimal target lexicon only containing the term *suicide* and its variants (*suicid**) to assess the impact of the addition of other target terms. For modifier terms, we used three previously published off-the-shelf lexicons: 1) negation terms used for detecting suicidality in adolescents with ASD ("AMIA2017") [11], 2) negation terms used to detect suicidal ideation ("SREP2018") [6], and 3) a collection of negation terms developed for a variety of clinical use-cases (not specifically suicidality) and languages ("MEDINFO2013") [16]. The off-the-shelf lexicon that yielded best results on the development set was then further iteratively adapted based on findings from manual error analyses. To assess the applicability of the lexicons on the development set, priority was given to optimizing performance on detecting *affirmed* suicidality at both document and patient level. The test set was held aside throughout the development phase.

Table 1 – Reference standard document label distributions

document label	development set	test set
non-relevant	2570	2393
suicidal	136	54
non-suicidal	46	33
uncertain	131	122
total	*2883*	*2602*

Table 2 – Reference standard patient label distributions

patient label	development set	test set
non-relevant	52	66
suicidal	37	26
non-suicidal	11	8
total	*100*	*100*

Evaluation

We measured inter-annotator agreement on a subset with Cohen's κ and accuracy. NLP performance was measured against the annotated reference standard development and test sets with precision (PPV), recall (sensitivity) and f1-score at a document- and patient-level, focusing on results for *affirmed* suicidality. Finally, qualitative error analysis on results was performed to inform future improvements.

Results

Reference Standard and Inter-Annotator Agreement

The overall distribution of the resulting annotations on a document and patient level is presented in Tables 1 and 2. Non-relevant documents are in the majority of both the development and test sets (89% and 92%, respectively). A 4.7% of the documents in the development set were positive for suicidality, and 2.1% in the test set. On a patient level, the distribution of patients labelled as suicidal was: 37% (development set) versus 26% (test set). Inter-annotator agreement on the subset of 100 documents was very high: κ 0.96, 98% accuracy.

Natural Language Processing Results

Adaptations of the target term lexicon involved adding terms like *end his/her life*, *kill him/herself*. Overall performance with these additions resulted in 15-17% f1-score improvement on document-level classification (baseline f1-score results using only *suicid** were 64-72% on the development set (56-68% on the test set). On a patient level, baseline results ranged between 70-79% on the development set (71-79% on the test set), compared to 83-86% using the extended target lexicons on the development set (82-83% on the test set).

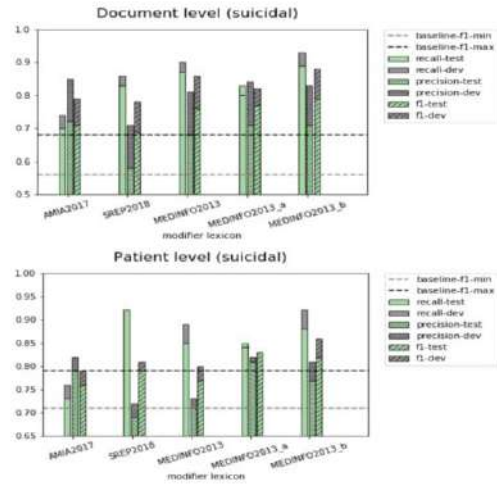

Figure 2 - Results (precision, recall and f1-score) on development (dev, grey) and test (green) sets for document (top) and patient (bottom) level classification (positive for suicidality). Each value on the x-axis represents a modifier lexicon configuration: 1) previous studies: AMIA2017 [11]; SREP2018 [6] and MEDINFO2013 [16] or 2) modifications to the MEDINFO2013 lexicon based on iterative error analysis on the dev set (MEDINFO2013_a and _b). The dashed lines represent f1-scores using the baseline target lexicon (suicid only) on the test set: grey line shows lowest results (min), black line highest results (max)*

Results for the different configurations of modifier lexicons are shown in Figure 2 (document-level on top, patient-level bottom). The precision results on the document-level ranged from 71% (using the SREP2018 lexicon) to 85% (using the AMIA2017 lexicon); recall results ranged from 74% (AMIA2017 lexicon) to 90% (MEDINFO2013 lexicon); f1-score results from 78% (SREP2018) to 86% (MEDINFO2013) without any further adaptation on the development set. The MEDINFO2013 lexicon resulted in best overall off-the-shelf f1-score results and was used for additional adaptation. Errors produced by the MEDINFO2013 lexicon were analysed and iteratively revised based on the development set by adding missing negation terms and revising conjunction terms. We present results for two adapted lexicons: MEDINFO2013_a and _b. In both lexicons, the following negation terms were added: *doesn't*, *doesnt* (sic), *never*, *none*. The main difference between the two adaptations is the list of conjunction/termination terms. In MEDINFO2013_b, 24 conjunction terms, such as *unless* and *whereas,* were added. Furthermore, some conjunction terms that were included in the original MEDINFO2013 lexicon were excluded in both adapted versions, like *patient*, *recent*, *today*.

[3] https://spacy.io/

Document-level results on the blind test set were overall lower compared to the development set (58-72% precision, 70-87% recall and 69-75% f1-score) when using the off-the-shelf modifier lexicons. The adapted lexicons also resulted in lower overall performance compared to the development set, except for recall using MEDINFO2013_a, which improved from 80% to 83%, and MEDINFO2013_b which improved from 88% to 89% (but resulted in lower f1-score).

On a patient level, results for the off-the-shelf lexicons ranged from 72-82% precision, 76-92% recall and 79-81% f1-score on the development set. The adapted lexicons resulted in more balanced, and, on average, higher precision and recall results (81-82%, 84-92% respectively) and slightly higher f1-scores (83-86%). On the blind test set, best f1-score results were obtained with the two adapted lexicons (82% for MEDINFO_a and 83% for MEDINFO_b).

On the test set, the lowest baseline f1-score document-level results were produced by the AMIA2017 lexicon (56%), the highest with the adapted lexicons MEDINFO2013_a and _b (68%). However, on patient-level results the highest baseline result was 79% (MEDINFO2013_b) but results were similar for MEDINFO2013 and MEDINFO2013_a (78%), the lowest results were produced with the AMIA2017 lexicon (71%).

Discussion

We have developed a new comprehensive manually annotated reference standard of EHRs from an adolescent mental health patient cohort. Most documents do not contain any suicide-related information (~90%), only 2-5% documents contain affirmed suicide-related information. On a patient level prevalence is higher (26-37%). This is slightly higher than was found in our previous work [11], but the definition of what constituted affirmed suicide-related information was not identical. Inter-annotator agreement on a small subset was high, indicating that the task is well-defined. Previous studies have shown that using diagnostic codes alone to identify risk of suicidal behaviour is insufficient [4,5,10]. We performed a preliminary assessment of this on our development data and found similar results: only 6 of 37 patients (16.2%) would have been identified as at risk of suicidal behaviour if using information from structured risk assessment forms only.

Our adaptation of pyConTextNLP resulted in similar or higher overall results as compared with our previous NLP approach [11] when applied on the development set, with the added benefit of more efficient processing time (approx. 10 times faster) mainly due to not requiring time-costly pre-processing steps such as syntactic analysis. This shows that a lexical, surface-level approach is sufficient to deal with syntactic phenomena such as negation in these contexts. Off-the-shelf modifier lexicons unsurprisingly yielded varying results – adapting these lexicons based on findings from iterative error analysis on the development set resulted in improvements also on the blind test set.

For our clinical use-case, accurate patient-level classifications are the priority, not document-level. In general, high recall was easier to achieve than high precision. This is probably due to the NLP approach failing to correctly classify certain types of negations (e.g. semi-structured forms, general advice paragraphs) and third party mentions (e.g. relatives), which generate false positives and lower precision, without effecting recall. Precision is of greater importance for this use-case, as false positives are a bigger concern than false negatives.

Extending the target lexicon with additional terms improved document-level results more than patient-level results. This indicates that the term *suicide* and its variants really is the key term overall on patient-level assertions (i.e., it is sufficient for one document to have one affirmed mention of *suicid**, and this term is by far the most common suicide-related term overall). However, if it is important for the end use-case to e.g. identify *when* the first mention of affirmed suicide risk is documented, optimal performance on the document level would be essential. To our knowledge, our study is the first of its kind to extensively analyse the relation between document- and patient-level assertions using this particular type of NLP approach. Our findings could be valuable for further studies in this area, e.g., distributions of suicide-related information in affirmed, as well as negated or other, semantic modifications overall in EHR notes, to inform post-processing heuristics or other data-driven representations of this clinical construct. All lexicons, guidelines and scripts are made available online[4].

Our study has some limitations. The majority of the documents were only annotated by one clinician. An extension of our work would involve double-annotating a larger subset for further inter-annotator agreement analysis. Because the agreement was high on our subsample, we would expect to get high agreement also on a larger sample. We have only focused on applying negation detection on this data and with this NLP approach. We plan to further study the uncertain and unrelated annotations and develop our lexicons to capture these semantic modifiers as well as filtering out third party mentions and references to the past. The off-the-shelf lexicons were not developed specifically for the NLP system we used in this study and in particular were not designed with the same approach for finding the scope of modifiers by defining conjunction terms. We have not studied the individual effects of these terms, which would be an interesting future area to study. In addition, we plan to extend the analysis of lexical terms with other external resources such as the UMLS and SNOMED-CT. Clinical text is often written in non-standard grammatical structures (e.g. long sentences, abbreviations, lack of subjects and/or predicates) which motivates further analysis in the pre-processing steps (sentence and word tokenization) as well as document sections. Furthermore, we have prioritized results on extracting asserted suicide-related information. It might be the case that improving results on the negation detection part would lead to improved results on the assertion detection part, which is something we will study further. Finally, lexicon- and rule-based approaches always suffer from poor generalizability in the sense that spelling variants and new terms need to be added manually. We plan to extend our comparison with other approaches such as Metamap, and also to apply more data-driven approaches for finding relevant terms e.g. by developing word- and sentence embedding models on larger datasets to automatically generate extended representations. However, because of the low prevalence problem on the document level, this approach will need careful study design to ensure that sufficient data samples are used. One approach, similar to Downs et al. [11], would be to filter documents using specific suicide-related target terms and use these documents for generating semantic representations. The applicability of this approach on EHR data from other institutions would also need further investigation.

By adapting and developing a simple NLP tool to identify text relating to affirmed mentions of suicidality, we have been able to identify a cohort of patients who are at higher risk of future adverse outcomes including self-harm. This cohort could be studied for a number of important clinical outcomes. Initially, we are planning a study which will explore socio-demographic,

[4] https://github.com/KCL-Health-NLP/camhs_pycontext_adaptation

clinical and educational risk factors for hospital presentations with self-harm in this high-risk population. This could provide additional information to clinicians on which to base assessments of risk for self-harm and could therefore have an important impact on clinical management.

Conclusions

We have developed a comprehensive manually annotated EHR corpus with rich suicide-related information from a general adolescent cohort. Our adaptation of a rule-based NLP approach and systematic analysis of existing lexicons applied to this data is a contribution to this understudied field for several reasons: we show that simple NLP approaches can have promising results; we confirm previous published results that most suicide-related information is written in free-text; we illustrate the challenges in defining patient-level labels based on mention- and document-level extraction for this low prevalence problem. Our adapted approach could be used in different populations and settings to define cohorts for similar use-cases. We look forward to seeing further developments of NLP approaches for this important problem.

Annotating Temporal Relations to Determine the Onset of Psychosis Symptoms

Abstract

For patients with a diagnosis of schizophrenia, determining symptom onset is crucial for timely and successful intervention. In mental health records, information about early symptoms is often documented only in free text, and thus needs to be extracted to support clinical research. To achieve this, natural language processing (NLP) methods can be used. Development and evaluation of NLP systems requires manually annotated corpora. We present a corpus of mental health records annotated with temporal relations for psychosis symptoms. We propose a methodology for document selection and manual annotation to detect symptom onset information, and develop an annotated corpus. To assess the utility of the created corpus, we propose a pilot NLP system. To the best of our knowledge, this is the first temporally-annotated corpus tailored to a specific clinical use-case.

Keywords:
Schizophrenia; Electronic Health Records; Natural Language Processing

Introduction

For patients with a diagnosis of schizophrenia, duration of untreated psychosis (DUP) is the period of time between the onset of first symptoms and the initiation of adequate treatment [1]. As shown in previous studies, prolonged DUP is associated with poor intervention outcomes, both in the first years of treatment and in the long-term [2,3]. Therefore, to enhance the management of symptoms and improve social functioning, timely treatment is crucial. For determining symptom onset and ultimately reducing DUP, the information collected in clinical practices could be successfully re-used.

With the rapid adoption of electronic health records (EHRs), clinical data are increasingly available in electronic format, allowing for large-scale retrospective research. However, especially in the field of mental health, clinically relevant information (e.g., symptoms, diagnoses, medication) is often documented in unstructured form (free text), for instance through letters and progress notes. To allow analyzing the information enclosed in such clinical text, natural language processing (NLP) techniques are becoming increasingly popular [4]. In the case of determining symptom and treatment onset from clinical notes, NLP methods are needed to both extract clinical concepts (events) and anchor them on a timeline. To this end, two types of temporal information have to be identified: time expressions such as dates and times (TIMEXes), and temporal links (relations) between these and the available events ({hallucinations} in {2002}).

In recent years, a few clinical corpora have been annotated for temporal relations (TLINKs), and used for developing NLP systems tailored to this task. The 2012 i2b2 Temporal Relations Challenge focused on temporal relations in narratives from an intensive care unit [5]: a total of 310 discharge summaries were annotated with events, temporal expressions, and 8 types of temporal relations (e.g., "before", "overlap"). Styler IV et al. developed a corpus (THYME) of 1,254 cancer patient records, which were annotated with clinical and temporal information [6]. This corpus was then used in the 2015 and 2016 Clinical TempEval challenges (440 and 591 documents, respectively), which focused on determining two types of TLINKs [7,8]: relations between events and the document creation time (DCT), and relations between an event or a TIMEX and a narrative container. Successful NLP systems developed on these corpora have mainly relied on supervised machine learning algorithms, using lexical, morphological and syntactical features. A few systems also included heuristics and rule-based components.

Despite the recent advances in temporal relation extraction, developing temporal NLP systems in different clinical domains remains a challenge, due to the inherent complexity of the task – each patient can have several EHRs with clinically relevant information, and in each document every clinically relevant event can in principle be linked to every TIMEX. In this paper, we address the problem of determining temporal relations in mental health records, with a focus on symptom onset identification for schizophrenia patients. To the best of our knowledge, this is the first study on temporal relation extraction that was driven by a specific psychiatric clinical use-case. The NLP task was defined from a clinical perspective, with the final goal to extract relevant information at the patient level. As a crucial initial step to reach this goal, we needed to not only identify the clinically relevant events to be extracted and anchored in time, but also the set of documents that were likely to contain this information.

We have three main aims in this study. First, we propose a methodology for selecting the most relevant documents for the considered use-case. Then, we develop a manual annotation process to temporally anchor all the relevant symptoms, thus enabling the extraction of symptom onset and other information of interest. Finally, we propose a preliminary NLP system to assess the utility of the created corpus.

Methods

Dataset

In this study, we used mental health records from the Clinical Record Interactive Search (CRIS) database [9]. This research

repository contains anonymized patient data (structured and unstructured), derived from the EHR system used at the South London and Maudsley National Health Service (NHS) Foundation Trust (SLaM). Textual documents typically consist of either notes related to specific events or attachments of different types (e.g., assessments, discharge letters). In the system, there are no structured elements indicating whether a document represents a first assessment, which would be helpful to identify relevant content for our use-case.

For selecting the records that would most likely include the information of interest, we focused on documents from early intervention services for people with first episode psychosis (FEP). We considered documents written within a 3-month window by six intervention teams from the team's acceptance date in April 2018, on the assumption that these "early" documents would include the initial assessment and the richest description of a patient's clinical history. The steps followed for document extraction are shown in Figure 1. We focused on longer documents, in which clinicians typically document the presenting history and mental state examination, and excluded questionnaires and forms consisting of short lines. To identify how symptom onset information was typically documented, 70 documents were double-annotated for relevant paragraphs such as: "difficulties were noted for the first time when the patient was 7 years old, as he was displaying aggressive behaviour."

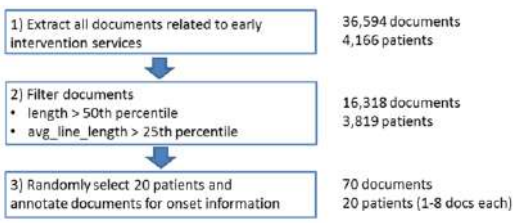

Figure 1 – First Document Extraction.

We analysed the annotated documents in terms of clinical and temporal content, automatically identifying symptoms (i.e., events) and time expressions. For extracting symptoms, we used a previously-developed keyword list [10] containing 598 psychosis-specific symptom terms. To identify TIMEXes, we used SUTime [11], a rule-based tool for temporal expression extraction which we have adapted to the mental health domain [12]. As a result of these analyses, we selected the final set of documents to be used for annotation. In general, documents do not follow a standard format. In some cases, there is a semi-structured format, with section headings (e.g., history of presenting complaint, clinical history, mental state examination), but there is a large variability. It is important to note that, while some events are reported with a specific date (e.g., "presented on 1st Jan. 2014 with hallucinations"), others are not clearly linked to a temporal point (e.g., references to "the past", ongoing symptomology).

Temporal Relation Annotation

Documents were pre-annotated with symptoms and time expressions, using the same tools as for corpus selection. Annotators were asked to try to link each pre-annotated event to a TIMEX, if such relation could be inferred from the text. In addition, they had to assign to each event a polarity value, which could be either "positive" or "negative" (e.g., "denied hallucinations"). This distinction is important, as negated symptoms would not likely indicate onset information, and should be represented differently on a patient's clinical timeline. Figure 2 shows an annotation example.

Figure 2 – Annotation Example.

The corpus was divided in batches, each including documents belonging to 9-10 patients (Table 1). Annotations were carried out by three medical students, and all documents were double-annotated. To guide the annotation task, two NLP researchers created specific guidelines, which were enriched with relevant example cases. To create the final version of the corpus, all annotated documents were adjudicated, resolving disagreements and performing corrections when needed.

To investigate if symptoms were linked to time points prior to the clinic visit, we also analysed, for each patient, how far back in time (in terms of days) a symptom referred to. In this analysis, we did not consider symptoms with negative polarity, as these are not likely to represent onset information.

Automated Temporal Relation Extraction

We used the annotated corpus to develop two NLP modules: TLINK extraction and polarity classification. The dataset was randomly split into training, development, and test sets. The training set was used for system development and manual rule engineering, with validation on the development set. The test set was set aside for final evaluation (in future studies).

In the temporal relation module, we addressed TLINK extraction (i.e., determining if the event can be linked to a time expression in the document) and TIMEX assignment (i.e., finding the normalized value of the TIMEX linked to the event) simultaneously. To perform both tasks, we developed a rule-based system relying on a number of features, such as the section in which the event is found and the presence of anchor dates in the text (admission, discharge, clinic dates). More specifically, section labels were identified by using a set of keywords (e.g., "history", "examination"), while anchor dates were extracted with regular expressions. System development was carried out on a subset of the training set, iteratively adding/refining rules. As a result, we developed ten rules to be applied following an order of relevance. For example, if only one TIMEX (representing a date like YYYY-MM-DD) is found in the same sentence including the symptom, a link is created. As another example, if a symptom is mentioned in a section named "mental state examination on admission" and an admission date is available, a link is created.

To assign a polarity value to events, we used ConText [13], a rule-based algorithm which relies on modifiers (e.g., "no", "denies") to determine whether a concept is negated. These modifiers are looked for in a window of words surrounding the event. In this paper, we used 11 "negation" modifiers representing the terms that were found in our corpus.

Evaluation

To evaluate the quality of the developed corpus, we computed inter-annotator (IAA) agreement. For polarity, we calculated accuracy on symptoms: an agreement is obtained when both annotators marked the same value. For the TLINK task, we defined an "adapted" accuracy, considering for each symptom two cases of agreement: i) both annotators identified 0 links, or ii) both annotators identified a link to the same time expressions (in terms of normalized value). All other combinations were regarded as disagreements. Automated extraction systems were evaluated with the same metrics.

Results

Corpus Selection

Figure 3 shows the results of the analysis conducted for corpus selection (on a subset of 70 documents). For each document, we computed the number of automatically extracted symptoms/TIMEXes (orange lines) and of manually annotated onset paragraphs (blue lines). Results (normalized counts) indicate that documents with many clinical/temporal elements are more likely to contain information on symptom onset.

Starting from this observation, we filtered the initial corpus by adding the following criteria: Symptom_count > 0 and Timex_count > 5. The number of symptoms was computed by using a list of 26 keywords developed by two psychiatrists, and the number of TIMEXes was found with the adapted SUTime. This filtering step led to a final set of 9,779 unique documents for 3,433 patients. From this corpus, we extracted 645 documents for 239 randomly selected patients (an average of 2.7 documents per patient) grouped into 24 batches.

Corpus Annotation

Table 1 reports the number of patients, documents, events, and TIMEXes in our corpus.

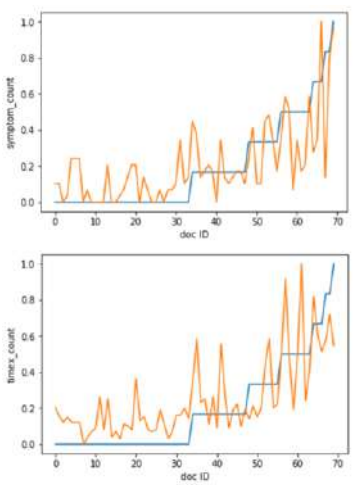

Figure 3 – Relation between Symptom/TIMEX Counts (orange lines) and Manually Annotated Onset Paragraphs (blue lines).

There are 2,590 symptoms (on average, 4 per document). The 5 most frequent (73% of events) are the following (raw counts between brackets): hallucinations (736), delusions (430), delusional (398), paranoia (179), and thought disorder (159). Each symptom was manually annotated for a Polarity value and an optional TLINK. Table 2 reports the IAA, while Table 3 shows the prevalence of Polarity values and temporal relations (for TLINKs, "Yes" represents the existence of a link). These counts were computed on the adjudicated dataset.

Table 1 – Patient, Document, Event and TIMEX Counts

	Total	Train	Dev
Patients (batches)	239 (24)	140 (14)	49 (5)
Documents	645	361	133
Events	2,590	1,465	515
TIMEXes	24,135	13,502	5,061

Table 2 – Inter-Annotator Agreement (IAA) per Annotated Item

Item	IAA (average)	IAA (range/batch)
TLINK	0.73	0.60 - 0.84
Polarity	0.95	0.81 - 1

Table 3 – Annotation Results for TLINK and Polarity

Item	Value	Total	Train	Dev
TLINK	Yes	1,661 (64.1%)	945	302
	No	929 (35.9%)	520	213
Polarity	Pos	1,900 (73.4%)	1,110	368
	Neg	690 (26.6%)	355	147

Starting from the adjudicated annotations, for each patient we computed the difference between the maximum and the minimum dates associated to any "positive" symptom (diff). It is important to note that, for those symptoms that were not explicitely linked to a date, this difference could not be computed. As a result, we were able to compute diff values for 206 patients (Figure 4). Out of these, 41 (20%) had a diff value longer than one year, while 71 (34%) had a zero diff value.

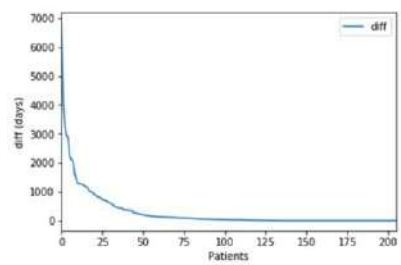

Figure 4 – Difference (in days) between Minimum and Maximum Symptom Dates for 206 Patients

Automated Temporal Relation Extraction

Table 4 shows preliminary results for the two developed NLP modules, using the same metrics as for IAA. For comparison purposes, we also report two baseline results: for the Polarity attribute we classified each event as "positive", while for TLINKs we did not link any event to any specific TIMEX.

Table 4– Performance of NLP modules

Item	Model	Train	Dev
TLINK	baseline	0.47	0.54
	Rule-based	0.67	0.58
Polarity	baseline	0.76	0.72
	ConText	0.93	0.95

Discussion

We have developed a corpus of mental health records for patients with schizophrenia who have been admitted to early onset intervention services, annotated with temporal relations to capture the onset of psychosis symptoms. To the best of our knowledge, this is the first temporally-annotated corpus that was developed for a specific clinical use-case besides clinical timeline reconstruction. In particular, our use-case is related to the analysis of symptom onset and to the calculation of DUP on a large patient cohort. To address this long-term goal, dataset selection was crucial: we applied symptom/TIMEX-based filtering steps to the available CRIS data, and selected multiple documents referred to each patient. Starting from a mention-level annotation task, we aim at proposing a framework that could be also relevant for information extraction on a patient-level. The guidelines and the keywords used in the annotation process, as well as the code for NLP development, are available at: https://github.com/medesto/.

Besides this underlying perspective, our corpus differs from related datasets (i.e., i2b2 2012 and THYME) in two main ways. First, to allow capturing onset information which can be reported across different sentences/paragraphs, we did not require linked entities to be close to each other: each event could be linked to any time expression written in the document. This is a first step towards reconstructing timelines across multiple documents, a problem that remains understudied in the clinical domain. Raghavan et al., for example, proposed a system for cross-document alignment of event sequences [14]. Second, to simplify the annotation task and still obtain useful data, we asked annotators to associate each event to only one time expression (the most relevant one), thus considering only one type of TLINK. Given these differences, we proposed the use of an adapted accuracy to measure the IAA on temporal links, with a final value of 0.73. This represents a promising result, especially considering the inherent difficulty of the task. In some cases, for example, annotators found it difficult to decide whether a symptom should be linked to a given date: even if a temporal link could be reasonably inferred, the relation was not clearly stated in the text. As another cause of disagreements, for a few symptoms that were clearly related to the visit date, this date was not explicitly written in the text: in these cases, the "most likely" date was often chosen. As for the Polarity attribute, we obtained a particularly high IAA, with an accuracy of 0.95. As expected, classifying a symptom as positive or negative was easier than contextualizing it from the temporal point of view.

In the adjudicated corpus, 1661 symptoms (64%) were linked to a specific date. It is interesting to note that 541 (33%) of these symptoms were negated, and therefore do not play a role for symptom onset extraction. As a matter of fact, 197 negated events (36%) were found in "examination" sections, thus representing results of patient visits. We aimed at capturing these temporal links as they could be important for general timeline reconstruction, however they might not be directly relevant to our long-term goal. To assess the utility of our data for symptom onset extraction, we analyzed the temporal gap between the first and the last symptom dates available for each patient. Our assumption was that symptoms going far back in time could represent the actual onset of psychosis. To verify this, we reviewed the documented "early symptoms" for 41 patients having a diff value of more than one year. Out of these 41 instances, 17 corresponded to a clear onset date, while 15 were a close approximation to the onset date (which was specified in other parts of the texts). An example of the first type is given by: "he has been suffering from psychosis since he was 10 years old when he started experiencing hallucinations". The remaining 9 instances resulted either from erroneous dates written in the text (3), or from a long temporal gap between documents associated to the same patient (6). These results indicate that the proposed annotation schema could be useful for correctly capturing information on early symptom onset, as well as for retaining more general temporal information for timeline reconstruction. To further assess this point, we plan to analyze the information annotated for the 165 patients with a diff value lower than one year.

As regards NLP system development, preliminary results indicate that our gold data are consisent enough to allow for automated system development (Table 4). However, the performance of the TLINK module on the development set (0.58) was lower than that on the training set (0.67), showing that more effort should be put into developing a generalizable system. To address this, we plan to both improve the available rules and explore supervised machine learning methods. Given the complexity of our problem, human-in-the-loop approaches could be explored [15]. Moreover, to support real-world usability, it would be important to focus on explainable methods [16]. Once the NLP system is completed, we will run it on a large patient cohort, to quantify the number of patients for which an early symptom onset is documented in free text. In addition, we are interested in assessing which types of TIMEXes are most frequently associated to onset information.

Our study presents two main limitations. First, given the huge amount of textual information available in CRIS, the proposed corpus selection might not be ideal. To investigate this, we are currently annotating different types of documents, in particular those related to first referrals to SLaM (without focusing on early intervention services). Second, the way in which we modeled the problem could be potentially improved. To simplify the annotation task, we only focused on a limited set of symptom keywords; however, these keywords are not suitable to capture more complex linguistic variants. Moreover, addressing the extraction problem at a mention-level is not necessarily the best option. As future work, we will investigate other ways to model our problem, for example by following a question-answering annotation approach. One drawback of this approach could be the low prevalence of symptom onset descriptions in the texts and the need to review even larger sets of documents.

Conclusions

In this study we described a gold standard for temporal relation extraction in the mental health domain, with a focus on symptom onset and DUP extraction. We presented a method for corpus selection and an annotation schema, with promising IAA results. As a proof of concept, we proposed an early rule-based system for TLINK extraction. In the future, this system could be used to temporally anchor symptoms and treatments extracted from mental health records, thus enabling the calculation of DUP and other relevant concepts.

Abstract

We propose a method to create large-scale Japanese medical dictionaries that include symptom names and information about the relationship between a disease and its symptoms using a large web archive that includes large amounts of text written by non-medical experts. Our goal is to develop a diagnosis support system that makes a diagnosis according to the natural language (NL) inputs provided by patients. To achieve this, two medical dictionaries need to be constructed: one that includes a wide variety of symptom names expressed in NL and another that includes information about the relationship between a disease and its symptoms. Dictionaries will then be used to predict the patient's disease via two developed methods that extract symptom names and disease–symptom relationships. Both methods retrieve sentences using WISDOM X and then apply neural classifiers to them. Our experimental results show that our methods achieved 93.8% and 88.3% in the F1-score, respectively.

Keywords:

Natural language processing, Pattern Recognition, Automated, Machine learning

Introduction

Recently, there have been rising expectations for the introduction of an automatic diagnosis support system (DSS) as advanced artificial intelligence techniques, including deep learning, have developed and electronic medical reports have become widely used in the medical field. To develop a DSS, first medical dictionaries that include a wide variety of symptom expressions and disease–symptom relationship information need to be created. To the best of the authors' knowledge, no such large-scale Japanese dictionaries exist.

This study aims to develop a DSS that can formulate diagnoses according to the NL inputs given by patients, such as short texts describing their health problems or symptoms. In this work, a method is proposed to create large-scale medical dictionaries that include NL expressions referring to symptoms and disease–symptom relationships. Hereafter, these NL expressions will be referred to as "symptom names."

To collect symptom expressions and relationships (shown in Table 1), various approaches using rule-based systems, NL techniques, and machine learning (ML) have been proposed. However, their target documents are relatively formal texts, such as medical textbooks, scientific papers, and electronic medical records. Unlike the texts written by medical experts, inputs given by patients contain a wide range of NL expressions about symptoms. For example, patients may state "tiredness" or "lack of energy" when referring to fatigue. In English, there are some available resources of patients' informal expressions such as the Patient-Free Term List [1] and Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE), a library of items for patient self-reporting of symptomatic adverse events (AEs) developed by the U.S. National Cancer Institute. PRO-CTCAE includes 78 symptomatic AE terms and is translated into Japanese [2], however, to obtain expressions more widely used in Japan, a Japanese medical dictionary that includes a comprehensive variety of NL symptom expressions needs to be created. In addition, to predict patients' diseases, another dictionary that includes information about the relationship between a disease and its symptoms needs to be generated. The disease–symptom relationships should cover a wide range of symptom names used by patients so that the system can predict diseases from the inputs given by the patients. This work aims to extract a broad range of symptom names and the causal relationship between diseases and their symptoms using a large web archive, which includes a large amount of text written by non-medical experts to cover symptom names as entered by the user and correlate the relationship to known diseases. To this end, the authors developed two neural methods that extract symptom names and information about disease–symptom relationships. Both methods initially retrieve sentences that include symptom candidate names using the open-domain question answering system WISDOM X [3], and then they apply two neural methods: one for extracting symptom names and one for extracting disease–symptom relationship. The experimental results show that the proposed symptom name extraction method achieved a 93.8% F1-score, and the disease–symptom relationship extraction method achieved an 88.3% F1-score. Moreover, the proposed methods can acquire symptom names that are not included in the training data and the existing Japanese medical term dictionaries; this finding exemplifies the possibility of developing this system further.

Definition of symptoms

In this work, all changes caused by the diseases of living organisms are regarded as symptoms and are referred to as "symptom names." They contain expressions of physical features observed by the patient and are hypothesized by the patient to be a sign of a disease. Symptoms are defined as such because the patients are expected to express general symptoms, including the expressed symptoms of subjective experiences (e.g., fatigue and paresthesia), the objectively observed findings (e.g., erythema and systolic murmur), and the disease names of the complications, to a DSS without distinction between these categories.

Methods

Materials

WISDOM X is a Japanese open-domain question answering system that uses four billion web pages as its information source (https://wisdom-nict.jp) [3]. It answers a wide range of questions, such as "What is AI used for?" and "What happens if global warming worsens?" This study used WISDOM X because it enabled the efficient extraction of sentences that include a symptom candidate. For example, when "What is caused by AMI?" was typed into WISDOM X, the program answered that "AMI causes life-threatening arrhythmia," in which "life-threatening arrhythmia" is regarded as a symptom candidate name (Figure 1).

A list of questions was created to be entered into WISDOM X; each of these questions consisted of a certain disease name and a question template (e.g., "what is caused by [DISEASE]"). First, 25,367 disease names were collected from the disease name master list of Japanese International Statistical Classification of Diseases and Related Health Problems Tenth Revision [4] and the doctor national examination question criteria [5]. This list was then expanded to 25,916 names using a contextually similar word database [6].

Figure 1 – An example of using WISDOM X.

Further, the authors manually generated 67 question templates (e.g., "What happens with [DISEASE]" and "What does [DISEASE] cause?") and obtained 1,736,372 questions by exhaustively combining disease names and question templates. All questions were entered WISDOM X and 3,894,833 sentences that contained both a disease name and a symptom candidate name were found. Out of the 25,916 disease names, 10,467 (40.4%) had at least one or more answers.

The symptom candidate names extracted as above contain expressions that are irrelevant to proper symptoms, and they were removed as follows. Specific noun classes were identified (10 classes) that contain expressions mostly relevant to symptoms in a noun semantic class dictionary created by applying the word semantic classification method [7] to a large-scale web document (containing approximately 600 million documents). For example, the classes mainly consist of suffixes related to illness, such as "-syndrome", "-ache" and "-emia". Then, expressions that include an entry in the selected 10 class dictionary were extracted from the above 3,894,833 sentences. As a result, 127,352 sentences were obtained. The number of unique disease names and unique symptom candidate names were 7,423 and 32,550, respectively.

Data construction for training and evaluation

In this work, data construction for training and evaluation was performed by the following two human judgment tasks. An example of the human judgment tasks is shown in Table 1.

Symptom Name Extraction (SNE)

Human annotators judged whether a given symptom candidate name is proper in a sentence or not. Even if a given expression is part of a longer symptom name, it was identified as proper (e.g., "loss" is regarded as SNE in the fourth example in Table 1).

Disease–Symptom Recognition (DSR)

Human annotators judged whether a given proper symptom name is caused by a given disease sentence. The disease–symptom relationship was judged based on the content of the sentence. In other words, the annotators did not care if the relationship is proper in the real world.

Table 1 – Annotation Examples
Examples were translated into English for readability. P and N denote proper and non-proper expressions (or relationships), respectively.

	EXAMPLES	SNE	DSR
1	This ($_{dis}$hay fever) has given me ($_{sym}$a runny nose).	P	P
2	($_{sym}$Method) for treatment of ($_{dis}$Aortic Regurgitation).	N	-
3	It causes such ($_{sym}$symptoms) as intracranial calcification, hepatosplenomegaly and liver disorder, jaundice, microcephaly, psychomotor development delay, convulsion, ($_{dis}$retinitis), and the like.	P	N
4	($_{dis}$Acute myocardial infarction) causes violent chest pain, cold sweat, and ($_{sym}$loss) of consciousness, ...	P	P

Seven annotators who are non-medical experts worked on these two tasks, and 50,000 sentences were sampled from the above 127,352 sentences used in the final dataset. Each sentence was triple-annotated for the SNE and DSR tasks. Then, the final label for each sentence was determined by a majority vote among the three annotators. As a result, 26,363 (52.7%) and 15,547 (31.1%) terms were labeled as proper symptom names and as disease–symptom relationships, respectively. The inter-rater agreement of Fleiss' kappa of SNE and DSR were 0.823 and 0.788, respectively, denoting substantial agreement.

The 50,000 samples were divided into training, validation, development and test sets, and they were used in the experiment's settings described later. A set was also created from the test (All) by excluding symptom candidate names contained within the training set, the validation set, and the existing Japanese medical term dictionaries [8, 9] to evaluate the system's ability to deal with newly discovered expressions (labelled as "Unknown" in Table 2).

Table 2 – Statistics of the datasets

	Total	Number of positive instances	
		SNE	DSR
Training	35,000	18,489	10,877
Validation	5,000	2,581	1,532
Development	5,000	2,624	1,608
Test (All)	5,000	2,669	1,530
Test (Unknown)	1,056	586	367

Neural network-based models for SNE and DSR

In the SNE and DSR methods, a multi-column convolutional neural network (MCNN) [10], which is a variant of a convolutional neural network [11], with several independent columns, was used. Each column has its own convolutional and pooling layers. The outputs of all the columns are combined in the last layer to provide a final prediction. MCNNs have been widely used in NL processing tasks, such as question answering [12]. MCNNs were also used in tasks such as causality recognition [13] and zero anaphora resolution [14], in which, target expressions and their surrounding contexts should be considered. In the study's tasks, such contextual clues are essential for DSR, it is expected that MCNNs will accurately recognize these relationships.

The architecture of the MCNN used and its inputs are shown in Figure 2. As an input to the MCNN, an input sentence was first divided into five consecutive word sequences: a symptom candidate name (SYM), a given disease name (DIS), the word sequence before the SYM (BFR), the word sequence between the SYM and the DIS (BTWN), and the word sequence after the DIS (AFTR). If the DIS precedes the SYM, the BFR is the word sequence before the DIS while the AFTR is the word sequence after the SYM. These five-word sequences are independently given to the corresponding columns (Column 1 to Column 5 in Figure 2). Additionally, the question used for retrieving the sentence (Q) was also used as the input for the other column (Column 6) to use the relationship between the Q and the corresponding answer. Hereafter, we refer to the combination of the DIS and the SYM as BASE and the combination of the BFR, BTWN, and AFTR as CONT[ext].

The divided word sequences lack the relative linear-position feature indicating whether the SYM precedes the DIS or not. To integrate the linear-position into the MCNN, one of the three symbols representing the relative position (i.e., L[eft] and R[ight] and S[ymptom]) was assigned to each word in the sentence. Each symbol was converted into randomly initialized 10-dimensional vectors and was concatenated with the original word embedding vector to use it as a column's input. Hereafter, we refer to the use of the position vectors as LOC[ation].

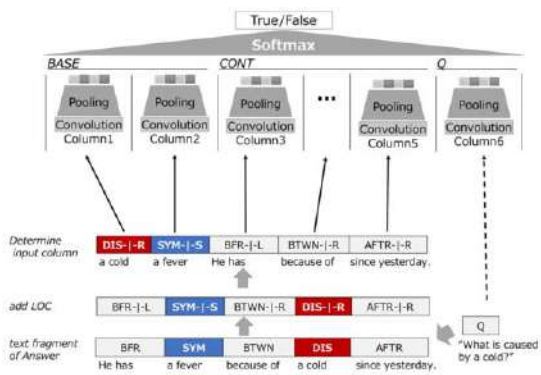

Figure2 – The MCNN architecture

Experimental settings

The performance of the proposed methods was evaluated using the datasets presented above. For the word embeddings used in the MCNN, 500-dimensional word embedding vectors were pre-trained for 1,658,487 words using the skip-gram model [15] on a set of all the sentences extracted from Wikipedia articles (jawiki-20150118; 35,975,219 sentences). Words that did not occur in the embedding vocabulary were treated as unknown words. Each of them was assigned a distinct random vector. The sentences in the datasets were tokenized by a Japanese morphological analyzer, MeCab [16].

For the convolutional layer of the MCNN, a combination of {100, 300} for the filter size and {(3, 4, 5), (4, 5, 6)} for the filter widths were tried. In the pooling layer, max-pooling is performed. The final layer has vectors coming from multiple feature maps in multiple columns. They are concatenated again and constitute a high-dimensional feature vector. The final layer applies a softmax function to produce the class probabilities of the SNE or the DSR labels: true and false. A mini-batch stochastic gradient descent (SGD) with the Adadelta update rule was used. To avoid overfitting, early stopping was administered using the validation dataset and the dropout; a dropout rate of 0.5 was applied to the final layer, and SGD with mini-batches of 100 and a learning decay rate of 0.95 were used. In training, the best epoch of the MCNN was selected by the F1-score on the validation set, and the optimal hyperparameters were selected using the development set.

To compare with our proposed method, we introduced two baseline methods. One extracts all symptom candidate names as proper ones and regards given pairs of a symptom and a disease name as proper disease–symptom relationships. This method was called the AllPositive method. The other is a traditional ML method of document classification based on support vector machines (SVM) with Latent Semantic Indexing features converted from a Bag of Words representation of context. This was called the SVM method. The McNemar test (α=0.05) was used to examine whether the classification performance of our method was significantly better than that of each of the baseline methods.

Results

The experimental results are shown in Table 3. On the evaluation of SNE, the results showed that the F1-score of our proposed method (Proposed (i.e. BASE+CONT+Q+LOC) in Table 3) was 93.8%, which was significantly better than those of the AllPositive and SVM (69.6% and 77.3%). We also conducted ablation test, that is, we evaluated performances of the Proposed methods that did not use one of Q, CONT, and LOC. However, as shown in Table 3, each of them didn't significantly contribute to performance improvement in both cases of evaluating test (All) and test (Unknown).

Of the DSR models, the Proposed method significantly outperformed the two baselines (AllPositive and SVM). In this case, the F1-score of the Proposed method was significantly better than the Proposed without CONT and that without LOC. That is, only the Q didn't contribute to performance improvement ($p = 0.071$).

The results using the test (Unknown) showed that the Proposed method significantly outperformed the AllPositive and SVM baselines in the cases of extracting unknown symptom names and recognizing unknown disease-symptom relationship, while F1-scores are relatively worse than those of the test (All).

Table 3 – Performance of Symptom Name Extraction (SNE) and Disease-Symptom Recognition (DSR)

Discussion

In the SNE task, the performance of the Proposed method was not statistically significant compared with the model without Q, CONT, or LOC. It means that SNE should be performed using the clues that are extracted from the words of symptom candidate names.

On the other hand, in the DSR task, performance of the Proposed method was significantly improved by the CONT and LOC. This indicates that the accuracy is increased by utilizing the contexts surrounding the DIS and the SYM and by considering relative linear-position of DIS and SYM. However, the performance was not increased by the Q. The relationship between a question and the corresponding answer was used in hopes of improving the model's performance. It may be because the questions are indirectly related to DIS and SYM, and thus has no significant positive effect for performance improvement, while they are important to extract sentences that include both DIS and SYM.

It was also expected that the following two issues eventually led to high F1-score in DSR. The first one is related to the annotation guidelines of DSR. In the annotations of DSR, annotators read the context where the DIS and the SYM both appear and then judge their disease-symptom relationship. That is, if disease-symptom relationship is easily interpretable by its context, annotators tend to regard it as proper relationship. We expect that such contextual clues are relatively easily captured by MCNNs through the word embedding vectors and convolution-pooling operations. The second issue is related to the text format in which the DIS and the SYM are described. In our dataset, the DIS and the SYM co-occurred in the titles of kinds of medical case reports and thus disease and symptom names appeared involving with typical templates, such as "a case of DIS exhibiting SYM," "DIS accompanying SYM," and "DIS with SYM," making the recognition easy.

Finally, the ability of the prediction models to extract new symptom names and causal relationships between diseases and their symptoms was examined. Although the F1-score slightly decreased compared to when the model was used with the test (All) dataset, the prediction models maintained high accuracy in SNE and DSR. To explore the final goal, classifiers were developed that may permit the automatic discovery of new terms without added human effort. The results of the test (Unknown) dataset exemplify the ability to achieve this object on a web archive.

Limitations

There were some instances where the prediction models misjudged the information and provided false positives and false negatives; these events were sampled from DSR cases. False positives/negatives were mainly caused by annotation errors. They were generally caused by obfuscated sentences and ones that were translated using an automated translator. These sentences tended to be unnatural as Japanese, so it made human judgment difficult. Another issue was medical reliability. To evaluate the medical reliability with respect to DSR, we sampled 100 pairs of the disease and the symptom from the pairs that were automatically recognized by each method (AllPositive, SVM, and Proposed in Table 3) and then a medical expert (a physician) confirmed them whether each pair was proper or not. Note that the samplings and judgment by the expert were performed for both test (All) and test (Unknown) cases. The percentage of proper relationship judged by the expert for each method is shown in Table 4. The result was like the precisions of DSR in Table 3 and even in this case, the performance of the Proposed method drastically better than those of the remaining methods. The misjudged cases were classified into improper symptom names, apposition, complements, inclusion relation, reversed relation of causality, and medical errors. Compared to the SVM method, our methods seemed good at reading contexts. Only a few medical errors were located and discussed about the medical reliability. For example, "($_{dis}$unstable angina) complicated with ($_{sym}$severe carotid artery lesion)" and "($_{dis}$steroid-resistant nephrotic syndrome) with ($_{sym}$relapse after transplantation)", which were controversial among medical professionals. In this research, the annotators were instructed not to care if the relationship was proper in the real world. To avoid such controversial cases at the annotation phase, it might be useful to present multiple examples at once to easily find controversial cases.

Table 4 – Evaluation of DSR predictions

	Accuracy of each 100 samples	
	Test (All)	Test (Unknown)
AllPositive	38%	52%
SVM	75%	81%
Proposed	93%	86%

The symptom names that were extracted by our method also have noises due to the parallel structure of noun phrases (e.g., this system recognizes "fever•cough•snivel" as a new word)

and word segmentation errors by Japanese morphological analyzer (e.g. “A-22” and “stomachache” was concatenated into a single word as “A-22stomachache”). For example, the proposed symptom extraction method outputted 488 symptom names on the evaluation using the test (Unknown) set, but the 28 symptom names in the output included noises due to the parallel structure and the 111 symptom names also included unnecessary characters by word segmentation errors. To exclude the effect of such noises, we manually corrected and recounted; the number of unique symptom names was 524, of which 378 cases (72.1%) were not included in the training data and the existing medical term dictionaries. Certainly, the 378 newly discovered symptom names contain variant ones that were in the training data, but we think that extracting such variants is also important for a DSS because a wide variety of symptom names are a key to bridge between actual symptom expression given by patients and the disease that causes the symptom as explained in the Introduction.

In this study, a portion of phrases requiring modified symptom expressions (e.g., "a condition in which I felt languid", "loss of one’s eyesight" [No.4 in Table 1]) were collected. It is necessary to collect modified expressions related to nouns (phrases) from this study to use with the NL processing technique to complete such expressions.

One of the limitations of the DSR data collected by the proposed method is the insufficient medical reliability. This is a result of the information being derived from web documents, which are less reliable than medical books. Additionally, some of the content acquired from the titles of case reports existed in the datasets, so it is possible that rare events were included as a symptom name associated with a disease, such as “A Case Report of [DISEASE] With Unusual Presentation and Clinical Course”. Therefore, it is necessary to be cautious about symptom names with low relevance to the target disease. That is, the difficulty of merging the knowledge of experts and non-experts must be rectified. To solve this problem, it is necessary to develop new technologies and methodologies that enable only reliable data to be stored in the database, such as extracting symptom names from reliable medical books and identifying the relationships between a disease and its symptoms. In some cases, manual verification may be required to judge the synonymy and the semantic similarity of the candidates of the disease names and the symptom names collected in this study using a deep learning technique.

Conclusions

In this paper, the authors developed a method to extract symptom expressions and the causal relationships between diseases and their symptoms through deep learning from a large web archive, which included a large amount of text written by non-medical experts. The acquired symptom names contain terms that do not exist in medical term dictionaries; thus, various new expressions can be obtained using the proposed methods. However, since expressions requiring corrections were present, along with the problematic medical reliability of web texts, the new content needs to be reevaluated before it is used. For further improvement, the experiment could be more efficiently performed by focusing on the probability score of the output as it might help to combine the knowledge of experts and non-experts.

Abstract

ICD-10-PCS coding is challenging because of the large number of codes, non-intuitive terms and paucity of the ICD-10-PCS index. We previously repurposed the richer ICD-9-CM procedure index for ICD-10-PCS coding. We have developed the MAGPIE tool based on the repurposed ICD-9-CM index with other lexical and mapping resources. MAGPIE helps the user to identify SNOMED CT and ICD-10-PCS codes for medical procedures. MAGPIE uses three innovative search approaches: cascading search (SNOMED CT to ICD-9-CM to ICD-10-PCS), hybrid lexical and map-assisted matching, and semantic filtering of ICD-10-PCS codes. Our evaluation showed that MAGPIE found the correct SNOMED CT code and ICD-10-PCS table in 70% and 85% of cases respectively, without any user intervention. MAGPIE is available online from the NLM website: magpie.nlm.nih.gov.

Keywords:

Controlled vocabulary, Operative Surgical Procedures, Clinical Coding

Introduction

In the U.S., ICD-9-CM procedure codes (also known as ICD-9-CM Volume 3, or ICD9V3 in short) had been used for over 30 years to encode hospital-based medical procedures and interventions for administrative and reimbursement purposes. In 2015, together with the replacement of ICD-9-CM Volumes 1 and 2 diagnosis codes by ICD-10-CM, ICD9V3 was replaced by ICD-10-PCS. Despite the similarity in name, ICD-10-PCS is not an evolutionary descendant of ICD9V3, but a brand-new procedure coding system [1-3]. While the tabular list of codes in ICD9V3 is a tree-shaped taxonomy similar to ICD-9-CM diagnosis codes or ICD-10-CM, ICD-10-PCS is built on a multi-axial structure. ICD-10-PCS codes are composed of seven characters. Each character is an axis of the classification that specifies some information about the procedure performed. Within a defined code range, an axis specifies the same type of information in that axis of classification. Within the Medical and Surgical Section (the first character is 0), which contains 87% if all ICD-10-PCS codes, the details of seven axes are shown in Figure 1.

Compared to ICD9V3, coding in ICD-10-PCS is more challenging because of three reasons. Firstly, there are 20 times more codes in ICD-10-PCS (78,705 codes in the 2018 version) compared to ICD9V3 (3,882 codes in the last updated version in 2013). Secondly, the terms used in ICD-10-PCS are not clinically intuitive. For example, in the clinical discourse, the three operations, extraction, removal and extirpation, are very close in meaning and can sometimes be used interchangeably. In ICD-10-PCS, those three operations are called 'root operations' and have very specific definitions within the coding system:

- Extraction - Pulling or stripping out or off all or a portion of a body part by the use of force
- Removal - Taking out or off a device from a body part
- Extirpation – Taking or cutting out solid matter from a body part

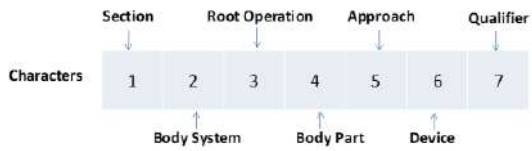

Figure 1— seven axes in ICD-10-PCS codes

This can be confusing to users of ICD-10-PCS, especially clinicians who may not be familiar with the definitions of root operation. For example, cataract removal is coded as extraction and not removal. Non-excisional wound debridment is coded as extraction, not excision or removal. Extraction of embolus (embolectomy) is coded as extirpation. Another area of potential confusion is the difference between resection and excision, which are mostly used interchangeably in clinical discourse. In ICD-10-PCS, excision is defined as "the cutting out or off, without replacement, a **portion** of a body part"; while resection is "the cutting out or off, without replacement, **all** of a body part". As a result, the removal of the appendix is coded as resection while partial nephrectomy as excision.

The third reason why ICD-10-PCS coding is more difficult is that the ICD-10-PCS index is not as rich as ICD9V3 index. The ICD9V3 index contains a lot of detailed terms that are commonly used in clinical records, including abbreviations and eponyms (e.g., Polya gastrectomy). As an example, Figure 2 and Figure 3 show the comparison of the entry for 'Gastrectomy' in the two indexes.

To overcome those challenges, the SNOMED CT to ICD-10-PCS Map Project Group is proposing an innovative solution called MAGPIE (Map-Assisted Generation of Procedure and Intervention Encoding). Our Project Group was formed under SNOMED International in 2015 and has been studying ways to map between SNOMED CT and ICD-10-PCS [4]. We have explored various ways of automatic mapping including lexical matching of the ICD-10-PCS index, ontological alignment between the SNOMED CT attributes and ICD-10-PCS axes, and the use of post-coordination to achieve logical equivalence

[5-9]. The latest study we carried out was repurposing the ICD9V3 index for ICD-10-PCS coding [10].

Figure 3 – ICD-10-PCS index

We harvested the rich ICD9V3 index terms and matched them to SNOMED CT through the UMLS. We mapped the ICD9V3 codes to ICD-10-PCS using the General Equivalence Map (GEM) published by the Centers for Medicare and Medicaid (CMS) (Figure 4) [11]. We showed that the re-purposed ICD9V3 index out-performed the native ICD-10-PCS index in the retrieval of ICD-10-PCS codes based on common surgical procedure names.

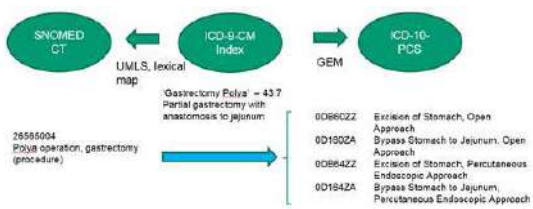

Figure 4– Repurposing the ICD9V3 index and mapping to SNOMED CT and ICD-10-PCS

Based on the repurposed ICD9V3 index and other lexical and mapping resources, we have developed the MAGPIE coding algorithm and tool that allow the user to search for SNOMED CT and ICD-10-PCS codes for a medical procedure or intervention.

Methods

Search Strategies

MAGPIE uses three innovative search strategies to help the user hone in on ICD-10-PCS codes in an interactive manner (Figure 5).

1. Cascading search

Starting from the search term that the user types in, MAGPIE looks sequentially for matches in SNOMED CT, ICD9V3, ICD-10-PCS tables, and ICD-10-PCS codes. The rationale for this approach is that SNOMED CT terms are closest to clinical parlance and meaning, so it is often possible to find a SNOMED CT term exactly matching the input search term. Identifying the correct SNOMED CT concept will help navigate the subsequent search for ICD9V3 codes. Going through ICD9V3 is necessary to take advantage of the repurposed ICD9V3 index and the GEM map. In the next step, MAGPIE will suggest candidate ICD-10-PCS tables that the user can pick to display for individual code selection. After the ICD-10-PCS code(s) are selected, MAGPIE will prompt the user for possible refinement of the SNOMED CT code in cases where the ICD-10-PCS codes selected could lead to a more specific SNOMED CT concept than the one chosen. At each step, MAGPIE will suggest

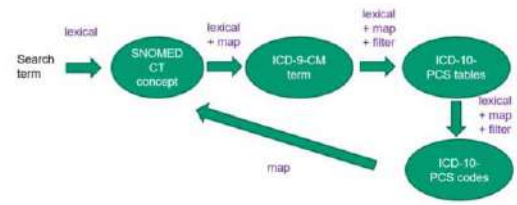

Figure 5 – Overall schema of MAGPIE search sequence and search methods

default codes, if available, based on lexical and map-assisted matching (see below), but the user can change the default if they see better matches. In this way, the user can guide MAGPIE interactively to arrive at the correct ICD-10-PCS codes.

2. Hybrid lexical and map-assisted matching

The first step of searching for a SNOMED CT code is based on lexical matching alone. (Figure 5) All subsequent steps use a combination of lexical and map-assisted matching. To support **lexical matching**, we have built synonym and entry term tables for SNOMED CT, ICD9V3 and ICD-10-PCS codes based on the UMLS, repurposed ICD9V3 index and ICD-10-PCS index. We use the open-source Apache Lucene information retrieval library functions as the search engine for lexical matching [12]. For each sequential search, we expand the search terms by including the synonyms of the selected code in the previous step. For example, the synonyms of the selected SNOMED CT concept are included in subsequent lexical searches for ICD9V3 and ICD-10-PCS codes. For **map-assisted matching**, we have built pairwise mapping tables between the codes from SNOMED CT, ICD9V3, and ICD-10-PCS based on the UMLS, repurposed ICD9V3 index and GEM. Based on the selected code at an earlier step, MAGPIE looks up the code-mapping tables to find target codes for the next step. For example, the selected SNOMED CT code will help to find ICD9V3 codes through the SNOMED CT to the ICD9V3 mapping table. Lexical matching almost always returns some codes, but the accuracy is variable. Map-assisted matching does not always return target codes but is generally more accurate. If both lexical and map-assisted matching return some codes, codes found by map-assisted matching will take precedence over lexical matching.

3. Semantic filtering

In the GEM map, one ICD9V3 code often maps to many ICD-10-PCS codes because of the different granularity between the two systems. For example, *65.29 Other local excision or destruction of ovary* maps to 21 ICD-10-PCS codes because of the combinations of the various options in laterality (left, right, bilateral) and approach (open, endoscopic, etc.). MAGPIE uses semantic filtering to narrow down the possible choices in the

suggestion of ICD-10-PCS tables and codes. (Figure 5) Semantic filtering is based on some keywords in the user's search string. For example, if the user types in 'left laparoscopic oophorectomy', MAGPIE will recognize the keywords 'left' and 'laparoscopic', and pre-select the ICD-10-PCS code *0UT14ZZ Resection of Left Ovary, Percutaneous Endoscopic Approach* while filtering out other choices pertaining to right ovary, bilateral ovaries, and open approach. To support semantic filtering, we have built keyword tables for body part and approach based on the ICD-10-PCS definition tables.

Evaluation

To evaluate the performance of MAGPIE, we use a list of the most commonly performed surgical procedures from a large health care institution that we have obtained in another project [13]. The procedure names have been manually mapped to ICD-10-PCS codes previously, and the maps are used as the reference standard to assess MAGPIE [10]. The procedure names are entered individually into MAGPIE and we evaluate the accuracy of the default SNOMED CT and ICD9V3 codes suggested by MAGPIE. We also evaluate the accuracy and completeness of the suggested ICD-10-PCS tables and ICD-10-PCS codes. If the correct ICD-10-PCS tables or codes are not found by the default selections, we would make necessary adjustments to the SNOMED CT and ICD9V3 code selections, just like a coder would normally do, to get to the correct codes.

Results

A testing version of MAGPIE was made available through the internet during the period of this study. Since the completion of the study, a stable version is now available from the NLM website: magpie.nlm.nih.gov.

MAGPIE users need to accept the UMLS user agreement since SNOMED CT is copyright protected. The users start searching by entering a procedure name, such as 'cesarean', and the autocomplete feature will show the matching terms based on our list of synonyms and entry terms. The users can either pick from the list or type in something not on the list. Upon submitting the search term, MAGPIE will suggest as default the SNOMED CT concept *Cesarean section (11466000)* and ICD9V3 code *Other cesarean section of unspecified type (74.99)* based on lexical and map-assisted matching (Figure 6).

In this case, both through lexical matching using the ICD-10-PCS index, and GEM mapping based on the selected ICD9V3 code, MAGPIE suggests the ICD-10-PCS table *10D Obstetrics | Pregnancy | Extraction*. The user picks the table (only one in this case) for further exploration. On opening the table, the codes found by the GEM map are pre-selected. (Figure 7) MAGPIE highlights the axes where there are multiple values in the GEM suggested codes (the Qualifier axis in this example) and prompts the user to narrow down the choices.

On picking the value 'Classical' for the Qualifier axis, the ICD-10-PCS code Extraction of Products of Conception, Classical, Open Approach (10D00Z0) is recorded by MAGPIE. MAGPIE further checks for potential refinement of the SNOMED CT concept based on the final ICD-10-PCS code. Based on the SNOMED CT to ICD-10-PCS map, the selected ICD-10-PCS code is related to three SNOMED CT concepts that are descendants of the concept Cesarean section (11466000). MAGPIE displays these concepts and asks whether the user wants to use one of these concepts instead. (Figure 8) On picking the refined SNOMED CT concept, MAGPIE displays the final result of the SNOMED CT and ICD-10-PCS codes selected.

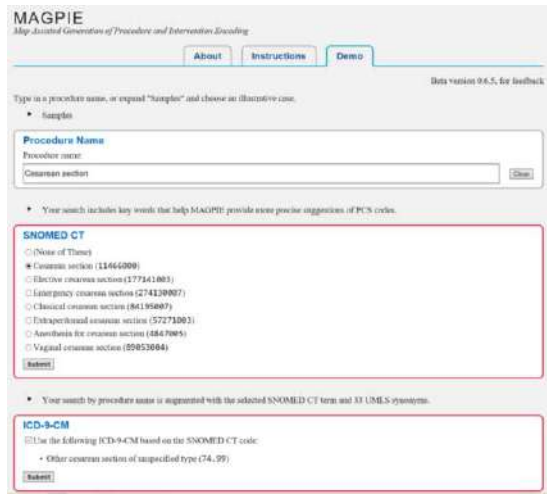

Figure 6 – MAGPIE screenshot 1 - default SNOMED CT and ICD9V3 codes for 'Cesarean section'

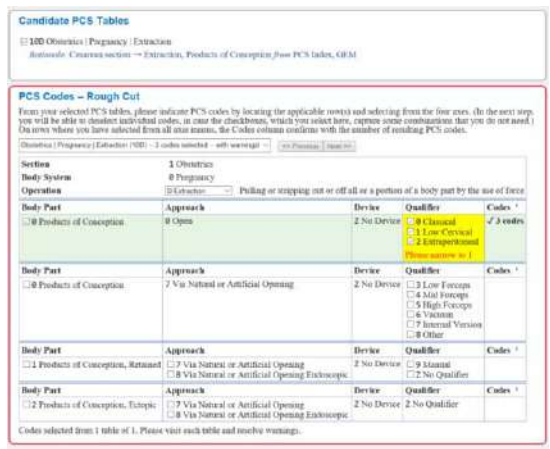

Figure 7 -- MAGPIE screenshot 2 - ICD-10-PCS tables and pre-selected codes for 'Cesarean section'

Evaluation

We used 88 common surgical procedure names to test MAGPIE. First, we evaluated the accuracy of the default SNOMED CT and ICD9V3 codes suggested by MAGPIE. The majority (70%) of the SNOMED CT codes were exact matches, while there were more close matches (48%) than exact matches for ICD9V3 codes (Table 1).

Figure 8– MAGPIE screenshot 3 - refinement of SNOMED CT codes and list of final codes.

Table 1 – Accuracy of default codes found by MAGPIE

Match category	SNOMED CT	ICD9V3
Exact match	62 (70%)	34 (39%)
Close match	26 (30%)	42 (48%)
Unrelated	0	12 (14%)
Total	88 (100%)	88 (100%)

Next, we assessed how well MAGPIE performed in finding the ICD-10-PCS tables and codes. Without changing the default SNOMED CT and ICD9V3 codes suggested by MAGPIE, the correct ICD-10-PCS table was found in 75 (85%) cases. The list of suggested tables was ranked by MAGPIE based on the number of corroborating sources. The sources included ICD-10-PCS index, ICD-10-PCS procedure name or GEM. The tables with the highest number of suggesting sources were ranked first. Among the 75 cases where the correct table was among the default MAGPIE suggestions, the correct table was ranked first in 55 (63%) cases. Overall, in 65 (74%) cases, the correct table was found among the top three (Table 2).

Table 2 – MAGPIE performance using the default selections

Result based on MAGPIE default choices	No. of cases (N=88)
Correct ICD-10-PCS table suggested	75 (85%)
- Ranked first	55 (63%)
- Ranked top 3	65 (74%)
Correct ICD-10-PCS codes suggested	25 (28%)

We further assessed the accuracy and completeness of the pre-selected ICD-10-PCS codes (suggested by GEM). Among the 75 cases where the correct table was found by MAGPIE, the pre-selected codes were exactly the same as in the reference standard in 25 (28%) cases. In the rest of the cases, the users need to adjust the pre-selected codes. Generally, the cases that needed user adjustment can be grouped into three categories. First, there were no pre-selected ICD-10-PCS codes because MAGPIE did not find any ICD9V3 codes, and so there were no GEM-suggested ICD-10-PCS codes. Second, the GEM suggestions were incomplete. One example was 'Ligation of Fallopian tube'. The default ICD9V3 code was *Other bilateral destruction or occlusion of fallopian tubes (66.39)*. GEM found only the bilateral codes, missing the codes for left and right Fallopian tubes in the reference standard. And in the last category, some of the GEM suggested codes were not in the reference standard. For example, in 'Hemorrhoidectomy, internal and external, simple', the GEM suggestions included codes for percutaneous approach, percutaneous endoscopic approach and use of extraluminal device, which were not present in the reference standard.

We further analyzed the 13 cases in which the correct ICD-10-PCS tables were not found by MAGPIE using the default selections. In some of the cases, there was more than one procedure involved. One example was 'Complete transurethral resection of the prostate including control of postoperative bleeding' which required two ICD-10-PCS codes for complete coding. MAGPIE was able to find the code for the 'resection' procedure, missing the 'control of bleeding' part. Some failure was caused by procedure names that were under-specified. One example was 'Shaving benign hyperkeratotic lesion, single'. In clinical discourse, this could be understood as referring to a procedure on the skin. However, since the skin was not explicitly stated in the search term, MAGPIE was not able to find the correct table. Had one used the search term 'Removal of skin lesion' MAGPIE would be able to find the correct codes. In some cases, the procedure could be coded in multiple ways in ICD-10-PCS and there was potential ambiguity. One example was 'Dilation and curettage of uterus'. If the operation was carried out in a non-pregnant woman, this would be coded as *0UDB7ZX Extraction of endometrium through natural or artificial opening*. However, if this was done for termination of pregnancy, it would be coded as *10A07ZZ Abortion of Products of Conception, Via Natural or Artificial Opening*.

Discussion

ICD-10-PCS is radically different from ICD9V3 and the traditional approach for ICD9V3 coding may not work equally well for ICD-10-PCS. Searching based on the ICD-10-PCS index will not work well because the ICD-10-PCS index is relatively lacking in useful clinical terms, compared to the ICD9V3 index. Searching based on the names of the ICD-10-PCS codes, which are generated from concatenating the values of the individual axes, will probably not work well either because some ICD-10-PCS terms (e.g., removal, extraction, extirpation, resection, excision) are not well-aligned with their meaning in clinical usage. We have shown in our previous study that recall and precision are both better when searching with the repurposed ICD9V3 index compared to the native ICD-10-PCS index. Based on the repurposed ICD9V3 index and other resources that the SNOMED CT to ICD-10-PCS Map Project Group has developed, we have built a tool that can be used for both ICD-10-PCS and SNOMED CT coding. SNOMED CT is an emerging international clinical terminology standard and is increasingly used in electronic health records. Using the MAGPIE tool, users can compare the two coding systems side-by-side and understand differences in their scope, granularity and organizing principles.

Since the goal of MAGPIE is to look simultaneously for both SNOMED CT and ICD-10-PCS codes, the cascading search approach is a natural choice. This is similar to the approach used in the I-MAGIC tool [14], which starts with a SNOMED CT concept then navigates to ICD-10-CM through a map. SNOMED CT is the preferred starting point because the SNOMED CT terms are closest to clinical parlance. SNOMED CT is also very comprehensive and has good coverage of both clinical diagnosis and procedures. The next link through ICD9V3 is necessary to make use of the repurposed ICD9V3 index and GEM. Since ICD9V3 is no longer in use, the ICD9V3 code is used only as a navigational pointer. In many cases, it is not necessary to find the perfectly matching ICD9V3 code to get to the correct ICD-10-PCS code, and an approximate ICD9V3 code match is sufficient, as shown in our results. While in only less than 40% of cases the default ICD9V3 codes are exact matches, overall 85% of the cases lead to the correct ICD-10-PCS tables by accepting the default values. The use of SNOMED CT and ICD9V3 codes as intermediate steps offers the opportunity for the user to 'correct course' if MAGPIE is going down a wrong path, which sometimes happens due to a vague or potentially ambiguous search term. One example is 'Construction of shunt', which can mean shunts for arteries, veins or the nervous system. The user can help to guide MAGPIE by choosing the correct SNOMED CT and ICD9V3 codes.

The mapping resources that MAGPIE depends on are used in either direction. Using maps in this way can sometimes be

problematic, especially when the source and target terms are not exactly equivalent. Sometimes maps may contain errors too. However, despite these limitations, our evaluation shows the performance of MAGPIE to be satisfactory.

One potential problem of the GEM is that one ICD9V3 code often ends up with multiple ICD-10-PCS codes because of the difference in the granularity of the two systems. In our previous study, three or four times more ICD-10-PCS codes were retrieved by the GEM compared to the reference standard. This is mostly the result of combinatorial explosion i.e., the total number of codes is the product of the number of options for each axis. To mitigate this problem, we use semantic filtering to prune the GEM-suggested ICD-10-PCS codes. If the user types in '*laparoscopic* excision of ovarian cyst', MAGPIE will exclude the options of 'open' or 'through natural or artificial orifice' from the approach axis. Similarly, if the user types in 'Total replacement of *left* hip', MAGPIE will exclude the values of 'right hip' or 'bilateral hips'.

One special feature of MAGPIE is that the final selection of the ICD-10-PCS code(s) can be used to suggest refinement for the initially selected SNOMED CT concept, in a way 'closing the loop' of the cascading search. In coding, one should always use the most specific code possible in a coding system for a clinical concept. However, coders tend to settle on the first code in the picklist that is applicable and do not look further for more specific codes. MAGPIE takes advantage of the information carried in the final ICD-10-PCS code to prompt the user to refine the initial SNOMED CT selection where appropriate. Therefore, in addition to helping with ICD-10-PCS coding, MAGPIE will also improve SNOMED CT coding.

We recognize the following limitations in our study. The list of common procedure names used in the evaluation was taken from one institution and might not be representative of other institutions. The reference standard for the evaluation was based on the judgment of two physicians with terminology expertise and was not independently validated. The assessment of the performance of MAGPIE was based on a single reviewer and a relatively small sample.

Conclusion

To overcome some of the difficulties in ICD-10-PCS coding, we have developed an innovative tool called MAGPIE (Map-Assisted Generation of Procedure and Intervention Encoding). MAGPIE makes use of the repurposed ICD-9-CM procedure index, which is much richer than the native ICD-10-PCS index. In addition, other lexical and mapping resources derived from the UMLS and GEM are also used. MAGPIE applies various innovative approaches to help the user hone in on the correct SNOMED CT and ICD-10-PCS codes. Our evaluation shows that MAGPIE finds the correct SNOMED CT code and ICD-10-PCS table in 70% and 85% of cases respectively, without any user intervention.

Acknowledgements

The authors thank Kaiser Permanente for providing the list of commonly performed procedure names. We also thank Phill Wolf for the development of the MAGPIE tool. Abstract

Cardiovascular disease is prevalent and associated with significant mortality rate. Robust lifetime risk stratification for cardiovascular disease is important for effective prevention, early diagnoses, targeted intervention, and improved prognosis. Health disparities, manifested as socio-behavioral factors, are believed to have multiple effects throughout life with great complexity. Multiple studies investigated lifetime cardiovascular-related mortality risk prediction focusing on subjects' pathophysiology and intervention profiles. In this study, we applied machine learning algorithms and focused on integrating socio-behavioral factors to pathophysiology and intervention profiles to predict cardiovascular-related mortality risk. Our results showed that multiple machine learning algorithms can predict risk with reasonable accuracy, using mixed types of features. Particularly, socio-behavioral factors contributed significantly to the improved accuracy of mortality risk prediction. Feature analysis identified the odds ratio of socio-behavioral factors for cardiovascular-related mortality and offered potential insights on how they impact subjects' long-term outcomes. Our results call for further investigation of this important topic.

Risk Factors, Cardiovascular Diseases, Machine Learning

Introduction

Cardiovascular Disease (CVD) is a major cause of disability and premature death throughout the world and substantially contributes to the escalating costs of health care, mortality, and morbidity [1]. According to the report from World Health Organization, an estimated 17.9 million people died from CVDs in 2016, representing 31% of all global deaths [2]. In the US, the mortality of cardiovascular disease is as high as 0.25 (95% CI 0.10-0.63) [3]. In order to reduce the physical, emotional, and economical burden caused by cardiovascular-related mortality, it is important to develop robust lifetime risk stratification algorithm that is accurate and that generalizes at a population level.

Previous studies revealed the association between cardiovascular disease and demographics, physiology, comorbidity, and medication features, such as body mass index [4], chronic kidney diseases [5], hypertension and obesity [6], anemia [7], etc. Social determinants and behavioral factors, such as education level, income level, smoking status, and diet habit, act upon populations at all times, and they have also been found to have wide-ranging health related effects across the life course of a population [8, 9]. For example, higher income is linked to better health outcomes, including lower prevalence of cardiovascular disease and lower mortality risk among populations with cardiovascular disease. With growing awareness of their importance, previous studies have explored relationships between social determinants and risks for developing cardiovascular diseases [10-13]. In addition to social determinants, behavioral factors, such as diet [14-16] and physical activity [17, 18], are investigated to be related to various mortality and cardiovascular-related outcomes. For example, poor diet, lack of physical activity, and cigarette smoking are all linked to premature deaths [19]. Unfortunately, a majority of existing studies focused on linking social and behavioral factors to risks for developing specific diseases, leaving systematic analysis on these factors' relations with mortality risks a largely uncharted territory. On the other hand, pooling the social determinants and behavioral factors together and utilizing more powerful approaches, such as machine learning [20-22], may shed more light on the landscape and yield a more robust mortality-risk prediction model.

In this study, we apply different machine learning models to predict cardiovascular-related mortality risks by integrating social behavioral factors with subjects' pathophysiology and intervention profiles as features. We aim to provide a comprehensive understanding of the socio-behavioral landscape and use the additional knowledge to improve cardiovascular-related mortality prediction. Our results demonstrate the impact of social and behavioral factors on cardiovascular health at population level and the feasibility towards more robust lifetime risk stratification by integrating them.

Methods

Study population

In this study, we used data from The Cardiovascular Disease Life Risk Pooling Project (LRPP) [23]. LRPP was designed as an individual-level pooled dataset from 20 US community-based cardiovascular disease cohorts that include demographics, physiological test results, medication status, socio-behavioral factors, and mortality indicators (for mortality of cardiovascular disease, coronary heart disease, and mortality resulting from all causes). From the overall sample size of 1,097,178 observations of 277,296 subjects, 40,711 completed cases with all predicting features available were selected for each mortality in this study. Shown in Table 1 is the data distribution after splitting training and test set into approximately 7:3 ratio.

Table 1– Data distribution

	Training set				Test set				All data			
	Total	Death	Non-event	% death	Total	Death	Non-event	% death	Total	Death	Non-event	%death
CVD	28,497	1,772	26,725	6.22%	12,214	846	11,368	6.93%	40,711	2,618	38,093	6.43%
CHD	28,497	1,772	26,725	6.22%	12,214	846	11,368	6.93%	40,711	2,618	38,093	6.43%
TOT	28,497	6,048	22,449	21.22%	12,214	2,703	9,511	22.14%	40,711	8,751	31,960	21.50%

CVD: mortality due to cardiovascular diseases; CHD: mortality due to coronery heart disease; TOT: all causes mortality

Statistical analysis

In total, 25 features were chosen from the entire LRPP dataset. They belong to the following domains: demographics, physiological test results, medication status, and socio-behavioral factors. Features were grouped into 3 different combinations, physiological test result (Phy), physiological test results combined with medication status (Phy+Med), and further including socio-behavioral factors (Phy+Med+Soc). While demographics were included in each group (Table 2).

Four supervised machine learning algorithms were applied for prediction of the three outcomes, including Naïve Bayes (NB), Logistic Regression (LR), Linear Support Vector Machine (SVM), and Random Forest (RF). Training and test set were split to approximately 7:3. Due to the imbalance of the data (incidence rate at approximately 6%), parameter *'class_weight'* was set to *'balanced'* for LR, SVM and RF. To reduce over-fitting and variance, five-fold cross validation was performed on training set. Best parameters for each model, tuned through cross validation, were then applied on test set to evaluate the predictive performance of each classifier. The area under the receiver operating characteristic curve (AUC) as well as predicted probability were acquired from each algorithm.

The AUCs of the three models are shown in Table 3, ranging from the lowest to the highest. Considering that the distribution of the predicted probability was unknown, permutation test [24] was applied to explore the difference between the probability of correct prediction of every two models (ie. tested between Phy and Phy + Med, Phy+Med and Phy+Med+Soc).

In RF, coefficient *'feature_importance'* was extracted to identify the importances of features. Generalized linear regression (logit link function) was employed to find the odds ratio (OR) to evaluate risk for mortality of each socio-behavioral factor. Data cleaning, permutation test, and generalized linear regression were performed by R 3.3.1. *'scikit learn'* package was used for machine learning algorithms.

Results

AUCs of different algorithms and models

Table 3 shows the AUCs yielded from each of the four machine learning algorithms as applied to predict the three outcomes, with the three combination of the features. P-value 1 was derived from the permutation test between the feature combination of Phy and Phy+Med, while P-value 2 shows the significance of difference between the feature combination of Phy+Med and Phy+Med+Soc. Result demonstrates that AUCs are in a range from 0.7263 to 0.8941 across all the models.

Table 2– Predictors features

Categories	Variable names	Description
Demographics	SEX	Gender
	AGE	Calculated age at exam, round to 0 .1
	BMI	Body mass index, kg/m^2
Physiological tests	SBP	Systolic blood pressure, mmHg
	DBP	Diastolic blood pressure, mmHg
	LDLCHL	LDL cholesterol, mg/dL
	HDLCHL	HDL cholesterol, mg/dL
	TOTCHL	Total cholesterol, mg/dL
	TRIGLY	Triglycerides, mg/dL
	GLU	Glucose level
	CVD_BASELINE	Prevalent of cardiovascular disease at enrollment
Medication statues	HXDIAB	Diabetic Medication Status
	RXCHL	Medication of lowering lipid
	RXHYP	Medication of anti-hypertension
Socio-behavioral factors	RACE	Race/ethnicity
	EDU	School education
	SMOKER	Current smoker
	FORSMOKER	Former smoker
	DRINKER	Current drinker
	ALCO_ML_DAY	Alcohol intake, mL /day
	DASH	Dietary Approaches to Stop Hypertension score
	aHEI	Alternate Healthy Eating Index score 2010
	aMed	Alternate Med diet score (all cohorts median)
	primary PA	Primary physical activity
	MVPA	Moderate to vigorous physical activity
Outcomes	CVD_DTH	Death caused by cardiovascular diseases
	CHD_DTH	Death caused by coronary heart disease
	TOT_DTH	All causes death

Table 3– AUCs of the three models and four algorithms

	Phy	PM	*P-val 1*	PMS	*P-val 2*
Mortality due to cardiovascular disease

PM: combination of Phy+Med; PMS: combination of Phy+Med+Soc

Considering NB algorithm as the baseline, overall result illustrates significant improvement in AUCs when applying LR, SVM, and RF algorithms. The Phy combination consisted of the 11 features from Demographics and Physiological tests categories. NB algorithm provided AUCs between 0.7263 and 0.7436 based on these features. RF showed a better performance within this combination that yielded AUCs of 0.8461 for prediction of mortality risk of CVD and CHD. The most promising algorithms for this model were LR and SVM which achieved AUCs of 0.8510 for prediction regarding CVD and CHD mortality. When adding the Medication status to the feature collection, we observed an elevation in all AUCs compared to the Phy model. Meanwhile, p-values ($\leq$0.001) generated from permutation test also confirmed the statistically significant improvement on the probability of correct prediction, except for SVM algorithm for CVD and CHD mortality risk prediction. Last but not least, much better performance was observed when integrating the Socio-behavioral factors into the feature combination. All AUCs yielded from RF algorithm became above 0.80, the highest AUC reached 0.8941. Comparing the AUCs to the previous model, this model with socio-behavioral factors demonstrated the best performance. Results from permutation test for difference between the correct prediction probability of Phy+Med and Phy+Med+Soc also helped verify the significant improvement.

Feature analysis

Shown in Figure 1 are the feature importances derived from RF for different feature combinations. In the combinations without socio-behavioral factors (Phy and Phy+Med), age served as the most important feature for classification. Blood pressure, BMI, triglycerides level, and the three kinds of cholesterol levels also played relatively important roles in the first two Phy and Phy+Med [25]. The pattern was different in the third feature combination (Phy+Med+Soc), race performed as the most important feature for all three outcomes, followed by age and SBP. Meanwhile, aHEI score also appeared to be an essential feature for classification. Other important factors shown in the previous two feature combinations still remained on top.

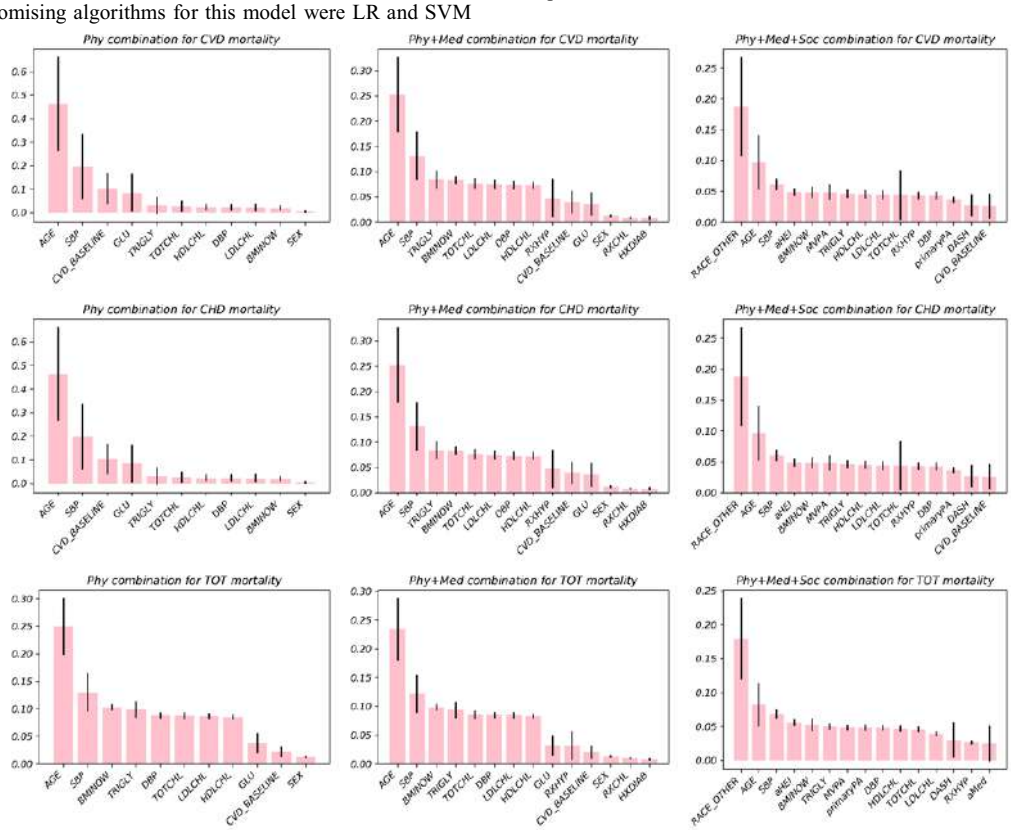

Figure 1– Feature importances for different feature combinations derived from Random Forest. For combination Phy+Med+Soc,only the first 15 highest ranked features were shown in the figure.

Discussions, Limitations and Future Work

With machine learning approaches, we were able to detect the hidden patterns within larg-scale data. Among the four algorithms applied in this study, LR, SVM and RF demonstrated reasonable accuracy. Among them, RF appeared to be the best for solving the current problem.

Significant improvements were observed from those machine learning configurations when adding socio-behavioral factors as well as medication status into predicting models. It should not be surprising to observe medication status (BP medication, lipids medication, and DM medication) as an important predictor, since only the subjects with such health disorders would take the medicine. Meanwhile, blood pressure disorders [26, 27], dyslipidemia [28, 29], and diabetes mellitus [30] were also found to be physiologically related with mortality caused by cardiovascular diseases. Eleven socio-behavioral factors were integrated to the previous models, covered the aspects of race, education, smoking, diet, and physical activity. To understand which sociobehavioral factors in particular have a higher risk for cardiovascular-related mortality, a further general linear regression (logit link function) was performed (Table 4). Comparing to Asian, subjects with race in African American and White were found to have odds ratio greater than 1 with p-values satisfying significant level, which indicates a higher mortality risk for African American and White population. Moreover, current smokers also experienced a higher risk than those who were not currently smoking. Compared with the educational level below, high school, higher educational level (high school or above) reduces the risk. Subjects with higher dietary scores (DASH and aHEI) were also found to be undertaking higher risk.

Previous studies with consideration of social factors were generally focused on social determinants [31] while ignored the importance of behavior. This study showed that socio-behavioral factors, such as smoking and diet, can also be essential predictors for mortality risk of cardiovascular diseases and is worthwhile to be included into predictive models. Similarly, socio-behavioral factors might also be worth considering for risk prediction of other health outcomes.

The LRPP study is a pooled project from a large variety of cohorts. Therefore, missing rate is relatively high for part of the features especially the socio-behavioral factors. This limited the size of training and test set and likely introduced biases. In future work, we will use modern imputation methods [32-34] to impute the missing data and scale our analysis on larger cohorts. Continuing from what we found in this study, we are planning to perform further analysis considering time sequence. With the dimension of time, we will generate more sophisticated models for prediction. At the same time, the approaches we demonstrated in this study could be applied to other CVD outcomes as well as other diseases.

Conclusions

In the present study, we applied multiple machine learning algorithms and integrated socio-behavioral factors with pathophysiology and medication profiles of subjects to predict cardiovascular-related mortality. All the machine learning algorithms, including Naïve Bayes, Logistic Regression, Linear Support Vector Machine, and Random Forest yielded reasonable accuracy. In addition to pathophysiological and interventional profiles, socio-behavioral factors were also included as predictive features. Integration of socio-behavioral factors brought statistically significant improvement of the all three mortality risk predictions, including the risk of mortality due to cardiovascular diseases, coronary heart disease, and mortality resulting from all causes. In the overall analysis, age, race, and blood pressure were found to be relatively more important for the prediction. While in the analysis for odds ratio of socio-behavioral factors, race, educational level, smoking, and diet were found to have significant impact on cardiovascular-related outcomes.

Given that socio-behavioral factors manifested long-term impacts on the health outcome disparities, we expect more exciting and promising developments of robust lifetime risk prediction algorithms with tighter integration of socio-behavioral factors to inform policy making and improve the population health and longevity.

Abstract

We aimed to develop a deep learning model for the prediction of the risk of advanced colorectal cancer in Taiwanese adults. We collected data of 58152 patients from the Taiwan National Health Insurance database from 1999 to 2013. All patients' comorbidities and medications history were included in the development of the convolution neural network (CNN) model. We also used 3-year medical data of all patients before the diagnosed colorectal cancer (CRC) as the dimensional time in the model. The area under the receiver operating characteristic curve (AUC), sensitivity, and specificity were computed to measure the performance of the model. The results showed the mean (SD) of AUC of the model was 0.922 (0.004). Moreover, the performance of the model observed the sensitivity of 0.837, specificity of 0.867, and 0.532 for PPV value. Our study utilized CNN to develop a prediction model for CRC, based on non-image and multi-dimensional medical records.

Introduction

Cancer has been the leading cause of death since 1986 [2] and colorectal cancer (CRC) has been ranked as the third cause of cancer-related death in Taiwan since 2008 [5]. The incidence rate of CRC was 43.6 per 100,000 population in 2015, the age-adjusted incidence rate of male was higher than female. In fact, it increased by 13% for male and 6% for a female since 2002. CRC is now a burden and challenge to Taiwan's health care [1]. Therefore, it is important to find the potential biomarkers that can contribute to early diagnosis of colorectal cancer.

Artificial intelligence (AI) and machine learning are taking all fields of science by storm including clinical medicine [7; 10]. Deep learning is a type of the highly flexible machine learning approach, has emerged a groundbreaking algorithm to enhance the performance of current machine learning techniques and to solve complex problems [7]. Several studies already showed that machine learning model can predict cancer that help physicians to reduce the number of false decisions and improve health outcomes.

In this study, we aimed to develop a deep learning model by applying all patients phenotypic information to detect the onset of colorectal cancer.

Methods

Data Sets

In this study, we used the reimbursement data from Bureau National Health Insurance (NHI) system in Taiwan that had registered all medical records since 1996 [8]. We obtained a randomization of two million population of the NHI claim data from January 01, 1999 to December 31, 2013. The study was approved by the institutional review board committee at Taipei Medical University and the need for informed consent was waived.

Study population

We initially identified all patients who were diagnosed with a primary diagnosis of colorectal cancer (CRC) (International Classification of Disease, Ninth Revision [ICD-9] codes 153, 154) between January 01, 1999, and December 31, 2013. The diagnosis accuracy of CRC was confirmed by both specific ICD-9 codes and inclusion in the Registry for Catastrophic Illness Patient (RCIP), a subpart of the NHI database [6]. Surgical pathological confirmation or undergoing treatment process of CRC is required for patients to be registered in the RCIP. However, the index date was defined as the date of diagnosis. Patients were excluded if they were younger than 20 years of age at the date of diagnosis CRC or if they did not have any outpatient claims at each calendar year of four years before the index date.

We then randomly selected 50,000 individuals without any cancer diagnosis during 15 years in the NHI claim database. All medical records of those were also collected. We defined the date of the last visit observed in the NHI database as the index date of patients with cancer-free. We then used the same conditions as CRC patients to cross-check their age and the history of medical data.

In this study, our purpose was to predict CRC in one year ahead; we, therefore, used the data of patients with and without cancer diagnosis from the fourth year to the first year before the index date and left out a year data to be the gap of developing CRC cancer **(Figure 1).**

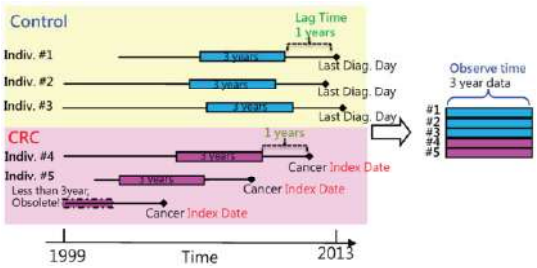

Figure 1. Observation Window and Lag Time

Feature definition

First, we checked the index date to observe the age and sex of overall individuals (i.e., with and without cancer diagnosis). We included the ICD9-CM 3-digit codes such as 001-999, V01-V91 in the features of the development of the model. The supplementary classification of external causes of injury and poisoning codes, E000-E999 were excluded in the feature list.

For the medications, the Taiwan medication codes were collected and mapped to WHO-ATC (Anatomical Therapeutic Chemical Classification System) codes. The ATC-4 (ie. ATC 5-digit) codes were used in the further development of the model. A total of 1931 features (ie. age, sex, 1099 ICD9-CM codes, and 830 ATC-4 codes) were used in the development of the CRC prediction model.

Time definition and data processing

We collected the data of all individuals in 1095 days (i.e., 3-year data). For each disease, the patient was considered as a diagnosis if at least three visits were observed with its ICD9 code during the 3-year period. For each medication, the patient was defined as a user if its ATC code was observed in the prescriptions, and the medication observation time was the number of days prescribed by physicians. For each patient, the 7-day data was summed up continuously, and the final data of 157 grids were derived from 1095-day data set **(Figure 2)**. The value of each feature of each patient was then normalized to scale up to the range in between 0 and 1 in order to make the similar severity of all individuals as the same cause. It expresses mathematically in (1) as: $x_{new} = {x - x_{min}}/{x_{max} - x_{min}}$ (1), where x = (x_1, …, x_n) and x_{new} is now the new normalized value. **Figure 3** shows an example of the normalized data.

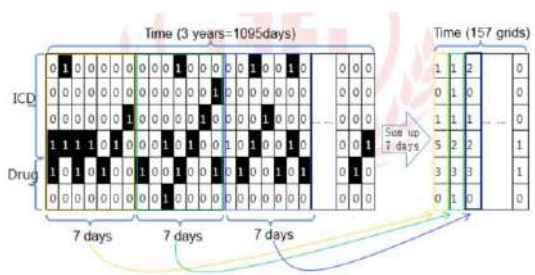

Figure 2. The processing of time data

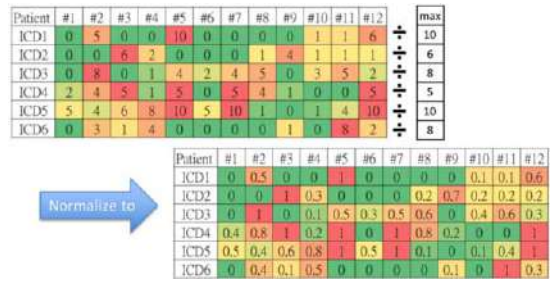

Figure 3. An example of normalized data

Development of the model

Deep learning is the process of training a neural network (a large mathematical function with millions of parameters) to perform a given task. **Figure 4** shows the convolution neural network (CNN) structure of the study. We created the function that computed the CRC severity from a large set of the matrix of all individuals. During the training process, the parameters of the neural network were initially set to random values. The total of 1929 features data including 1099 ICD9 codes and 830 ATC codes, were categorized into 19 groups (i.e., 18 groups for ICD9, for example, 001-139-infectious and parasitic disease group, and one ATC group) for all patients. We created two convolutional layers with 32 feature maps for each category. Two max-pooling layers with the filters of size 1x3 were applied to reduce the number of parameters, and to control overfitting. After that, we flattened the pooled feature maps with the addition of age and sex into another layer in order to process the artificial neural network. A hidden layer of 400 neurons was used in this fully-connected layer.

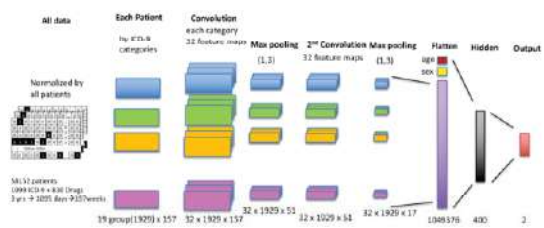

Figure 4. CNN structure of the study

The optimization algorithm used to train the network weights was a distributed stochastic gradient descent with a mini-batch size of 32. The model was optimized using Adadelta optimizer [13]. The input and hidden layers used a Rectified Linear Unit (ReLU) activation function (refs), while the output layer used the Softmax activation function. The dropout value of 0.1 used to prevent the overfitting and was applied to the input and hidden layer [9].

The average k-fold cross-validation accuracy, with a k-value of 5, was used as the metric to determine the best performance, optimizer, and loss functions of the model. We computed the area under the receiver operating curve (AUC) value, sensitivity, specificity, and positive predictive value (PPV) to observe the model performance.

The software was implemented using python v.3.7 and the model was created and trained with the Tensorflow framework v.1.9.

Results

The demographic characteristics of cancer and non-cancer patients are summarized in **Table 1**. Following the conditions, there were 58152 patients including in the study, of which 10185 diagnosed with CRC and 47967 patients were without a cancer diagnosis. The mean age (SD) of patients with CRC diagnosis was 62.7 (14.2) compared to patients without cancer of 47.6 (17.3). Most of the patients diagnosed with CRC were male (54.1%). In addition, the average number of diagnosis of a CRC patient was significantly higher compared to a non-cancer patient before the index date (e.g. 41.2 vs. 26.4 in the first observed year).

Table 1. Characteristics of patients in this study

	Case (n=10185)	Control (n=47967)
Age mean (sd)	62.7 (14.2)	47.6 (17.3)
Male sex (%)	5513 (54.1%)	23109 (48.2%)
Diagnosis count	1119580	3735982
Average in 1 year before index date*	41.2	26.4
Average 1~2 year before index date*	39.9	28.6
Average 2~3 year before index date*	37.7	27.4

*Note: * Number per patient per year*

Figure 5 shows the AUROC of the model with 5-fold cross-validation. The mean (SD) of AUC of the model was 0.922 (0.004). The performance of the model observed with the sensitivity of 0.837, specificity of 0.867, and 0.532 for PPV value.

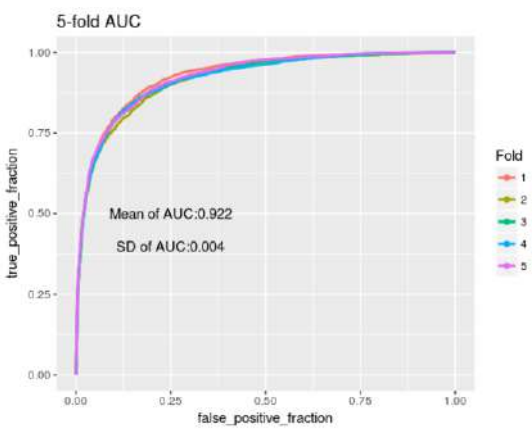

Figure 5. AUROC of the model with 5-fold cross-validation

Discussion

Our study findings demonstrate that the CNN model could appropriately predict CRC based on non-image and multi-dimensional medical records (ie. phenotype, diseases and medication). The results showed higher AUC (0.922) with very good sensitivity and specificity. This automated system for the detection of CRC offers several advantages, including consistency of interpretation (it could be a good screening tool for CRC for any person before deciding to take further some examination tests).

In this study, we tried to observe the features weight by using the odds ratio (ORs) and stepwise feature extraction (i.e., ANN model). We also selected top 10 features and most of the features were related to cardiovascular diseases. Comparing to other studies [3; 4; 12], our study showed higher performance (Area under receiver operating curve, sensitivity, and specificity). Since, our government has already launched a nationwide screening program of CRC since 2004 and a free fecal immunochemical test is offered biennially to individuals aged 50 to 75 [11]. According to our findings, the program may extend to cover all patients beyond this age range.

The main strength of this study lies in a use of a population-based cohort with a large and nationally representative sample, which increases its generalizability in Taiwan. However, there are several limitations in our study that need to be addressed. First, this is a retrospective cohort study, so selection bias and misclassification may be introduced. Second, inherent limitations of NHIRD hinder our ability to get some information related to the CRC, such as smoking habits, alcohol consumption, body mass index (BMI), family history of CRC, diet, and physical activity. However, we have included the comorbidities as surrogates for some risk factors of CRC, such as COPD and a stop-smoking clinic for smoking, alcohol-related illness for alcohol, and obesity for BMI. Finally, many chronic diseases such as diabetes mellitus (DM) and hypertension are not labeled every time on diagnosis, which may lessen the importance of those diseases.

Future direction

The ultimate goal of our study is to develop a web service for the public, helping them make predictions of risk of getting CRC one year before based on prior three-year-diagnosis and medication records. Therefore, this model provides a cheap and instant first-line screening for CRC which doesn't require medical examination in the first place. In the future, we would like to include more features in our study, including lifestyle, physical characteristics, smoking history, lab examination, and genetic information that help predict the risk more accurately.

Conclusions

In our study, we developed a deep learning model to predict CRC based on non-image and multi-dimensional medical records (diagnoses and medications). Our model showed higher performance for detecting CRC one year ahead. Indeed, previously published literatures did not show any time frame to predict CRC and traditional methods are not able take time frame consideration for predicting CRC. But, time sequence matters in the real world clinical setting. Therefore, our model can be considered in the real clinical settings.

Abstract

Discovering disease similarities are beneficial for the diagnosis and treatment of mental diseases. In this research, we proposed a data driven method, that is, integrating a variety of publicly available data resources including Unified Medical Language System (UMLS) Metathesaurus, Systematized Nomenclature of Medicine -- Clinical Terms (SNOMED CT) and cui2vec concept embedding to construct a mental disease similarity network. The resulting mental disease similarity network offered a new view for navigating and investigating disease relations; it also revealed popular mental disease in the literature in terms of the number of connections and similarities with other diseases. It shows that ***depressive disorder*** *is directly connected with nine other popular diseases and connects 52 other diseases in the network. The top three popular mental diseases are* ***depressive disorder****,* ***dysthymia (now known as persistent depressive disorder)****, and* ***neurosis****. Future research will focus on studying the clusters generated from the similarity network.*

Keywords:

Mental disorders, Disease similarity, Word2Vec, Concept embedding.

Introduction

Disease similarity study promises to enable better understanding of disease relations and to accelerate treatment discoveries based on disease relations.[1, 2]. It can also reveal the pathogenesis of common diseases [1] and help infer the mechanisms of complex diseases [2], which can yield insights into disease etiology and suggest treatment that can be appropriated from one disease to another [3]. Additionally, it provides a starting point for associating diseases to their genes as well as to help find potential targets for drugs [4].

We are motivated to study disease similarity using mental health as an example domain for methodology illustration. Mental disease/illnesses involve the change of people' emotion, thinking and behavior [5]. According to National Alliance on Mental Illness (NAMI), "…*One in five adults experiences a mental health condition every year. One in 17 lives with a serious mental illness such as schizophrenia or bipolar disorder. … Half of mental health conditions begin by age 14, and 75% of mental health conditions develop by age 24...*" Mental disease has become one of the most consequential health concerns in the US and in people across nations, races, and gender nowadays.

This research investigated mental disease similarity by leveraging word embedding, a language modeling technique that transform the vocabulary of an input corpus into low-dimensional vector representation. This leads to our research questions: Is it feasible to use existing literature and research repositories to explore the most popular mental disease topics? Would it be possible to create a mental disease similarity network so that relations of mental diseases could be identified, and similar mental diseases could be grouped together?

The objectives of this research are to investigate mental disease similarity and analyze similarity network. In particular, we intent to utilize the semantics of the mental disease concepts in the knowledge base and leverage data driven based method to analyze the closeness (similarities) among concepts extracted from the knowledge base.

Background

Related work for disease similarities

Various methods have been defined to measure or compute disease similarities. In [6], a method for measuring disease similarity has been proposed that integrates semantics and gene functional association, where two functions, one calculating functional similarity and the other calculating semantic similarity, are combined to measure disease similarity. In [2], a matrix-based method was introduced to measure disease similarity that incorporates the uniqueness of shared genes. For each disease pair, the uniqueness score was calculated, and disease similarity matrices were constructed using Online Mendelian Inheritance in Man (OMIM) and Disease Ontology annotation. An ontology-based disease similarity network was described in [7] for disease gene prediction based on semantic similarity measures on phenotype ontology database. In [4], an online system called DisSim was introduced for exploring similar diseases. The system implemented five state-of-the-art methods to measure the similarity between Disease Ontology (DO) terms and provided the significance of the similarity score. Some other disease similarities methods include International Classification of Disease (ICD) based disease similarity, probability-based disease similarity, and machine learning-based approaches.

Word embedding and concept embedding

Word embedding is an emerging technique that transforms a word from the literature (text corpus), to continuous decimal and low dimensional vectors based on the context of the word. There are two popular word embedding algorithms: word2vec and GloVe. Word2vec was first developed by a team of researchers led by Tomas Mikolov at Google [8]. The word2vec utilized two model architectures for computing continuous vector representations of words from very large data sets: the skip gram model and the continuous bag-of-words (CBOW) model, where the former uses the current word to predict the surrounding context words and the latter predicts the current word from surrounding context words [8]. The softmax

function was applied to calculate the probability of a word w given its context c:

$$p(w|c) = \frac{\exp(h^\top v'_w)}{\sum_{w_i \in V} \exp(h^\top v'_{w_i})}$$

Another embedding algorithm is a "count-based" model called GloVe proposed by Pennington [9] that tabulates how frequently words co-occur with one another in a given corpus that offered a way to train over larger scale of data.

As healthcare data come in a variety of forms, the aforementioned word embedding algorithms like word2vec and GloVe that were originally developed for text cannot be directly applied to many kinds of healthcare data. In this research, we leveraged medical concept embedding referred to as *cui2vec* developed by Harvard [10] which links word2vec to traditional count-based methods that are based on co-occurrence statistics. The pre-trained embedding *cui2vec* utilized an extremely large collection of multimodal medical data including insurance claims for 60 million Americans, 1.7 million full-text PubMed articles, and clinical notes from 20 million patients at Stanford [10]. The *cui2vec* contains embedding for 108,477 medical concepts.

Methods

Research pipeline

In the context of this paper, we assume the disease similarity is disease concept similarity without considering about biological, molecular, genetic information of the disease.

To calculate mental disease similarities, we need to retrieve as many mental disease concepts in computable format from the literature as possible. The Diagnostic and Statistical Manual of Mental Disorders (DSM), a widely used diagnostic manual that offers standard criteria for the classification of mental disorder, has included over 450 different definitions of mental diseases. For each disorder, there is a set of diagnostic criteria associated with specific symptoms that characterize the disorder. However, the definitions of the diseases on DSM are very subjective, the classifications are too vague, and the descriptive codes are not in computable format, which makes it impractical to be used for computational purpose.

The clinical terminologies or ontologies like The Systematized Nomenclature of Medicine Clinical Terms (SNOMED for short) can serve as a valuable resource to expand the search queries so that more mental disease concepts at varying levels of granularity can be captured. SNOMED is a standard clinical terminology system with more than 350,000 concepts released twice every year on January and July respectively. In this research, we retrieved SNOMED concepts under the Mental disorder hierarchy for three reasons: First, the total number of SNOMED mental disease concepts are approximately four times the size of the DSM codes and nine times the size of ICD listed concepts. Second, as we use *cui2vec* that utilized 500-dimension vectors (see Step 1) to represent a UMLS unique identifier (CUI), SNOMED ConceptIDs could be easily mapped to UMLS CUIs, so that we can apply pre-trained embedding to represent semantic similarities of mental disease concepts. Lastly, SNOMED is both a clinical vocabulary and an ontology. Due to SNOMED's broader concept coverage and richer relations, not only can we extract mental disease related concepts, but we can also capture the hierarchical relationships among them.

The major steps of our research pipeline are illustrated in Figure 1.

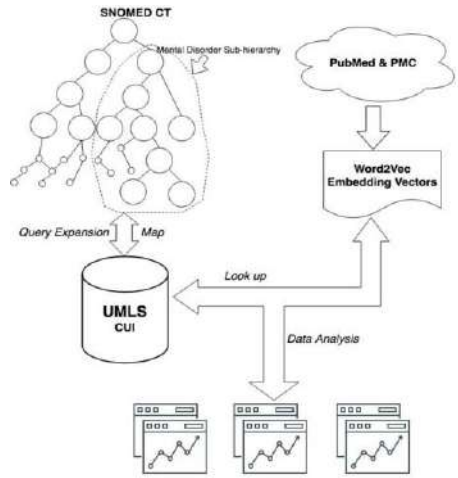

Figure 1. Illustrates the major steps for the research project.

Step 1. Identifying the mental disease concept hierarchies and mapping the extracted SNOMED concepts to UMLS CUI. In this step, we map SNOMED ConceptID, which is SCUI in MRCONSO of the UMLS Metathesaurus Rich Released Format to UMLS CUI.

Step 2. Matching the UMLS CUIs against the pre-trained *cui2vec* embedding vectors.

Step 3. Calculating pairwise disease similarities among the selected diseases based on cosine similarity.

$$sim\,(i,\,j) = cos\,(\theta) = \frac{vec(CUIi)\;\; vec(CUIj)}{\|vec(CUIi)\|\;\|vec(CUIj)\|}$$

$$= \frac{\sum_{k=1}^{n} veck(CUIi)\;\; veck(CUIj)}{\sqrt{\sum_{k=1}^{n} veck(CUIi)^2}\sqrt{\sum_{k=1}^{n} veck(CUIj)^2}}$$

Gensim, a free Python library, is used to calculate the cosine similarity with the results ranging from -1 to 1, where 1 means extremely similar and -1 means the opposite.

Step 4. Visualizing the disease similarity network based on the pairwise disease similarities and analyzing the similarity network. All networks are visualized using Cytoscape's Biolayout[11].

Mental disease similarity network analysis

We developed a network based on pairwise similarities among mental disease concepts. Let us assume that a mental disease concept is a vertex (a node) and an edge (a link) between two vertices represents a relation between the two concepts. In this context, relation refers to similarity. The value associated with each edge is the similarity value, where the higher value it is the more similar the two concepts are. The mental disease similarity network can be considered as graph G (denoted as G=(V,E)), consisting of a non-empty set of vertices V and a set of edges E.

As one of the research Methods in this study is to use literature and research repositories to find the most popular mental disease topics, we have defined the term "popular topics" (PT). Let us first define "Degree": The degree of a vertex *i* is a count of number of edges the vertex tie to other vertices, which can be denoted by D(*i*).

Now let us define the popular topics (PT). The term "popularity" is borrowed from the Latin term popularis, which originally meant "common." In a social network, the popularity of a person can be thought of as being liked or having influence on other people. According to Wikipedia, with respect

to interpersonal popularity, there are two primary divisions: sociometric popularity and perceived popularity. The former means how liked an individual is and the latter means how well known among their peers as being popular.

In the context of the mental disease similarity network, popular topics take into account both "sociometric" and perceived popularity. We use similarity to represent the sociometric popularity and use degree to represent the perceived popularity.

Popular topics in the graph are considered as all vertices in the disease similarity network whose similarity values with other vertices are no less than a threshold and the degrees of the vertices are also no less than a threshold. Here the "popularity" of a topic can be considered as a disease concept is that not only closely related to other concepts (high similarity value) but also possessing more connections to other concepts (high degree value). In a symbolic form, it can be represented as a set of vertices i as follows:

$$\{\forall i(\forall j\,(sim\,(i,\,j) > \theta) \rightarrow D\,(i) > \delta)\} \quad \text{where } i,\, j \in N$$

We use a popularity value to measure a popular topic. If a vertex i is a popular topic in the disease similarity network, then the popularity of a vertex i, denoted by *popularity*(i), can be defined as the aggregated similarity values of a vertex i with all vertices associated with the vertex i.

$$popularity(i) = \sum_{j=1}^{D(i)} sim(i, j)$$

Results

Using *cui2vec* to calculate disease similarities

We retrieved 1,756 concepts from the "Mental Disorder" subhierarchies of Clinical Finding hierarchy. Note that this research only concentrates on the concept level without considering about the synonyms or term level descriptions.

The retrieved ConceptIDs were mapped against the UMLS CUIs using the UMLS MRCONSO Rich Released Format. As each source SNOMED concept may be mapped to more than one CUIs (i.e. the SNOMED concept **Dissociative disorder** has been mapped to two UMLS CUIs C0020701 and C0020703), the Mental disorder concepts of SNOMED have been mapped to 1,768 UMLS CUIs.

After that, we matched the 1,768 UMLS CUIs with the *cui2vec* and we obtained 401 unique CUIs out of the 109,053 unique UMLS CUIs where each CUI is represented by 500 dimensions continuous decimal numbers. The Gensim package in Python is utilized to calculate similarities of a pair of disease concepts represented by CUI embedding vectors. For example, the CUI for **Hypomania** is C0241934 and the CUI for **Mania** is C0338831, and the similarity value is sim(*Vec*(C0241934), *Vec*(C0338831)) = 0.9901.

The results for similarities of all pairs of CUIs are summarized in Table 1. We categorized the disease pairs based on their similarity values. There are five major categories as illustrated in Table 1. Altogether, we obtained 80,200 pairwise similarity values out of the 401 unique CUIs based on cosine similarity measures (see **Method** section).

Mental disease similarity network

A mental disease similarity network was developed based on pairwise similarities (See **Method** section), where each disease concept was represented by a vertex (i.e. V = {**Depressive disorder**, **Hypomania**, **Mania**}) and an edge connecting between two vertices represented that there is a similarity value no less than certain threshold θ (i.e. θ = 0.9, E = {{**Hypomania**, **Mania**}, {**Severe major depression with psychotic features,**

Table 1– Similarity values and example pairs of mental diseases

Similarity value range	Number of pairs	Description	Example pairs
[0.9, 1)	488	Extremely similar	(hypomania, mania)
[0.8, 0.9)	1,432	Very similar	(identity disorder, moderate depression)
[0.5, 0.8)	9,915	Weakly similar	(asperger's disorder, psychoactive substance-induced withdrawal syndrome)
[0.0, 0.5)	59,820	Similar	(alzheimer's disease, developmental articulation disorder)
<0	8,545	Connect	(receptive language delay, acute depression)
			In total, there are 80,200 pairs

Mania}, ……}). Figure 2 presented a partial mental disease similarity network. In total, there are 252 vertices and 1,920 edges. In addition, we can easily observe that some disease concepts are naturally grouped together which offered a new view of among the same kind of disease.

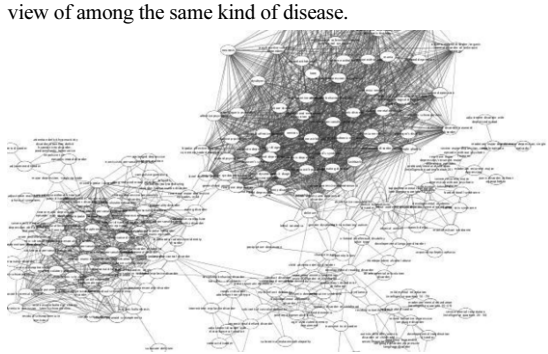

Figure 2. Partial mental disease similarity network θ = 0.8

Furthermore, we explored the popular topics in the literature (PT definition can be found in **Method** section). Table 2. showed top ten popular topics in the mental disease literature. As is seen in Table 2, the most popular mental disease topic is **Depressive disorder** (with popularity value = 121.7807), a synonym of **Depression**, which is a common but serious mood disorder causing a person persistent feeling of sadness and loss of interest in things that used to bring pleasure. **Depressive disorder** listed as the top one popular topic indicates that **Depressive disorder** possess most connections with other mental illnesses. This is due to the prevalence of depressive disorder and homogeneity of subthreshold form of depression [12]. The finding is also confirmed by WebMD that states "Depression can be triggered by other mental illnesses, but it can also lead to certain mental illnesses" and "Depression's link to 9 other mental illnesses." The UPMC released five major categories of mental illnesses: Anxiety disorder, Mood disorders, Schizophrenia and psychotic disorder, Dementia, and Eating disorder. As Table 2 is shown, the majority of the top ten PTs can be categorized into Mood disorders; **Psychoactive substance dependence** is associated with **Anxiety disorder**; **Neurosis** is characterized by both anxiety and depression.

Table 2. popular topics with $\delta = 50$ and $\theta = 0.8$

Disease Names	*popularity*(*i*)	CUI(s)
Depressive disorder	121.7807	C0025193/C0349217/ C0011581/C0344315/ C1269683
Dysthymia	88.4942	C0282126/C0011581/ C0013415/C0221508
Hypomania	46.0239	C0241934
Neurosis	45.5589	C0027932
Bipolar I disorder	45.284	C0853193
Mania	45.0888	C0338831
Severe depression	44.8137	C0588008
Reactive depression (situational)	44.5026	C0011579
Psychoactive substance dependence	44.3936	C0038580/C1510472
Agitated depression	44.3462	C0235136

Figure 3 illustrated an excerpt figure from Figure 2, which demonstrated the top ten most popular topics in mental disease similarity network along with the connections with other mental diseases. It shows that **depressive disorder** is directly connected with nine other popular diseases and in fact it connects 52 other diseases in the network.

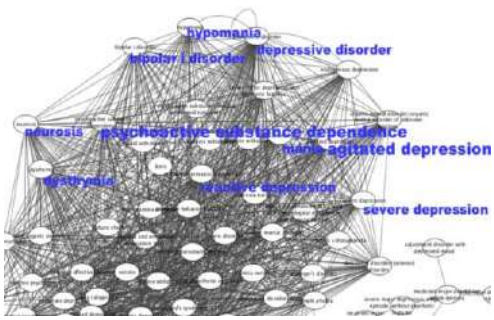

Figure 3. Excerpt mental disease similarity network for most popular topics mental diseases

Discussion

There are two major contributions in this research. First, we initially propose to integrate word embedding results and disease ontologies such as SNOMED-CT to generate a disease similarity network. Second, we defined the most popular topic based on the disease similarity network. The similarity network could serve as a starting point to navigate complex disease network and could be used to detect popular topics in literature.

Word2Vec to explore disease similarity

We create a mental disease similarity network integrating public data including Harvard *cui2vec*, UMLS *Metathesauru*, and SNOMED-CT. The proposed research pipeline can be generalized to build other disease related network.

The concept embedding captured the semantics of medical concepts in the literature and offered opportunity to study the underlying relations among disease concepts, which forms the foundation of the disease similarity network. Using the mental disease similarity network, we can observe that biologically and genetically related mental diseases are often grouped together, indicating that similar disease also often being studied together in the literature.

Our results have been reviewed by a psychiatrist, one of the co-author of the paper (HP). We obtained some interesting observations. For "Extremely similar" pairs, like **Hypomania** and **Mania** with similarity value of 0.9901, **Hypomania** is in fact a less severe version of **Mani**a. **Bipolar affective disorder, current episode depression** and **Depressive disorder** has similarity value of 0.9897 because bipolar patients who are in the midst of a depressive episode, by definition meet criteria for major depressive disorder. We can also observe that some mental disorders with very high similarity values are very similar conditions. For example, **Bulimia nervosa** and **Binge eating disorder**. Lastly, some share very similar symptoms or may co-occur. For example, **Panic disorder** and **Simple phobia (**with similarity value of 0.9663). Both conditions share same symptoms including intense fear, feelings of anxiety, and panic attacks. According to information found in the DSM-5, both conditions are classified as "anxiety disorders." However, panic disorder and phobias are considered separate conditions, each with a distinct set of diagnostic criteria.

Interestingly, some of Mental disease concepts pairs are negative related called "Connect", for example, **Receptive language delay** and **Acute depression** (with similarity value = -0.956). However, having negative similarity do not necessarily mean they are not related. They coexist but with negative similarity value may but not limited due to the following factors: (1) The two disease conditions may occur at different stage of one's life. For example, **Receptive language delay** and **Acute depression** with the former occurring in very young children. Another example, **Separation anxiety disorder of childhood** and **Schizoaffective disorder, bipolar type,** with the former only take place in children. One might speculate that separation anxiety during the childhood probably may cause schizophrenia in adulthood. (2) Two disease conditions are in different categories but can co-occur. For example, **Sexual relationship disorder** and **Acute depression**. (3) Two diseases have very different levels of severity. For example, **Adjustment disorder with mixed disturbance of emotions and conduct** and **Schizoaffective disorder, bipolar type** with the latter much severe than the former (4) Using variant terms to represent the same condition. For example, **Developmental receptive language disorder** and **Receptive language delay**. There are quite a few pairs with negative similarity values just because it makes no sense to put them together. For example, **Schizoaffective disorder, bipolar type** and **Facial tic disorder**.

Several mental diseases pairs with very high similarity values do not make sense to be together like **Nondependent alcohol abuse** and **X-linked intellectual disability atkin type** (similarity value = 0.968). It may imply that in the literature they are typically being studied together, which actually indicates a potential for future research studies. A number of mental diseases form a natural cluster implying that they potentially share common genes, proteins and chemicals. For instance, schizophrenia, bipolar disorder, autism, ADHD and depression share common gene *CACNA1C* and *CACNB2* [13].

The research pipeline can be used to assist pathologist or physicians to predict potential genetic relatedness of diseases, before rigorous experiment is conducted. It can also serve as a complementary method for existing disease similarity analysis.

Limitation and future work

Due to the granularity of the SNOMED concepts and the lack of occurrence of the CUI embedding, only less than a third of the SNOMED concepts can find the exact match in the *cui2vec* embedding, which limited our research scope.

The results of the disease similarity network highly depend on the quality of the concept embedding. The *cui2vec* embedding is based on the statistics of occurrences of medical concepts, and thus less frequently appeared concepts might not have their corresponding CUI embedding. Future research can explore

word embedding generated from other resources like electronic health records and derive the similarity network.

Besides, as the disease similarity network is developed based on concept embedding which is generated out of the existing literature, it is not applicable to use the disease similarity network for unknown/new disease discovery. Therefore, it is desirable to have more high quality and high medical concept coverage embedding publicly accessible.

Another limitation of the research is that due to many-to-many characteristics of the mapping process, which may affect the accuracy of the popular topic result. For example, each UMLS CUI may have multiple SCUIs, that is, each CUI can be mapped to more than one SNOMED concepts (i.e. the UMLS CUI C0025362 can be mapped to two SNOMED concepts: **Development academic disorder** and **Mental retardation**), the 401 unique CUIs in the vocab for Mental disorder can be mapped to 406 SNOMED concepts. In this research, we merged concept names if they share the same CUIs. For example, two SNOMED concepts **Delusional disorder** and **Paranoid disorder** share the same CUI C1456784. In the experiment, we merge them as one concept "**Delusional disorder / Paranoid disorder**". The merger of the concepts may affect the accuracy of the results.

As the development of disease similarity network, it is feasible to analyze disease clusters based on the similarity network. We can also interpret underlying meaning of the "centrality" of the cluster and the "connected components" among cluster. It is interesting to compare existing disease classification with the generated clusters. As many joint symptoms may appear for two different diseases, which may result in diagnostic mistakes. In the future, we may analyze the possibilities of using the similarity network to predict such situations.

At the same time, the disease similarity network reveals the potential to enrich existing ontologies as we observed a number of hierarchical relationships, such as **Bipolar affective disorder, current episode depression** is-a **Depressive disorder**.

Conclusions

This research integrates ontological method and machine learning method, concept embedding in particular, to develop a disease similarity network and observed several interesting findings regarding mental disease similarities. Popular topics are identified based on the similarity network. The top three popular topics are **depressive disorder**, **dysthymia (now known as persistent depressive disorder)**, and **neurosis**. Part of the findings are confirmed by the literatures or domain experts.

Process Mining in Primary Care: Avoiding Adverse Events Due to Hazardous Prescribing

Abstract

Process mining helps healthcare professionals understand processes within healthcare. While often used in secondary care, there is little work in process mining using primary care data. Serious adverse events that result from hazardous prescribing are common and costly. For example, non-steroidal anti-inflammatory drugs (NSAIDs) and antiplatelets can cause gastro-intestinal bleeds (GiBs). Prescribing typically occurs during primary care; therefore we used this setting to attempt process mining. We extracted events (drug started, drug stopped, GiB) for understanding three prescribing pathways, and applied process mining. We found NSAIDs are often short-term prescriptions whereas antiplatelets are often long-term. This perhaps explains our finding that co-prescription of gastro-protection is more prevalent for antiplatelets than NSAIDs. We identified reasons why primary care data is harder to process mine and proposed solutions. Process mining primary care data is possible and likely useful for improving patient safety and reducing costs.

Keywords:
Data mining, Patient safety, Primary care.

Introduction

Process mining describes a collection of methods for extracting information about processes from event logs [1]. There are three distinct stages: detecting the underlying process from the event logs (process discovery); identifying deviations from what was expected (conformance checking); and generating suggestions for redesigning and improving the processes (enhancement) [1]. Process mining adds a temporal dimension to standard data mining methods. Originally applied to business processes, more recently has been applied to other domains including healthcare. In a recent literature review, we showed that while process mining within secondary and tertiary care has become more common, there is almost no work within primary care [2].

Patient safety is fundamental to healthcare systems. Within UK primary care this is true for medication prescribing where life-threatening errors appear in 1 in 550 prescriptions [3]. A recent economic analysis showed that: adverse drug reactions (ADRs) cost the NHS up to £1.6 billion a year; more than one third of ADR related hospital admissions are caused by non-steroidal anti-inflammatory drugs (NSAIDs), antiplatelets and anticoagulants; and half of the deaths associated with primary care ADRs are due to gastro-intestinal bleeds (GiBs) [4]. Studying the relationship between the prescribing practice of NSAIDs and antiplatelets with ADRs including GiBs is therefore important.

In the UK there are several large databases of coded primary care records available for research [5]. While the quality of coding may not be universally high [6], all practice-based prescribing in primary care is electronic so therefore this would be a suitable place to attempt to apply process mining.

While the epidemiology of hazardous prescribing in primary care has been extensively studied using large electronic health record databases, to date little is known about the typical processes that lead to such prescriptions. To design effective interventions for reducing hazardous prescribing, it is essential to get a better understanding of these processes. This could lead to better decision support systems for prescribers, and ultimately improve patient safety and reduce cost by reducing the number of ADRs.

Our objective was therefore to process mine UK primary care data to explore the relationship between the prescribing of NSAIDs, antiplatelets and the adverse outcome of gastro-intestinal bleeds.

Methods

A process model is a graphical representation of a process showing the events and how they interrelate via directed edges. Process discovery is the extraction of a process model from an event log via the application of an algorithm. There are many algorithms with various strengths and weaknesses. For example the α-algorithm is simple and therefore easy to undersand, but it does not deal well with noisy event logs which are typical of real world processes [1]. Heuristic Miner and, in particular, Fuzzy Miner are better able to deal with this noise [7]. Here we focus on process discovery to prove that process mining can be applied to primary care data, and use the Fuzzy Miner to best handle the messiness of routinely collected health data.

Anonymised patient data was obtained from the Salford Integrated Record (SIR); a data warehouse with contributions from 43 general practices in Salford, UK (population 0.25M). All coded data, including diagnoses and medications, for patients who have not opted out (1.5% opt outs) was available to extract from a SQL Server database. The earliest records are historic diagnoses from the 1940s, but the bulk of the data collection is from 2000 onwards. Approval was granted by the SIR governance board and all data was obtained pseudonymised (random identifier, no name, year of birth instead of age, geographic region instead of address).

A review by Spencer *et al.* [8] identified 56 prescribing safety indicators for use in primary care to improve patient safety. They each try to prevent a particular adverse outcome through safer prescribing, e.g., patients with chronic kidney disease should not be prescribed an NSAID because of the increased risk of acute renal failure. A subset of these indicators are

included in: electronic audit and feedback initiatives such as the national PINCER [9] rollout and the SMASH intervention [10]; and clinical decision support systems such as OptimizeRx [11]. We selected three prescribing safety indicators for further analysis that focus on NSAIDs and anticoagulants, and are designed for preventing GiBs in cohorts of patients at increased risk such as the elderly and those with a history of peptic ulceration. The indicators and the descriptions used in our analyses are provided in Table 1.

Table 1– Prescribing Safety Indicators for Preventing GiBs

Id	Short name	Description
I1	Age≥65 + NSAID	Patients aged 65 and over who are prescribed an NSAID should also be prescribed a gastro-protective medication (GPM).
I2	Pep + NSAID	Patients with a history of peptic ulceration who are prescribed an NSAID should also be prescribed a GPM.
I3	Pep + Antiplatelet	Patients with a history of peptic ulceration who are prescribed an antiplatelet should also be prescribed a GPM.

Prescription events are recorded automatically in a patient's record; however, the stopping of medication is not recorded. We have previously developed an algorithm to convert these prescription events into more meaningful events such as when a drug is started and stopped, and when a dose is changed [12]. This process is done by evaluating: the date of the prescription; the amount prescribed; and the rate at which it is consumed. For the medications of interest (NSAIDs, GPMs, and antiplatelets), we extracted the start and stop events.

For each indicator, we developed queries that would extract the patient data. First, we defined the cohort of patients from an initial event. For indicator I1, it was when a patient turned 65, and for I2 and I3, it was the first instance of a peptic ulceration. Next, we extracted the start and stop events for all medications of interest. Finally, we extracted other relevant events: GiB and peptic ulceration classified as either the first bleed, or a subsequent bleed; patient turned 65; and patient died. Clinical code sets were constructed for each event of interest [13].

The initial output of our medication algorithm gives the start and stop events for individual active ingredients so, for example, for two different NSAIDs we would have two different start events. However, we are only interested in whether any NSAID (or other medication) is started if the patient is not already taking an existing one. Similarly, when a drug is stopped it is only relevant if the patients are then not taking any other drug of the same type. An additional processing script was therefore required to produce the final event log. This additional data processing was done using JavaScript and nodejs [14].

The data was extracted on 2nd November 2018 and process mining was performed by the lead author. Process mining was performed using Fluxicon Disco (academic licence) [15] on a Dell XPS 15 laptop running Windows 10. All clinical code sets and processing code is at https://zenodo.org/record/1493640.

Results

The demographic information for the patient cohorts for each indicator are displayed in Table 2. The median duration time, interquartile range, and number of transitions between events are shown in Tables 3-5. For example, in Table 3, the event "Bleed" immediately followed the event "Age 65" in the event logs 390 times, with a median transition time of 49 (IQR [19,112]) months. The process mining diagrams extracted from Disco are shown in Figures 1-3. The numbers on the nodes in the diagrams represent the number of times each event occurred, while the edge numbers are the number of times the target event directly followed the source event.

Table 2– Patient Characteristics for Each Cohort and the Population of Salford. Values are n (%) unless otherwise specified.

Demographic	I1		I2, I3		All patients

Table 3– Median Duration in Months of Transitions between Key Events for Indicator I1. IQR in [square] brackets. Number of transitions in (round) brackets. NSAID – non-steroidal anti-inflammatory drug, GPM – gastro-protective medication.

Next event / Event	Bleed	NSAID (no GPM)	NSAID (GPM)	NSAID Stopped	GPM Started	GPM Stopped
Age 65	49 [19,112] (390)	33 [11,74] (10925)	17 [6,39] (1385)	9 [2,28] (1684)	48 [15,111] (9366)	12 [3,37] (1617)
Bleed	1 [0,5] (523)	14 [3,47] (48)	22 [7,46] (75)	1 [0,3] (54)	0 [0,3] (582)	10 [2,34] (276)
NSAID (no GPM)	6 [1,36] (34)			1 [1,3] (24106)	0 [0,0] (9478)	
NSAID (GPM)	2 [1,32] (11)			1 [1,3] (8733)		1 [1,5] (566)
NSAID Stopped	20 [5,57] (292)	11 [5,26] (14923)	10 [5,22] (4553)		18 [5,46] (6913)	0 [0,5] (7769)
GPM Started	5 [1,23] (483)		9 [3,27] (3966)	1 [1,2] (6548)		1 [1,5] (28868)
GPM Stopped	13 [3,38] (231)	11 [5,25] (5719)		1 [1,4] (2724)	6 [2,14] (21444)	

For indicator I1 there were 45,479 NSAID start events. Of these, 9,981 (22%) were for patients already prescribed a GPM. A further 9,478 (21%) then started GPM at a median duration of 0 days suggesting co-prescription. However, 24,106 (53%) NSAID start events were followed by an NSAID stop event at a median duration of 1 month (IQR [1, 3] months), suggesting a short term prescription without co-prescription of a GPM.

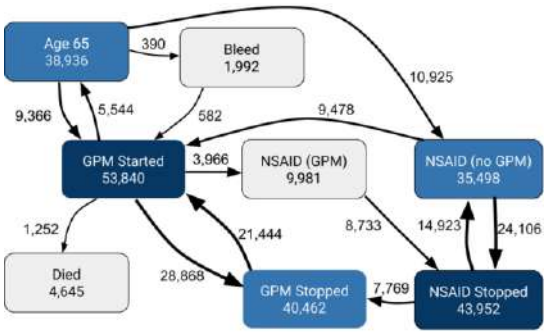

Figure 1– Process Diagram for Indicator I1. NSAID – non-steroidal anti-inflammatory drug, GPM – gastro-protective medication.

Table 4– Median Duration in Months of Transitions between Key Events for Indicator I2. IQR in [square] brackets. Number of transitions in (round) brackets. NSAID – non-steroidal anti-inflammatory drug, GPM – gastro-protective medication.

Next event / Event	Bleed	NSAID (no GPM)	NSAID (GPM)	NSAID Stopped	GPM Started	GPM Stopped
Initial Bleed	3 [0,60] (603)	154 [46,283] (564)			2 [1,71] (2102)	
Bleed	2 [1,7] (752)	57 [17,107] (125)	18 [4,52] (88)	1 [0,8] (21)	1 [0,24] (729)	5 [1,24] (299)
NSAID (no GPM)	1 [0,6] (14)			1 [1,2] (2388)	0 [0,1] (861)	
NSAID (GPM)	5 [1,27] (11)			1 [1,3] (1416)		2 [1,5] (112)
NSAID Stopped	15 [4,38] (157)	14 [7,30] (1437)	11 [6,25] (695)		13 [4,36] (910)	1 [0,11] (912)
GPM Started	4 [1,19] (501)		13 [4,33] (819)	1 [1,3] (630)		2 [1,7] (6884)
GPM Stopped	9 [3,27] (226)	13 [6,33] (1147)		1 [0,3] (305)	6 [3,14] (5551)	

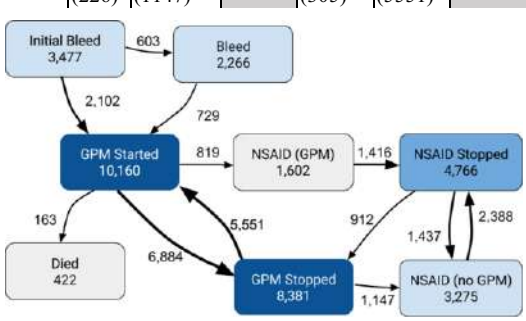

Figure 2– Process Diagram for Indicator I2. NSAID – non-steroidal anti-inflammatory drug, GPM – gastroprotective medication.

Similar results were found in indicator I2 when out of 6,368 NSAIDs, 25% (1,602) were for patients with a pre-existing GPM, 14% (861) were followed almost instantly by a GPM, and 38% (2,388) were for a short-term prescription without a GPM. The results for indicator I3 suggest that GPMs are more frequently co-prescribed with APs with only 22% of AP start events (513 out of 2309), neither having a pre-existing GPM or immediately followed by a GPM.

The event most likely to precede a GiB or peptic ulceration is a previous GiB or peptic ulceration. This is to be expected as it is known that a strong predictor of gastro-intestinal adverse events is a previous bleed or ulceration.

Table 5– Median Duration in Months of Transitions between Events for Indicator I3. IQR in [square] brackets. Number of transitions in (round) brackets. AP – antiplatelet, GPM – gastro-protective medication.

Next event / Event	Bleed	AP (no GPM)	AP (GPM)	AP Stopped	GPM Started	GPM Stopped
Initial Bleed	3 [0,77] (621)	78 [1,287] (390)			4 [1,120] (2197)	
Bleed	2 [1,7] (758)	39 [2,122] (81)	12 [4,54] (52)	11 [2,40] (59)	1 [0,35] (761)	5 [1,24] (286)
AP (no GPM)	7 [1,36] (33)			2 [1,7] (451)	0 [0,6] (851)	
AP (GPM)	7 [2,24] (51)			5 [1,25] (482)		8 [2,31] (160)
AP Stopped	7 [1,23] (30)	6 [2,13] (326)	6 [2,14] (353)		8 [3,29] (181)	0 [0,6] (480)
GPM Started	5 [1,25] (525)		14 [2,47] (540)	7 [2,26] (445)		2 [1,7] (7337)
GPM Stopped	10 [3,33] (246)	10 [2,31] (566)		4 [1,21] (144)	7 [4,18] (6165)	

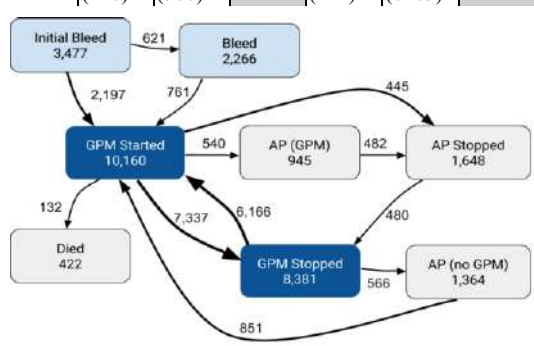

Figure 3– Process Diagram for Indicator I3. AP – antiplatelet. GPM – gastro-protective medication.

The median duration of NSAID and GPM prescriptions is 1 month, suggesting that these medications are typically short-term. Antiplatelets are prescribed at a median length of 5 months and 2 months for patients with and without a pre-existing GPM respectively, suggesting longer term prescriptions.

Discussion

Summary of findings and comparison to existing literature

Little published work on process mining in primary care exists [2]: Dagliati et al. [17] used primary care data to investigate care pathways related to cardiovascular risk of Type II diabetes patients. However, the majority of their data was obtained from secondary care. Another paper used primary care data, but didn't report any results [18]. A further 4 papers used insurance data [19–22] which probably included primary care data, but also secondary care and tertiary care data. Also, the level of data included in insurance datasets is different to that which is routinely collected in primary care for the provision of care. To the best of our knowledge, the process mining performed for this paper is the first performed exclusively using primary care electronic health data.

A GPM was more likely to be co-prescribed to patients receiving a course of antiplatelets than it was to those receiving NSAIDs. The difference in prescription lengths is one possible explanation. When a clinician prescribes a short-term NSAID course, perhaps in response to an acute injury or minor illness, he/she may decide the risk is small enough that co-prescription of a GPM is unnecessary. However, when prescribing a longer-term course, the risk is increased. This might also be true for those on longer courses of NSAIDs for chronic pain conditions. Stratifying medications depending on whether they are short or long term might give further insight into clinicians' behaviour.

GPMs such as proton pump inhibitors can be prescribed for a variety of reasons. For treating an active bleed, to manage the symptoms of gastrointestinal irritation of reflux, or prophylactically for patients at high risk of a bleed – especially when increased because of other medications. Attempting to stratify the GPM events accordingly could again lead to more understanding of prescribing behaviour.

Implications for practice and research

In order to achieve our results, there were several challenges that needed to be overcome which could explain why process mining in secondary care is more prevalent.

Data quality

The quality of healthcare data is limited for many reasons. Events can be incorrectly recorded, unrecorded, or uncoded. All of which limit the confidence and utility of any results generated. Researchers must try and understand the limitations in their data to make best use of it. Primary care data can be thought of as snapshots of coded information that are generated on every contact with the health system. This is different for inpatient secondary care where the entire duration of treatment can be observed and recorded.

While many events recorded in a primary care system may have uncertain veracity, the generation of a prescription is an event we can mine with confidence because, in the UK, virtually all prescriptions are electronically generated in primary care. This is not true for the adverse event of bleeding which may occur in secondary care and may not be coded in the primary care record. To mitigate against this, linked primary and secondary data would be required, and is another reason why process mining exclusively in primary care is not done. Future work should focus on pathways that occur almost exclusively in primary care such as the diagnosis, monitoring and treatment of certain chronic conditions such as hypertension.

Start and end points

Within secondary care, the start of a process can clearly be defined as the admission to hospital, while the end of the process is discharge or death. A patient visiting hospital more than once can be treated as two separate pathways. Within primary care, processes are often cyclical and entangled with other processes. Taking indicator I2 as an example, should the start event be the first instance of peptic ulceration, or should it be the first prescription of an NSAID in a patient with previous peptic ulceration? The former means that each patient only has one pathway, but with potentially multiple cycles, while the latter separates each NSAID prescription into a separate process but then doesn't take the patient's history into account. Detailed consideration must be given to determine whether the primary care processes under analysis have well defined end points, and queries structured to separate data into these individual processes.

Event granularity

The coded events within primary care are not necessarily the events that should make up the event log on which process mining depends. An example is medications where the patient record contains the prescription events, whereas the events of interest on a care pathway would be when the clinician has started, stopped, or altered the dosage of a medication. This is also true for measurements, where a series of blood pressure (BP) values do not necessarily constitute events, but the occurrence of two systolic BPs >140 mmHg within two weeks might be a trigger to investigate a diagnosis of hypertension and could therefore be considered an event to process mine. However, this introduces a bias as the researcher must decide *a priori* what constitutes an event. Is it that a BP was taken, that the BP was high or that some combination of values was measured over a certain period of time? Careful consideration must be made to convert the raw data into an event log, but this is not straightforward and is largely subjective.

Medications

The lack of a stop event for medications requires an extra processing step to determine when a patient's medication has expired. There is also no way of knowing whether a medication once collected is in fact consumed by the patient, or if the patient is using over the counter medications. This is less of an issue in inpatient secondary care when the both the prescription and administration of medication can be monitored and recorded.

Memory

The process mining diagrams that we have produced are heuristic nets which are memory-less: each transition in the process map is taken in isolation without consideration of prior events. By redefining the start events of NSAID and antiplatelets to take into account whether a GPM was already prescribed allowed us to introduce an element of memory into the system. This is useful to better understand the various pathways, however future work using other process mining modelling techniques, such as causal nets [23], might produce better results.

Conclusions

Primary care data in the UK has reliably coded prescribing information and process mining can be successfully applied leading to results that may be useful for clinical decision support systems and improving patient safety.

However primary care data presents several unique challenges. Careful pre-processing must first be undertaken, but this is subjective and must therefore be sensibly performed and meticulously recorded in order to facilitate scrutiny and reproducibility. The use of a clinical reference group to review and confirm data quality and provide insight into the direction of research would be beneficial. Other more powerful process mining and machine learning techniques could be applied now that the initial problems with primary care data have been considered and to some extent addressed.

Abstract

Misspellings in clinical free text present potential challenges to pharmacovigilance tasks, such as monitoring for potential ineffective treatment of drug-resistant infections. We developed a novel method using Word2Vec, Levenshtein edit distance constraints, and a customized lexicon to identify correct and misspelled pharmaceutical word forms. We processed a large corpus of clinical notes in a real-world pharmacovigilance task, achieving positive predictive values of 0.929 and 0.909 in identifying valid misspellings and correct spellings, respectively, and negative predictive values of 0.994 and 0.333 as assessments where the program did not produce output. In a specific Methicillin-Resistant Staphylococcus Aureus use case, the method identified 9,815 additional instances in the corpus for potential inaffective drug administration inspection. The findings suggest that this method could potentially achieve satisfactory results for other pharmacovigilance tasks.

Keywords:
Natural Language Processing; Machine Learning

Introduction

Pharmacovigilance is "The process and science of monitoring the safety of medicines and taking action to reduce the risks and increase the benefits of medicines" [1]. Pharmacovigilance is "relevant for everyone whose life is touched in any way by medical interventions" [2] and was initiated in a systemic method on a global level by the World Health Organization in 1961 in response to manifested congenital deformities in infants caused by thalidomide. In the United States, pharmacovigilance efforts are conducted by many agencies, including the Food and Drug Administration (FDA) (e.g., [3]), the Centers for Disease Control (CDC) (e.g., [4; 5]), and many state and regional organizations. An example pharmacovigilance task is monitering for the use of ineffective treatments for pathogens like Methicillin-Resistant Staphylococcus Aureus (MRSA). Treating MRSA with antibiotics to which there is an established resistance can exacerbate infections, thus compounding an already serious condition [6].

EMR data is a common source of information for pharmacovigilance efforts. Text mining this data typically consists of rule-based systems that utilize vocabularies from sources such as the Unified Medical Language System (UMLS) to locate named entities, comparing terms from the clinical narrative to vocabulary entries [7]. One shortcoming of this approach is that UMLS vocabularies generally consist of drug terms in a standard form, yet clinical text is often rife with misspellings, in some instances constituting 5% of all content [8], and over 17% of content addressing the pharmaceutical domain [9]. Misspellings of drug terms have a proportional relationship to the character length of their respective standard forms [10]. Differences between the correct and misspelled forms can be measured by the Levenshtein edit distance [11], which is the quantitative difference between two strings or words in terms of their characters. For example, the Levenshtein distance between "amoxicillin" and "amoxycilline" is 2, because there is a "y" in the second form where there is an "i" in the first, plus the second form has an added "e" on the end.

Related Work

Several groups have addressed misspellings in electronic medical record (EMR) data. Danielsson-Ojala analyzed ICU Finnish clinical text addressing wound care [12], finding many instances of misspellings, and abbreviations. Ruch, Baud, and Geissbühler built a spellchecker consisting of three modules [13]. These modules sequentially applied edit distance analysis, part of speech tagging, contextual morpho-syntactic analysis, and word sense filtering (utilizing UMLS) in assessing misspelled terms and candidate corrections. As part of an ontology mapping task, Dziadek et al. used journal articles and EMR text in Swedish as input for a system that employed a commercial spell checker, Levenshtein distance, and trigrams to identify and correct misspellings [14]. Meystre et al. used fuzzy string matching and a constrained Levenshtein edit distance to identify misspelled medications in 3000 randomly selected clinical notes from a larger annotated corpus [15]. Levin et al. annotated clinical text to train and test an algorithm for normalizing misspelled drug terms in clinical text [16] utilizing RxNorm and LVG Metaphone, NLP products from the National Library of Medicine.

Word Embedding (a technique mapping words to real number vectors) facilitated by Word2Vec models [17], holds promise in identifying words with both correct and incorrect spellings. Word2Vec models implement simple neural networks to create word vectors, using either a skip-gram or continuous bag of words (CBOW) approach. The skip-gram approach identifies multiple words in a contextual window, given a single word. The CBOW approach applies the opposite logic, identifying a single word given the other words in the window. The end-products of either method are word embedding vectors that can be used to identify words that have similar word embeddings, or that are found in similar contexts. Word embeddings and similar methodologies have been used as one of several components in identifying spelling errors in consumer-generated text [18]. They could potentially contribute to spelling analysis research involving EMR data.

The Veterans Health Administration (VHA) is one of the largest integrated health care systems in the world [19], providing care to over 9 million patients each year, at 1,243 facilities [20]. Efforts to computerize VHA data began in the 1970's, resulting in the creation of VistA, one of the first EMR systems [21]. This has resulted in the creation of a vast electronic clinical data resource, which VHA maintains in their Corporate Data Warehouse (CDW). These data are made available for research activities through the Veterans Affairs Informatics and Computing Infrastructure (VINCI), a secure platform enabling data research.

Goals of this Work

The primary goal of this study was to identify misspellings of drug names for a specific pharmacovigilance task, namely to identify the potential use of antibiotics for which certain infections have developed a resistance. As an additional exploratory task, we sought to identify the corrected forms of misspellings also used in such a task. We created an application (see https://qtzeng.smhs.gwu.edu/redmine/projects/drug-term-word-analysis for documentation) that identifies misspellings and correct spellings of words in clinical text. This approach leverages the hypothesis that comparing words that share the same contexts in text, utilizing Levenshtein edit distance [11] constraints and a lexicon containing the correctly spelled terms could enable identification of misspellings or correct spellings, depending on the need. By operationalizing this hypothesis, our system identified both the correct and incorrect spellings of terms used in the pharmacovigilance task, given the original input forms, according to predictive value, the evaluative focus of this work

As a test case, we used a list of both correct spellings and misspellings of antibiotic terms. This list had previously been used in a CDC drug-resistance pharmacovigilance task. Two annotators evaluated the results, measuring positive predictive value (PPV) for application output, and negative predictive value (NPV) for when the application produced no output.

Methods

Data Procurement

We used a corpus of 400,000 clinical notes randomly pulled from the VA's TIU tables (i.e. text note tables) through VINCI, of document types addressing infectious diseases. These records were created from October 1999 to May 2018, representing 138190 patients, 131681 males, and 6509 females. The mean age was 65.4 years old.

We obtained a list of 112 antibiotic terms and phrases from the CDC that are regularly monitored in an antibiotic resistance surveillance task to use as input. This list contained both numerous misspellings and a select number of correct spellings of antibiotic terms. Because the focus of this study was individual words, we split phrases such as sulfamethoxazole/trimethoprim into two separate words, and then removed duplicates, producing a list of 108 individual terms

Method Process, including Corpus Treatment

We trained a Word2Vec model, implementing the Genism Word2Vec library in Python [22], for the task of locating words found in the same contexts within the corpus as the 108 pharmaceutical terms. Preliminary work indicated that a model with a feature vector dimensionality of 600, using the Continuous Bag of Words algorithm, with a context window of 8 words, implementing the softmax function with no negative sampling, and 10 iterations produced the most effective model for this given task. In producing the final model, we built word embeddings for all words in the corpus, regardless of frequency. This last measure ensured that we could observe the final efficiency of this method even for terms that occurred just once in the corpus. The Word2Vec model contained a vocabulary of 354,559 terms.

To determine frequency of useful terms in the corpus, we subjected it to a separate, independent process, tokenizing the content, removing many common words (e.g., articles, prepositions, ordinal numbers), specific punctuation patterns that were typical of noise in VA notes, and transformed the remaining tokens to lower case. Superfluous punctuation was also removed. This resulted in a set of 285,909 tokens that were particularly information-bearing, for which we calculated the frequency of each and stored the results.

We built a customized lexicon of standard spellings using the RXNCONSO file from RxNorm [23] for use in the method. The goal of this process was to harvest standardized RxNorm terms for both trade and generic drug names. This automated process placed all such RxNorm terms in a separate resource that contained 19,732 unique drug terms.

The application processed each term from the prepared CDC list of antibiotics using the following methodology. First, the program determined if the input term was correctly spelled, using the customized lexicon, and if the word was present in the Word2Vec model vocabulary. Properties such as dosage were not relevant to the analysis process. If the input term was not in the vocabulary, this fact was recorded for output. If the input term was in the vocabulary, rules facilitated its comparison to the word embeddings of words in the corpus or words in the customized lexicon of standard drug terms, specific to one of three possible scenarios:

Scenario 1: If the input term was correctly spelled, the program retrieved other corpus words that occurred in similar contexts, by ranking the similarity scores between the target input word and other words in the Word2Vec model vocabulary, using the default cosine measurement, retrieving a maximum of 1000 similar terms. For each of these "context" terms, the program calculated the Levenshtein edit distance between it and the input term. If the edit distance was equal or less than the integer floor value of the character count of the input term divided by three (minimum threshold of three after division), and the context word did not end in "s" (i.e., a probable plural form), and did not occur in the customized lexicon (i.e., a probable standardized spelling of a different drug), the program identified it as a misspelling of the input term.

Scenario 2: If the input term was a misspelling, the program first identified candidates from the retrieved context terms also appearing in the customized lexicon that met one of these conditions:

1. The edit distance between the input term and the context term was equal or less than the absolute value of the character count of the context term minus that of the input term (or alternatively four, if this length was less than four). This cast a sufficient yet not overly large net, based on Kilicoglu et al. observations [18].
2. The input term and the context term began with the same three letters.

All these candidate terms were weighted with a simple metric that computed the given candidate's word embedding similarity score, divided by the inverse of the frequency's $\log_2$ value, with

the highest scoring candidate term selected as the logical correct spelling.

Scenario 3: If the input term was a misspelling and the previous step did not identify a logical correct spelling, the input term was compared to terms in the lexicon where the edit distance was three or less. The term(s) with the smallest edit distance that also began with the same first three letters was chosen as the correct form(s).

The edit distances used in Scenarios 2 and 3 were determined through common heuristics (i.e., an optimal maximum edit distance will be a proportion of the input term's length) and testing. The weight metric used in Scenario 2 was guided by two additional heuristics: (a) the correct form will have a high similarity score, and (b) will occur frequently in the corpus. Taking the log value of the frequency scales its influence so that it proportionately affects the value. The metric used in Scenario 3 was guided by the heuristic that the alternative correct form would otherwise be the closest in character variation to the misspelling and begin with the same characters. Edit distances were also determined through preliminary testing on another dataset.

Figure 1 provides a graphical representation of this process.

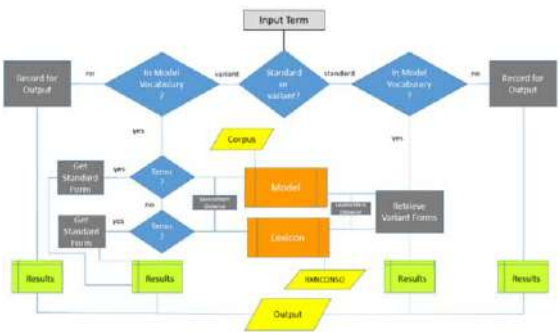

Figure 1. Application process

Evaluation of Output

Two authors (GD, TEW) reviewed the method's output. For each input term, they considered the following questions to identify valid output values:

Where the program produced output:

- For correctly spelled input words, how many candidate terms identified by the program are logical misspellings of the associated term (true positives)? How many are not (false positives)? (*evaluation Oa*)
- For misspelled input words, did the program identify a logical correct spelling (true positive), or not (false positive)? (*evaluation Ob*)

Where the program did not produced output:

- For correctly spelled input words, for each context word, could it logically be a misspelling of the word (false negative), or not (true negatives)? (*evaluation Na*)
- For misspelled input words, did a logically correct spelling of the term appear in the corpus or lexicon (false negative) or not (true negative)? (*evaluation Nb*)

To answer these questions for each input term, the annotators could use a reference standard, such as a dictionary or lexicon. Additionally, occurrences of output terms were analyzed in the corpus to assure they were likely used as drug terms.

We calculated Cohen's Kappa to assess inter-annotator agreement. Disagreements were settled by consensus. We calculated the positive predictive value (*True Positives/(True Positives + False Positives*)) and negative predictive value (*True Negatives/(True Negatives + False Negatives)*) to evaluate performance. Positive predictive value is used to evaluate the application's performance in terms of its output (*evaluation Oa* and *evaluation Ob*). Negative predictive value is used to determine how the program performed when it produced no output (*evaluation Na* and *evaluation Nb*), in terms of not identifying valid output (i.e., false negatives).

Results

Raw Application Output

Input terms were organized by six classifications, in accordance with the application. Input words that were correctly spelled drug terms (a) were in the corpus, and the application produced misspellings (33 input terms), (b) were in the corpus, and the application did not produce misspellings (20 input terms), or (c) were not in the corpus (37 input terms). Similarly, input words that were misspelled drug terms (d) were in the corpus, and the application identified a potentially correct spelling (10 input terms), (e) were in the corpus, and the application did not identify a potentially correct spelling (3 input terms), or (f) were not in the corpus (5 input terms). Terms were considered correct if they appeared in the customized lexicon.

For the 33 correctly spelled input terms in the corpus where the program did produce output, there was a total of 184 misspellings, prior to annotator review. For the 10 misspellings where the program produced output, there was a total of 11 potential correct spellings identified (there were 2 identified for "septran").

Inter-Rater Agreement

In terms of Cohen's Kappa (Table 1), agreement was fair for *evaluation Na*, substantial for *evaluation Oa* and *evaluation Ob*, and essentially perfect for *evaluation Nb* [24], with percentages ranging from 90% to 100% for all. For *evaluation Na*, the Cohen's Kappa agreement was borderline fair / moderate, yet the percentage of overall agreement was 99.68%. This discrepancy is likely due to Cohen's Kappa's vulnerability to skewed data [25].

Method Performance

For *evaluation Oa*, of the total 184 misspellings output by the application, 171 were determined to be logical misspellings of their given correctly spelled input forms, thus producing a PPV of 0.929 for this task. For *evaluation Ob*, of the 11 correct forms output by the application, 9 were determined to be logical representations of their given input misspellings. This produced a PPV of 0.909 for this task (Table 1).

For *evaluation Na*, there were 619 true negatives, and four false negatives, producing an NPV of 0.994. For *evaluation Nb*, there were 1 true negative and 2 false negatives, producing an NPV of 0.333. For these input misspellings we checked if a logical correct spelling occurred in the corpus or lexicon. Of the three terms, logical corrections appeared in the corpus for two, therefore there were two false negatives, and one true negative (Table 1).

Table 1. Inter-Rater agreement and application performance

	Raw(Valid) Terms	Disagreements (Agreement %)	Cohen's Kappa	Performance Metric(Value)
Oa	184 (171)	6 (96.74%)	0.733	PPV (0.929)
Ob	11 (9)	1 (90.90%)	0.621	PPV (0.909)
Na	623 (4)	3 (99.68%)	0.398	NPV (0.994)
Nb	3(1)	0 (100%)	1	NPV (0.333)

Examples of how some terms were used in the corpus follow, with indications of the correct and incorrect spellings:

- **Bactrim/bactim:** "the pt will be best tx with bactim i will order this drug as well"
- **Clindamycin/clindamcyin:** "was initally started on vancomycin and switched to clindamcyin po 600mg tid"
- **Zosyn/zozyn:** "agree with outpatient treatment with zozyn and clindamycin for 7 days"

Misspelled Antibiotic Terms Identified

For the task of monitoring clinical text for mentions of the antibiotics on the list, the program identified 171 logical misspellings after annotator review and consensus. This equals an average of 5 additional representations per correct spelling, of the 33 correctly spelled words from the CDC antibiotics list.

For example, the correctly spelled input term Cefazolin occurred in the corpus. It was matched to the contextual misspellings "cafazolin", "cefazoin", "cefazoline", "cefezolin", "ceftazolin", "cefzolin", and "cephazolin" (all true positives for *evaluation Oa)* using the edit distance constraint and lack of presence of these contextual words in the customized lexicon, as described in Scenario 1.

Correct Spellings Identified

There were 18 misspellings in the original CDC list. All but 5 of the 18 misspellings were also found in the corpus. Of those 13, the application identified logical correct spellings for 10, including two for "septran". After annotator review and consensus, 9 terms were identified as valid corrections for 9 misspellings.

To illustrate a Scenario 2 output for the input misspelling "zithromycin", Azithromycin had a similarity score of 0.3403 and occurred 22556 times in the corpus, producing a score of 4.9212:

$$(0.3403) / (1/ \log_2(22556)) = 4.9212$$

The highest score of all candidate corrections, and is a true positive for *evaluation Ob*.

To illustrate Scenario 3, the application identified "Tetracycline" as the logical correct spelling of the misspelled input term "tetraycycline", because among terms in the customized lexicon, it had the smallest edit distance from "tetraycycline" and began with the first three letters. This is another true positive for *evaluation Ob*.

Discussion

The application identified 171 valid misspellings of the correctly spelled antibiotic terms, thus providing additional material for review in a pharmacovigilance task. As a specific use case, consider Penicillin G, Tetracycline, and Amoxicillin, to which MRSA demonstrates resistance [26]. The correct spellings of these exact terms occur 15,317 times in the corpus. The application found a total of 19 misspellings of penicillin, tetracycline, and amoxicillin. In the corpus, these misspellings (in the case of "penicillin", appending the misspelled variations with "g") occurred 9,815 times, representing 9,815 additional occurrences where these drugs may have been used to treat MRSA, thus meriting scrutiny.

Method Output Performance

The application achieved PPV of 0.929 and 0.909 in identifying misspellings of correctly spelled input terms, and logical corrections of misspelled input terms, respectively. By combining similarity scores provided by the word embeddings with the edit distance constraints, the application was able to identify misspellings from the many words that occur in the same context as a given correctly spelled word. For the correctly spelled input word "tetracycline", the application identified "tetracyclin", but not "tegecycline" as a logical misspelling. The latter term, which occurs in the corpus, is within the edit distance constraint, but did not occur in the same context as tetracycline and is more likely a misspelling of Tigecycline. For the misspelling "amoxicilline" the program identified "amoxicillin" as the correct spelling instead of the other candidate "amoxi" because it produced a score of 4.8849, whereas the score for "amoxi" was 2.2499. A visual comparison of the three terms suggests that "amoxicillin" is the valid correct spelling. For the two misspelled input terms "septran" and "tetraycycline" for which no context word met the Scenario 2 criteria, the method of finding the customized lexicon term with the shortest edit distance that began with the same three letters identified logical corrections for each.

The application performed well in terms of NPV where correct spellings were used as input, but not as well for input misspellings, where no output was produced. *Evaluation Nb* determined that in most cases, among all context words, there were no valid logical misspellings for the twenty correctly spelled input terms for which the method did not produce output. In this evaluation, there were only four false negatives and 619 true negatives. For the three input misspellings with no output, we identified two false negatives and one true negative. This has been targeted as an area of improvement in future work.

Overall, the application demonstrated good performance for identifying both misspelled and correctly spelled antibiotic terms for the pharmacovigilance task, using the randomly selected 400,000 VA notes as a corpus. Although this is a small study addressing antibiotic use, these results suggest that this method could achieve satisfactory results for other pharmacovigilance tasks.

Limitations

For testing purposes, we designed the application to produce word embeddings for terms that occurred at any frequency in the corpus, but generally Word2Vec is not as efficient in modeling highly infrequent words. The task of identifying logically correct forms of input misspellings should be interpreted as such, and not as an attempt to identify the exact intended term. For example, it would be impossible to truly ascertain from the text whether or not a clinician meant "Amoxicillin" and not "Amoxil" when using a similar misspelling. This is a small study addressing 108 antibiotics but demonstrates the program's potential value in a pharmacovigilance task. The VHA serves a predominantly older adult male population. However, because the VHA is so large, with so many patients as well as healthcare practice specialties, and significant populations of both adult male and

female patients of various ages, these results can be generalized to a certain extent.

Conclusions

We developed a novel method to identify misspellings and correct spellings of pharmaceutical terms in clinical text using Word2Vec, Levenshtein edit distance constraints, and a customized lexicon, evaluating it for a real-world pharmacovigilance task using a corpus of VHA clinical notes and a CDC surveillance list of pathogen-resistant antibiotics, achieving PPV of 0.929 for identification of misspellings and 0.909 for identification of correct spellings in output, and NPV of 0.994 and 0.333 for these tasks where there was no output. As a specific use case, the method provided 9815 additional occurrences in the corpus of three MRSA-resistant drugs.

Abstract

Cluster analysis aims at separating patients into phenotypically heterogenous groups and defining therapeutically homogeneous patient subclasses. It is an important approach in data-driven disease classification and subtyping. Acute coronary syndrome (ACS) is a syndrome due to sudden decrease of coronary artery blood flow, where disease classification would help to inform therapeutic strategies and provide prognostic insights. Here we conducted an outcome-driven cluster analysis of ACS patients, which jointly considers treatment and patient outcome as indicators for patient state. Multi-task neural network with attention was used as a modeling framework, including learning of the patient state, cluster analysis, and feature importance profiling. Seven patient clusters were discovered. The clusters have different characteristics, as well as different risk profiles to the outcome of in-hospital major adverse cardiac events. The results demonstrate cluster analysis using outcome-driven multi-task neural network as promising for patient classification and subtyping.

Keywords:

Acute Coronary Syndrome, Cluster Analysis, Computer

Introduction

Precision medicine is a healthcare approach which aims at developing more effective ways to improve health and treat disease by taking individual traits into account [1]. One attempt toward precision medicine is to provide the best available care for patients based on their disease subtypes within a disease of common biological basis. Patient cluster analysis comprises a solid step towards precision medicine, which fulfils the task of disease classification and subtyping [2]. Cluster analysis has been used for subgroup analysis of type 2 diabetes [3], accurate phenotyping of heart failure and related syndromes [4,5], as well as identifying meaningful patient clusters for developing specific treatment programs in geriatric stroke patients [6]. The results support cluster analysis as a useful tool to discover disease classes and subtypes, which can inform therapeutic strategies like individualizing treatment regimens and providing prognosis insights.

Cluster analysis is performed based on a similarity or distance measure. Commonly used similarity measures include Euclidean distance, cosine similarity, Jaccard similarity, and so on. Traditionally, as no associating outcome measure is available for cluster analysis, the methods are unsupervised, and thus the similarity measure takes all patient characteristics as equally important, the results of which are less desired when we target the clustering results at reflecting specific patient traits. It has been recognized that patient similarities for cluster analysis are commonly context-based and are sometimes associated with clinical outcomes of interest. Outcome-driven clustering (sometimes referred to as 'semi-supervised clustering' or 'supervised clustering') is applied when outcome measures are available and can serve as a noisy surrogate for the (unobserved) target cluster [7], which has been proven useful in patient cluster analysis for precision cohort finding [8] and clinical decision support [9].

Neural network has been increasingly used as a successful data modeling paradigm, which solves tasks such as pattern recognition and classification through a learning process and has been recently used in medical informatics research for representation learning [10]. Multi-task learning is a strategy where multiple learning tasks are solved at the same time to benefit from their commonalities and contrasts. Neural networks adapt to multi-task learning intuitively by designing specific network structure and cost function [11]. Though useful, neural network is often criticized for lack of interpretability. Attention mechanism is thus introduced to neural network to increase model interpretability as well as performance [12] and has been applied to healthcare research [13]. Thus, a joint use of the three techniques would facilitate representation learning, leveraging information from different tasks in an interpretable manner.

Acute coronary syndrome (ACS) is a syndrome due to sudden decreased coronary artery blood flow. A treatment objective of ACS is to prevent major adverse cardiac events (MACE) during hospitalization. ACS can be classified into ST elevation myocardial infarction (STEMI), non-ST elevation myocardial infarction (NSTEMI), and unstable angina (UA) by cardiac marker and manifestation of ST-elevation in electrocardiogram. However, exploration of biomarkers for disease classification and subtyping has never stopped [14,15]. In this study, we present outcome-driven clustering of ACS patients based on biomarkers as well as clinical indicators. We desired using patient state (which is an abstract characterization of patient traits regarding the disease) for clustering and decided on four outcome measures as surrogates to indicate the patient state: antiplatelet treatment, beta-blockers treatment, statins treatment, and in-hospital MACE. The four measures are supposed to reflect different facets of the patient state. Therefore, a joint consideration would enable a more comprehensive and targeted depiction of the patient state. Cluster analysis has been conducted on ACS patients to discover symptom clusters [16], assess the differences in mortality between symptom clusters [17], discover clusters of different lifestyle risk factors [18], and to detect critical patients using medical parameter time series [19]. However, all the above studies are unsupervised and none of them use neural network as the modeling framework.

In this study, we conducted outcome-driven patient clustering on hospitalized ACS patients, identified underlying patient clusters, and profiled the cluster characteristics, especially risk factors to in-hospital MACE. Novelty of our study includes:

(1) using outcome-driven cluster analysis to guide cluster analysis; (2) using multi-task neural network to learn a multi-faceted representation of patient characteristics; and (3) attention mechanism was introduced to the neural network model to increase model interpretability and facilitate feature importance profiling.

Methods

Cohort Construction

The multi-center, retrospective cohort study was conducted at 38 urban and rural hospitals in China. Adult hospitalized patients (aged $\geqslant$18 years) with a final diagnosis of ACS identified at the time of death or discharge were included. Each hospital enrolled the first five consecutive patients on a monthly basis from January 1, 2008 through December 31, 2015. We excluded patients who: (1) had potentially lethal diseases (e.g., incurable cancer, decompensated cirrhosis, multisystem organ failure); (2) had an expected life span below 12 months; or (3) died within 10 minutes of arrival at the hospital. A patient needs to have age, gender, ACS type recorded to be included in the analysis. A total of 26,986 patients were included in this study.

Feature Construction

Patient data was identified and reviewed by trained investigators to record clinical information. We included 41 patient characteristics as features, including: disease types (ACS type and Killip class), demographics, personal disease history, comorbidities, habits, laboratory test results, and procedures. Data outliers determined based on clinical knowledge were removed and represented as missing data. Missing values were imputed by multiple imputation utilizing the 'mice' package in R [20]: continuous variables by predictive mean matching, binary variables by logistic regression, and a proportional odds model for ordinal variables. We conducted one-hot encoding on categorical variables with more than two categories, and standardized continuous values by removing the mean and scaling to unit variance.

Classification with Multi-task Neural Network Model

Multi-task neural network with attention was used as the framework. A schematic representation of the neural network design is shown in Figure 1. The attention layer was implemented as a hidden layer with softmax activation, with the same number of nodes as the shared input layer. Attention was added to the attention layer by multiplying element-wise with the shared input layer.

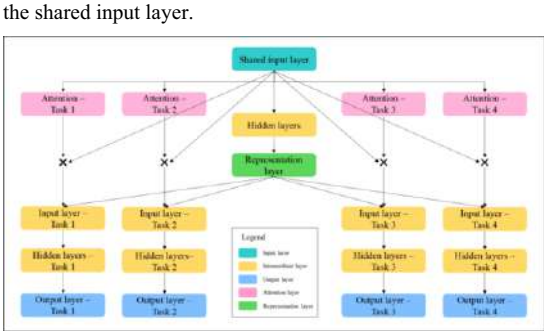

Figure 1. *Illustration of the Neural Network Design.*

Following the shared input layer are hidden layers, then a representation layer which learns a joint patient representation. The four classification tasks are optimized simultaneously. For each task, the input for the task was formed by concatenating the representation layer with the features in the shared input layer after adding attention to each feature. It then reaches the final output layer after adding hidden layers in between.

During training, features mentioned in the 'Feature construction' section were used as input for in the shared input layers, and the ground truth of the four patient traits (MACE, antiplatelet treatment, beta-blockers treatment, and statins treatment) were used as output in the four output layers for each task.

Binary cross entropy loss was used for each classification task. For task j (j in 1, 2, 3, and 4), the task weight is denoted as w_j, the ground truth and predicted probability for an instance i are denoted as y_{ij} and $\widehat{y_{ij}}$ respectively, and $H\left(y_{ij}, \widehat{y_{ij}}\right)$ is the binary cross entropy loss. The cost function for neural network we used is defined as:

$$C \triangleq \frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{4} w_j H\left(y_{ij}, \widehat{y_{ij}}\right)$$

where n is the number of training samples. In our experiments, we assigned equal weight to all classification tasks.

Parameters were optimized using 'Adam'. Training was conducted with a batch size of 512 and 50 epochs. Class weights were added to balance the biased proportion of positive and negative cases respectively for all four tasks.

To validate the performance of the neural network for the classification tasks, cross validation was conducted 10 times by each randomly splitting data into training set and validation set at a ratio of 4:1. For patient clustering, all samples were used for neural network training.

Post-Classification Analysis Workflow

Analysis after classification with multi-task neural network model included three steps: (1) evaluating neural network classification performance; (2) clustering patients using values from the representation layer; and (3) profiling risk factors for in-hospital MACE in each patient cluster using the attention values.

Patient Clustering

For each patient, values of the representation layer after training were used as the vector for clustering, which is a 32-dimension vector. K-means was used for patient clustering. Model selection was conducted using Bayesian Information Criteria to choose the model from a range of different K (number of clusters) settings (2 to 15). We selected K = 7 for K-means clustering.

Implementation

Cohort construction, feature construction and post-classification analysis were conducted using R 3.4.1. Neural network training and analysis were conducted using Python 2.7.14, Keras 2.2.4, and Theano 1.0.3.

Results

Neural Network Classification Performance

We used the multi-task neural network for the four selected classification tasks. Proportions of positive cases in four classification tasks are shown in Table 1, which are largely imbalanced. Classification performances are evaluated by AUROC (area under the receiver operating characteristics) and AUPRC (area under the precision recall curve) on the validation set in a cross validation setting (Table 1). From the results, MACE and antiplatelet treatment were best classified while beta-blockers treatment had the lowest classification performance. The results suggest that the learned neural network model is a greater reflection of the patient states corresponding to MACE and antiplatelet treatment.

Table 1. Neural network classification performance

Task	Positive case	Performance		
		AUROC	AUPRC (class 0)	AUPRC (class 1)
MACE	3.54%	0.8602 (0.0141)	0.9926 (0.0007)	0.2924 (0.0551)
Antiplatelet treatment	80.50%	0.8634 (0.0078)	0.5799 (0.0197)	0.9640 (0.0038)
Beta-blockers treatment	68.87%	0.6881 (0.0131)	0.5035 (0.0199)	0.8184 (0.0097)
Statins treatment	89.24%	0.7725 (0.0167)	0.2842 (0.0275)	0.9635 (0.0045)

Note: In performance cells, the numbers denote mean value (standard deviation).

K-means Clustering

K-means was conducted on the representation layer to cluster patients into seven groups. Clustering results are visualized in Figure 2, where t-SNE was conducted to reduce the 32-dimension data in the representation layer to 2 dimensions and used color to denote the assigned cluster membership. We see clear separation of the clusters in the low dimension representation.

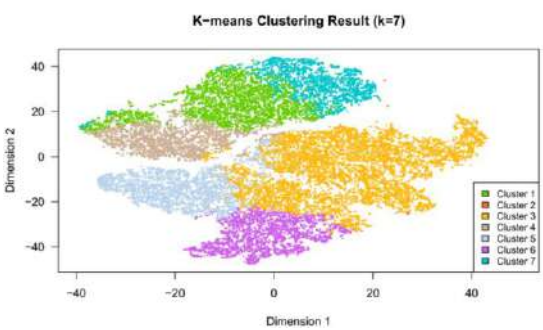

Figure 2. *Visualization of Patient Clustering using t-SNE plot.*

Distribution of cluster size, and the properties relating to classification tasks are shown in Table 2. Clusters were organized based on descending MACE onset rate. The seven clusters have different cluster size, MACE rate and treatment rate. Cluster 2 has only 5 samples and is thus not included in later comparison. The largest cluster (9,889/26,986; 37%) had the highest MACE rate, and lower treatment rate compared to the overall cohort.

Table 2. Distribution of Cluster Size and Classification Labels

	Size	MACE	Anti-platelet treatment	Beta-blockers treatment	Statins treatment
Overall	26,986 (100%)	955 (3.5%)	21,708 (80.5%)	18,572 (68.9%)	24,066 (89.2%)
Cluster **3**	9,889 (37%)	760 (7.7%)	7,768 (78.6%)	6,210 (62.8%)	8,496 (85.9%)
Cluster **4**	3,163 (12%)	74 (2.3%)	3,139 (99.2%)	2,361 (74.6%)	3,064 (96.9%)
Cluster **1**	4,353 (16%)	82 (1.9%)	4,346 (99.8%)	3,225 (74.1%)	4,284 (98.4%)
Cluster **7**	2,709 (10%)	23 (0.8%)	2,708 (100.0%)	2,292 (84.6%)	2,690 (99.3%)
Cluster **6**	3,212 (12%)	14 (0.4%)	1,119 (34.8%)	1,788 (55.7%)	2,214 (68.9%)
Cluster **5**	3,637 (13%)	2 (0.1%)	2,623 (72.1%)	2,691 (74.0%)	3,313 (91.1%)
Cluster **2**	5 (0%)	0 (0.0%)	5 (100.0%)	5 (100.0%)	5 (100.0%)

Note: In each cell, the numbers denote count (proportion). In column 'Size', the proportion is the proportion in the overall patient cohort. In other columns, the proportion is the proportion in the specified cluster.

Profiles of patient clusters were analyzed. Notable features of each patient cluster are presented in Table 3. Specifically, Cluster 3 has more severe conditions as shown by the highest average age, proportion of patients with elevated cardiac enzyme levels, and the lowest average left ventricular ejection fraction (LVEF [%]). Cluster 4 also has comparatively severe condition as is shown by the Killip class. Cluster 1 does not show severe disease, but the MACE rate is still high, which is potentially associated with bad living habits (highest proportion of current smoker and current alcohol drinker) of this cluster. Cluster 7 is featured by the highest proportion of STEMI patients and lowest proportion of UA patients. Though STEMI patients are far more prone to in-hospital MACE compared to UA and NSTEMI, this cluster is not associated with a high MACE rate, potentially as a combined effect of the less complicated disease manifestation and the high level of treatment. Cluster 6 has the highest proportion of UA patients, and are less prone to MACE even though they have the lowest treatment rates. Cluster 5 is featured by the low disease severity, and correspondingly, the lowest MACE rate.

Risk Factors for MACE in Each Patient Cluster

For each patient, a feature's attention value for the MACE classification task from the neural network is used as its importance in predicting MACE. For each patient cluster, a feature's importance is calculated as the average attention value of all patients in the cluster. Feature importance in each patient cluster is shown in Table 4. Features with different importance or high clinical relevance are selectively listed. The largest value in each row is shown in bold. Different clusters have different feature importance, indicating different risk profiles. As an example, smoking is a more important risk factor for MACE in Cluster 1 and Cluster 7, current comorbidity of hypertension more important for Cluster 4, 5 and 6, age and systolic blood pressure are more important in Cluster 3 than in other clusters.

Table 3. Profile of Patient Clusters

Cluster	Has the highest	Has the lowest
3	MACE rate Age Proportion of NSTEMI patients Cormobidity of atrial fibrillation Elevated cardiac enzyme levels	LVEF (%)
4	Killip class History of myocardial infarction	
1	Current smoker and current alcohol drinker	
7	Antiplatelet treatment Beta-blockers treatment Statins treatment Proportion of STEMI patients	Proportion of UA patients Killip class Proportion of patients with cormorbidity Proportion of patients with disease history
6	Proportion of female patients Proportion of UA patients	Antiplatelet treatment Beta-blockers treatment Statins treatment
5	LVEF (%) Cormobidity of hypertension History of vascular disease History of established coronary artery disease History of percutaneous coronary intervention History of coronary artery bypass grafting History of other conditions confirmed by computed tomography angiography	MACE rate Elevated enzyme levels

Discussion

Attention Mechanism and Feature Importance

Attention model in neural network is inspired by brain's neural mechanism of attention and is simplified here as: in each sample, including a numerical weight ('attention value') for each predictor associated with each outcome. When we normalize the weights for each sample to be all larger than 0 and have a sum of 1, the attention values look similar to a probability distribution to show the feature importance. In our study, we considered the outcome of in-hospital MACE. For each feature, we calculated the average attention value of patients in a cluster and used it as its importance in this cluster. When a feature has an importance larger than 0, we regard it as a risk factor to the outcome, where the feature importance is taken as the importance of the risk factor. The attention mechanism makes the neural network models, otherwise 'black boxes', interpretable to some degree, but is still less clear compared to logistic regression models, where both the feature importance and the action directionality (positive or negative impact) are shown with odds ratio, confidence intervals, and coefficient p-values.

Choice of Outcomes

Multi-task learning is an approach to transfer domain knowledge contained in related outcomes and learn in parallel using a shared representation [21]. The incentive for this approach is that the outcomes are reflections of different facets of a common latent representation. To better know the latent representation, we learn from different outcomes. When thinking of the patient state as the latent representation, we need to choose outcomes that are reflections of the patient state. In our study, antiplatelet, beta-blockers, and statins treatment are prescribed based on doctors' perception of the patient based on domain knowledge. MACE outcome is a direct result of the patient disease state. We thus include all four outcomes to better represent the patient. After assessing the classification performance, the patient representation better characterizes the patient state regarding MACE and antiplatelet treatment than the patient state regarding beta-blocker treatment.

Table 4. Feature Importance in Each Patient Cluster

Cluster	**3**	**4**	**1**	**7**	**6**	**5**
Ethnic group (Han)	0.046	0.070	0.048	0.050	**0.127**	0.088

ACS Type (STEMI)	0.002	0.002	0.003	**0.003**	0.002	0.002
ACS Type (UA)	0.085	0.134	0.059	0.045	0.138	**0.208**
Current smoking	0.046	0.052	0.091	**0.095**	0.032	0.030
Current Hypertension	0.032	0.103	0.036	0.033	0.127	**0.146**
Current Diabetes	0.032	0.033	**0.053**	0.034	0.034	0.028
Current atrial fibrillation	0.082	0.055	0.078	**0.085**	0.056	0.025
Current Percutaneous coronary intervention	0.064	0.071	**0.101**	0.086	0.018	0.032
Elevated enzyme levels	0.047	0.043	0.050	0.060	**0.080**	0.061
Killip Class	**0.048**	0.029	0.035	0.036	0.005	0.011
Age (years)	**0.045**	0.029	0.033	0.027	0.008	0.013
Systolic blood pressure (mmHg)	**0.033**	0.017	0.018	0.019	0.010	0.012
White blood cell count (×10^9/L)	0.029	**0.031**	0.020	0.020	0.019	0.029

Pitfalls in Interpretation of the Results

Two points need to be addressed regarding interpretation of the results. First, algorithmically meaningful clusters are not necessarily clinically meaningful clusters. Though the clustering result has implication for disease prognosis, whether it can inform clinical practice needs further clinical research. Second, risk factors cannot be directly translated to clinical intervention. As an example, though comorbidity of hypertension and high systolic blood pressure are risk factors for in-hospital MACE, the results are not sufficient to claim the intensity of hypertension treatment required for different clusters.

Suggestions for Future Study

Our suggestions for future study using similar approach include: (1) carefully select clinically meaningful outcomes to be used; (2) use fewer features and easily acquired ones would make the results more applicable; and (3) identify cluster-specific interventions considering treatment effectiveness would add extra clinical value to similar studies.

Conclusions

In this study, we used multi-task neural network with attention as a modeling framework to support learning of patient state representations, cluster analysis of patients, and profiling of feature importance. Seven patient clusters were discovered, which have different characteristics and risk profiles to in-hospital MACE. The results demonstrate cluster analysis using outcome-driven multi-task neural network as a promising approach for ACS patient classification and subtyping.

Abstract

Acute Kidney Injury (AKI) is the most common cause of organ dysfunction in critically ill adults and prior studies have shown AKI is associated with a significant increase of the mortality risk. Early prediction of the mortality risk for AKI patients can help clinical decision makers better understand the patient condition in time and take appropriate actions. However, AKI is a heterogeneous disease and its cause is complex, which makes such predictions a challenging task. In this paper, we investigate machine learning models for predicting the mortality risk of AKI patients who are stratified according to their AKI stages. With this setup we demonstrate the stratified mortality prediction performance of patients with AKI is better than the results obtained on the mixed population.

Keywords:

Acute Kidney Injury, Critical Care, Forecasting

Introduction

Acute Kidney Injury (AKI) is defined as a sudden (within hours) decrease in nephritic function, including both renal structural damage and functional disorder [1]. It has been shown AKI is the most common cause of organ dysfunction in the critical care setting, and AKI is associated with a significant increase on the morbidity and mortality risk [2]. Early prediction of the mortality risk for AKI patients can help clinical decision makers better understand patient conditions in time and take appropriate actions.

There has been prior research on building mortality risk prediction models for AKI patients. For example, Luo et al. [3] created a scoring model based on multivariate logistic regression to predict the 90-day mortality risk of AKI patients. Skarupskienė et al. [4] adopted logistic regression to predict the mortality risk of AKI patients requiring renal replacement therapy after cardiac surgery. Demirjian et al. [5] used logistic regression to predict the 60-day mortality risk of the AKI patients who are enrolled in the Veterans Affairs/National Institutes of Health Acute Renal Failure Trial Network study. Ohnuma et al. [6] compared the ability of various mortality prediction models in a retrospective, multi-centric cohort of 343 Japanese patients with AKI requiring continuous renal replacement therapy in 14 ICUs captured between January and December 2010.

All of these existing research tried to build a unique predictor for the entire AKI patient cohort. However, it has been demonstrated AKI is a heterogeneous disease with various kinds of causes and clinical manifestations [7]. In this case, it would be challenging to build a single model that is capable of predicting the mortality risk over the entire AKI patient population.

With the above considerations and previous studies [8,9], we propose to perform a stratified prediction in this paper. Specifically, we will first stratify the AKI patients according to their disease stage (I, II, and III). Then, a mortality risk prediction model will be built for each patient strata. In addition to logistic regression, we will also test the performance of other machine learning models including random forest and gradient boosting tree. The Medical Information Mart for Intensive Care III (MIMIC-III) database [10] is used for empirical evaluations. Our results demonstrate the performance of stratified mortality prediction considering different AKI stages is higher than the mortality prediction on the entire mixed population. Additionally, the experiment results show different features play different roles for mortality prediction in patients with different AKI stages.

Methods

Data source

The Medical Information Mart for Intensive Care III (MIMIC-III) database is employed to extract patient data [10], which includes 58,976 admissions of patients. This database has comprehensive information (e.g., patient demographics and vital signs) regarding ICU admissions, which is open-source and freely accessible. The MIMIC-III dataset is passive and de-identified [11], which is in compliance with the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule and does not make a significant impact on patient privacy.

AKI stages

The criteria of AKI stages has experienced some development progress based on the studies of researchers and clinicians. In particular, there are four AKI criteria: Risk-Injury-Failure-Loss-End (RIFLE) criteria [12], pediatric RIFLE (pRIFLE) criteria [13], Acute Kidney Injury Network (AKIN) criteria [14], and Kidney Disease: Improving Global Outcomes (KDIGO) criteria [15]. KDIGO criteria unified previous criteria in 2012, which improves the sensitivity of AKI diagnostic criteria and has been widely used by researchers and physicians [1]. In this study, we employed the KDIGO criteria to stratify patients into different AKI stages:

Stage 1: 1.5-1.9 times baseline, which is known or presumed to have occurred within the prior 7 days; or not less than 0.3 mg/dL (not less than 26.5 mol/L) absolute increase in serum creatinine (SCr); or urine volume less than 0.5 mL/kg/h for 6-12 hours.

Stage 2: SCr not less than 2.0-2.9 times baseline; or urine volume less than 0.5 mL/kg/h for not less than 12 hours.

Stage 3: SCr not less than 3.0 times from baseline; or increase in SCr not less than 4.0 mg/dL (not less than 353.6 mol/L); or

initiation of renal replacement therapy; or urine volume less than 0.3 mL/kg/h for not less than 24 hours; or anuria for not less than 12 hours; or renal replacement therapy required.

Patient features

A large number of features from MIMIC-III are extracted, which is shown as follows. Additional details about features can be found at: https://github.com/xuzhenxing2018/amia/blob/master/features_name.xlsx.

1. Demographics: Gender, age, and ethnicity.
2. Medications: Medications the patient took from the patients' ICU admission until prediction time. We focused on the following categories: diuretics, non-steroidal anti-inflammatory drugs (NSAID), radiocontrast agents, and angiotensin.
3. Comorbidities: We considered all comorbidities (e.g., congestive heart failure, peripheral vascular, hypertension, diabetes, liver disease, myocardial infarction (MI), coronary artery disease (CAD), cirrhosis, and jaundice) that patients already had. There were a total of 31 comorbidities in our dataset.
4. Chart-events: Vital signs measured at the bedside. We mainly focused on diastolic blood pressure (DiasBP), glucose, heart rate, mean arterial blood pressure (MeanBP), respiration rate, blood oxygen saturation level (SpO2), systolic blood pressure (SysBP), and temperature.
5. Lab-events: Laboratory test results. We considered bicarbonate, blood urea nitrogen (BUN), calcium, chloride, creatinine, hemoglobin, international normalized ratio (INR), platelet, potassium, prothrombin time (PT), partial thromboplastin time (PTT), and white blood count (WBC).

Data pre-processing

We mainly pre-processed two types of features: time-dependent continuous features and discrete features. For continuous features (e.g., lab and chart-events), we computed statistics including the first, last, average, minimum, maximum, slope, and the count based on observations during the observation window. The final encoding of the continuous features was represented by a vector representation with real numbers. The discrete features (e.g., medication and comorbidities) were encoded as zero-one multi-hot vectors. If there were missing demographics and discrete features for an ICU stay record, we deleted that ICU stay. Finally, each ICU stay was represented by a feature vector with a 224 dimension, which was indexed by icustay_id.

Experimental setting

In this study, we predicted whether a patient with AKI in different stages would die within the next seven days. Specifically, a predictive modeling setting with a rolling observation window design was adopted. We supposed t was the elapsed time (in hours) after a patient was admitted to the ICU, and the patient records in t were used to predict the mortality risk for the next seven days, where t took the value of 24, 48, 72, 96, 120, and 144 hours. An illustration of this rolling window design is demonstrated in Figure 1.

For each ICU stay, the AKI severity stage was identified based on whether the criteria in KDIGO stages were satisfied in an observation window, and then we put this ICU stay into corresponding cohorts (AKI Stage-I cohort, AKI Stage-II cohort, and AKI Stage-III cohort). If an ICU stay experienced multiple AKI stages during the observation window (from ICU admission to prediction point), we only chose the last AKI stage. Based on the built three cohorts, we predicted whether a patient with AKI in different stages would die within the next seven days. If an ICU stay did not meet one of the three AKI stage criteria in the observation window, we excluded the ICU stay from the prediction.

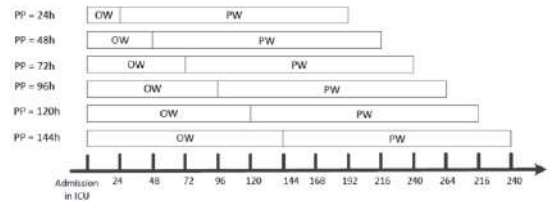

Figure 1 - An illustration of mortality prediction for patients with AKI in different stages. PP: Prediction Point; OW: Observation Window; PW: Prediction Window

Predictive models

Several popular machine learning methods including Logistic Regression (LR) [16], L2 norm regularized Logistic Regression (Ridge) [17], Random Forest (RF) [18], and Gradient Boosting Decision Tree (GBDT) [19] were utilized to build predictive models using free and publicly available software. Specifically, for the implementations of LR, Ridge, and RF, we employed the Scikit-learn software library [20]. For the GBDT, we used the XGBoost software library [21]. For each predictive model, we used the 5-fold cross validation to assess the performance of these algorithms, and employed several popular and important metrics (AUC, recall, and precision) to evaluate the performance of these models.

Note that, the number of cases (mortality patient with AKI) and controls (alive patient with AKI) was imbalanced (e.g., an approximate 1:10 case to control ratio in 24 hours for AKI Stage-I) in our dataset. More statistics for all AKI stages are shown in Table 1. With such an imbalanced dataset, most classifiers had a potential to support the majority class (alive patient with AKI) because they were considered to maximize the overall number of correct predictions, thus resulting in poor performance in the minority class (mortality patient with AKI) prediction [22].

To address this imbalanced issue, we used case-control matching techniques [23] in this study, which matched each case with a control by considering the APACHE II score [24], Charlson comorbidity index [25], and demographic information. A matched control met two conditions: (1) has the same gender as the case and the age difference is within 5 years; (2) has the highest similarity score with the case measured by Manhattan distance on the basis of APACHE II and Charlson comorbidity index. By this technique, a resampled balanced training set was constructed with matched cases and controls.

Results

Comparison of different methods with all patient features

We tested the performance of different predictive models with different AKI stages using all patient features with varying data observation windows. Figure 2 shows the performance of these methods in terms of AUC. In order to compare the performance of mortality prediction on subpopulations completely, we constructed a mixed cohort, which combined all the patients with different AKI stages together. This mixed cohort is represented as Stage-I-II-III in Figure 2. For the performance in terms of precision and recall, please refer to https://github.com/xuzhenxing2019/MedInfo.

Table 1 - The number of mortality and alive patients with AKI in different stages

		24h	48h	72h	96h	120h	144h
Stage-I	Total	7506	8181	5801	4252	3222	2416
	Mortality	756	816	715	647	567	493
	Alive	6750	7365	5086	3605	2655	1923
	Mortality Rate	10.07%	9.97%	12.33%	15.22%	17.6%	20.41%
Stage-II	Total	3216	2895	2025	1576	1267	1007
	Mortality	514	514	421	386	347	310
	Alive	2702	2381	1604	1190	920	697
	Mortality Rate	15.98%	17.75%	20.79%	24.49%	27.39%	30.78%
Stage-III	Total	408	414	404	398	380	367
	Mortality	188	167	176	159	158	161
	Alive	220	247	228	239	222	206
	Mortality Rate	46.08%	40.34%	43.56%	39.95%	41.58%	43.87%

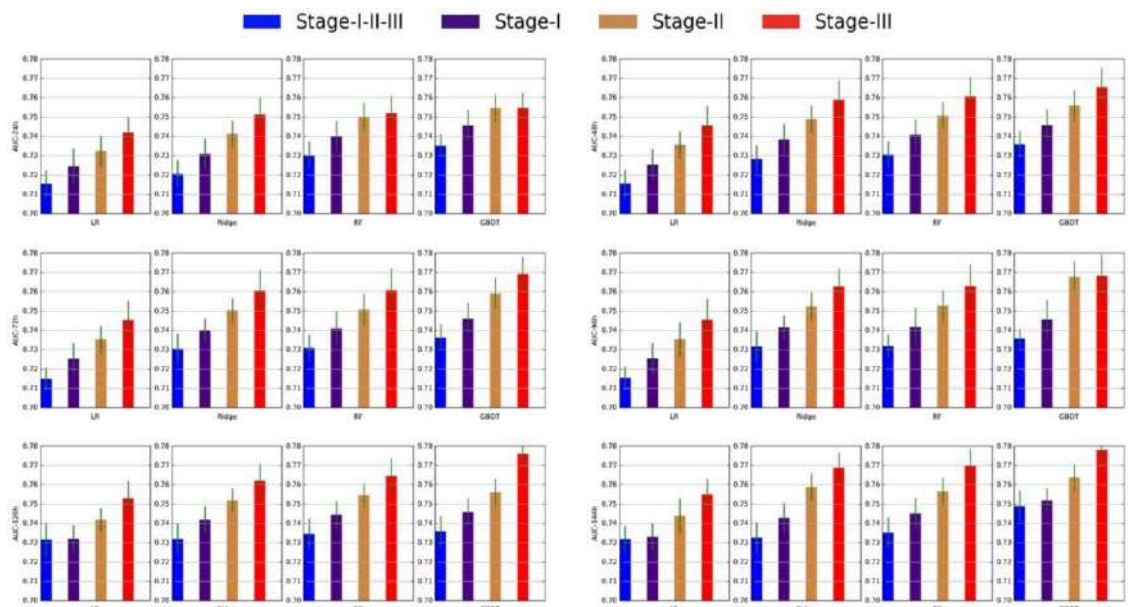

Figure 2 - The AUC of different methods with 24-144 hours of data observation window in terms of different AKI stages

From Figure 2, we observed that:

1. The technique of stratifying patients with AKI into different stages obtained a better performance compared to the mixed cohort. This provided some evidence for our assumption that stratifying patients with AKI into different stages has the potential to improve the performance of mortality prediction because of AKI's complex etiology and pathophysiology.
2. The technique of constructing a mortality predictor based on different cohorts has the potential to consider different AKI causes. This predictive modelling strategy can be viewed as a case for local learning [26], which first splits the data space into multiple local areas and constructs different predictors for the areas.
3. Comparing the Stages, Stage-III shows a higher mortality predictive performance. One implication is the AKI patients in Stage-III who are going to die had more distinctive clinical manifestations compared to the control patients.
4. Comparing the performance of four predictors, GBDT acquires better results.

Comparison of feature group predictability with GBDT

Five different groups of features were employed to build mortality predictors for patients with different AKI stages. In this section we explored the prediction performance of GDBT with different feature groups within a 24 hour data observation window. The mortality prediction results are demonstrated in Table 2.

We observed feature groups played different roles when patients were in different AKI stages. For example, the laboratory features acquired better performance than other feature groups when patients were diagnosed with AKI Stage-

I. Chart features played a more important role in predicting mortality when patients were in Stage-II and III. One potential reason for this is the chart events had a finer time resolution, and for patients with a later stage of AKI, these events provided more in-time information of the patients' condition which progressed rapidly. In addition, there were no obvious differences between comorbidities and medications feature groups. The demographic feature group contributed the least to mortality prediction in patients with different stages.

Table 2 - The performance of different group features in all AKI stages on the basis of 24 hours data

	Demographics	**Medications**	**Comorbidities**	**Chart-events**	**Lab-events**
Stage-I	0.6823±0.0219	0.6971±0.0218	0.7027±0.0233	0.7031±0.0241	**0.7237±0.0223**
Stage-II	0.7029±0.0222	0.7128±0.0221	0.7139±0.0237	**0.7339±0.0246**	0.7331±0.0243
Stage-III	0.7134±0.0238	0.7236±0.0247	0.7239±0.0251	**0.7424±0.0255**	0.7334±0.0249

The important features chosen from all feature groups

There were 224 features extracted in total for mortality prediction in different AKI stages. The importance of each factor in mortality prediction was further explored in our experiments. The GBDT model was employed to acquire the importance score of each feature based on 24 hour data. The range of the feature importance score for mortality prediction in AKI Stage-I, Stage-II, and Stage-III were 0.0015-0.0457, 0.0015-0.0556, and 0.0019-0.0316, respectively. The top ten features are shown in Table 3.

From the table, we can observe HeartRate, CREATININE, CHLORIDE, WBC, HEMOGLOBIN, and RespRate were more important because there were strong associations between these features and mortality in patients with AKI. These results aligned well with some previous studies [27-32]. For example, the magnitude of increase in serum creatinine levels can determine the severity of AKI [27], which was associated with worse survival rates [28]. Chloride levels are also associated with the severity of AKI [29] and Shaw et al. demonstrated an association between higher intravenous chloride loads and hospital mortality [30].

Table 3 - The top 10 features selected from all feature groups on the basis of importance score

	Stage-I		**Stage-II**		**Stage-III**	
	Features	**Importance**	**Features**	**Importance**	**Features**	**Importance**
1	POTASSIUM_count	0.0457	HEMOGLOBIN_slope	0.0556	HeartRate_last	0.0316
2	metastatic_cancer	0.0365	HeartRate_last	0.0278	MeanBP_last	0.0247
3	CREATININE_avg	0.0350	CHLORIDE_slope	0.0200	HEMOGLOBIN_slope	0.0237
4	BUN_last	0.0289	WBC_min	0.0185	RespRate_last	0.0237
5	PTT_avg	0.0274	CREATININE_slope	0.0173	BICARBONATE_slope	0.0221
6	WBC_min	0.0243	CHLORIDE_max	0.0170	CREATININE_slope	0.0217
7	PLATELET_last	0.0223	SysBP_last	0.0168	BUN_slope	0.0198
8	HeartRate_max	0.0213	HeartRate_avg	0.0164	Glucose_min	0.0198
9	Temp_avg	0.0213	Temp_last	0.0156	DiasBP_last	0.0198
10	RespRate_avg	0.0182	HeartRate_max	0.0154	age	0.0178

Discussion and Conclusions

Accurate prediction of the mortality risk for AKI patients is helpful for clinicians to understand the condition of the patients and take appropriate actions. AKI has a complex etiology and pathophysiology, so it is challenging to construct a single model that can accurately predict the mortality risk over the entire AKI patient cohort. This study investigated the impact of different AKI subpopulations on the performance of mortality prediction. We stratified the AKI patients on the basis of their disease stage (I, II, and III), and then a mortality risk predictor was constructed for each patient cohort. Several popular machine learning models (e.g., logistic regression, RF, and GBDT) were built based on these subpopulations for the mortality prediction in patients with AKI. GBDT showed a better performance than other methods for the mortality prediction in this study.

Prior models of risk prediction of mortality in critically ill patients with AKI typically employed mixed cohorts [5,6]. The utilization of stratification mechanisms performed in this study provides a chance to predict mortality in patients with AKI specific to each stage. This technique of constructing a mortality predictor based on different cohorts has the potential to consider different AKI causes. In addition, dynamic real-time data may allow for clinical monitoring of mortality risk beyond a solely static prediction upon ICU arrival. The utilization of dynamic clinical monitoring algorithms for mortality prediction may allow for its incorporation into the electronic medical record [33].

With the ability to identify patients at high risk of mortality by employing real-time data may allow for initiation of earlier interventions to prevent or reduce mortality [34]. It might be useful to incorporate more information (e.g., imaging and genomic biomarkers) to further improve the performance of dynamic clinical mortality risk prediction models. In the future, we will consider some advanced models (e.g., recurrent network) with stronger learning capabilities to improve the performance of prediction.

Abstract

Diabetes is one of the largest global health emergencies of the 21st century. As a chronic disease, diabetes requires continuous medical care and constant patient self-management. Such care involves several stakeholders to improve health outcome and patient quality of life. This paper makes use of World Wide Web network analysis to highlight how stakeholders, providing information about online diabetes communities, link to each other. To achieve this, we capture the network of diabetes related websites as a digital trace of a non-digital phenomenon. Furthermore, this helps us to understand the current situation of diabetes organizations from a digital perspective. The methodology involves state-of-the-art tools to crawl (Hyphe) and visualize (Gephi) topic-sensitive networks. While neither of these tools is new in itself, their combination provides a promising way to analyze chronic disease stakeholders, organizations and communities, representing a large proportion of the knowledge and support diabetes patients have access to nowadays.

Keywords:

Diabetes Mellitus, Data Analysis, Data Visualization

Introduction

Diabetes is a chronic disease that occurs either when the pancreas does not produce enough insulin or when the body cannot effectively use the insulin it produces. According to a WHO report, an estimated 1.6 million deaths were directly caused by diabetes in 2015. Diabetes is also a major cause of blindness, renal failure, heart attacks, stroke, and lower limb amputations. The global economic cost of diabetes in 2014 was estimated to be US$612 billion. In the past two years, there were 415 million people with diabetes and this figure could rise to 642 million by 2040 [1].

Therefore, the recent dramatic rise of diabetes occurrences raises several questions that need to be addressed: how do people react after they are diagnosed with diabetes? What will they do for long term self-management? Where can they find relevant information and how easy is it to access it? How can they get psychological support and community help?

Diabetes can be treated and its consequences could be avoided or delayed with a specific diet, physical activity, medication and regular screening and treatment for complications. This helped us establish a preliminary list of possible key stakeholders: hospitals, physicians, research laboratories, pharmaceutical companies, medical and social relay structures, associations, health-related NGOs (non-governmental organizations), patients and their families, publications around diabetes care. All of these key diabetes actors play their own roles in the health care system but the nature of their relationship with each other, if any, remains unexplored outside of a patient-centric paradigm. Our hypothesis is that all stakeholders involved in diabetes have connections of some sort that can be revealed on the World Wide Web (abbreviated WWW or the Web) as an organized world of communities rather than a randomly organized network. This study aims to visualize the network of diabetes in the digital world represented by the Web to find key health web players connections with each other and to figure out the nature of their relationships.

Since its invention at the beginning of the 1990's, the Web has gradually become a major media platform itself hosting billions of resources accessible from a URL (Uniform Resource Locator) and dozens of sub-media in the form of specific websites hosting social media (like Facebook or Twitter), scientific knowledge or any other niche [2]. The Web is also the source of scientific investigation in itself and the network structure of a hyperlinked environment can be a rich source of information for whom looking for an effective means to collect, analyze and understand it [3; 4].

Exploring web structures is a proxy to human organizational structures [5]. Thus, we propose to map the hyperlink structure of diabetes stakeholders online. As a matter of fact, the web contains crucial aspects of the embodiment of social factors: personal blogs, institutional websites, health-oriented media, etc. To address the relationship with stakeholders in the diabetes area, we have examined how classical studies of network explorations can be brought to use in the context of diabetes to answer the following questions: Who is connected to whom by which means? Which organizations receive support from which ones? What resources or information are published through which platforms? What is the relationship between charities and governmental agencies? How individuals, companies, and organizations interact together? What is the ecosphere of the diabetes world? Therefore, our objective is to provide a replicable practical methodology to visualize the diabetes network of websites to make sure all key health web players have connections with one and another. And then, the previous questions can be addressed by studying the resulting map of diabetes online communities. A corollary expected impact is that this map can help the diabetics to access useful information regarding the neighboring context (such as information on diet or physical activity) that search engines do not display at first when looking for information about diabetes. At the same time,

this can also help pharmaceutical companies and NGOs to find influencers or key opinion leaders and help governmental agencies to take effective actions that reflect more efficiently the needs of diabetes communities. The visual representation will be helpful to quickly and effectively identify areas on the graph where improvements can be made.

To achieve our objectives, we take advantage of two state-of-art tools to assist the creation of website networks maps on diabetes. These two tools are combined in a robust methodology to collect the websites links and visualize it in detail. They are presented in the next section.

Background

Web networks belong to a complex network family that display properties such a power law distribution of the node degrees, high clustering coefficient or small world phenomenon [6]. While these properties often contribute to networks analysis, they are less effective to explore local structures inside the network. In order to do so, one can use mature large graphs visualization software. Graph visualization is an effective approach to spatialize the complex networks [7]. Using a visual display helps identify features in a network structure and data while relying on human very efficient perceptual abilities.

Creating and analyzing topic specific websites network is a methodology that has been applied to various contexts, although not yet in the healthcare field. In order to produce a visualization map of diabetes online communities which does not exist, we propose to combine two separate existing tools that could support the creation of such map in the context of diabetes. The map will provide proxies to generate key insights about the community.

Hyphe[1] is a web crawler[2], developed by the Médialab department of Sciences Po[3] in Paris, France, which is a tool to build web corpus by crawling web pages and generating networks between "web entities"[4] [8], connected with each other using hyperlinks. Hyphe has been successfully used in many published papers in social science. Hyphe allows to methodically gather web entities and visualize the network aiming at data journalists [9]. A team of librarians and sociologists delineated the debate on climate change on the web, notably measuring the unexpected large presence of climate skeptics [8]. Even more, people tried to study through the "Alternative for Germany" (AFD) Facebook wall which has already become one of the largest right-wing forums on the German-speaking internet to see how social media plays a crucial role for the party's mobilization strategy [10]. Yet, Hyphe has never been used in public health care to assess chronical disease online communities' structure. Moreover, even if Hyphe does include basic network visualization capabilities, it quickly reaches its limits as the networks grows beyond one hundred nodes.

Gephi[5] is an open source software for network visualization and analysis. It uses a 3D render engine to display large networks in real-time allowing researchers to explore their network. Gephi embeds a large variety of algorithms, filters and layouts to provide fine tuning over the network analysis and display [11]. It can deal with large network (i.e. over 20,000 nodes) and, because it is built on a multi-tasks model, it takes advantage of multi-core processors. In addition, nodes and edges designs can be personalized to create map-like visualization for communication purposes, ideal for a diabetes community map.

In this context, we have developed a methodology to uncover the online organization of diabetes websites. We leveraged and made best out of these tools to collect information using Hyphe and then visualize their properties and links using Gephi to produce the network on diabetes websites and finally provide key insights about this community.

Methods

The proposed methodology consists in a workflow embedding the following milestones:

- collecting diabetes community websites
- analyzing the resulting websites' structure
- visualizing the diabetes community network as a navigational map

These milestones can be decomposed into a more detailed process potentially applicable to any online community analysis (see figure 1). The methodology thus follows the following steps:

1. gathering a list of starting websites
2. creating a pre-crawl corpus
3. consolidating the pre-crawl corpus
4. launching and performing a full-scale crawling
5. extracting the websites network
6. visualizing the network structure

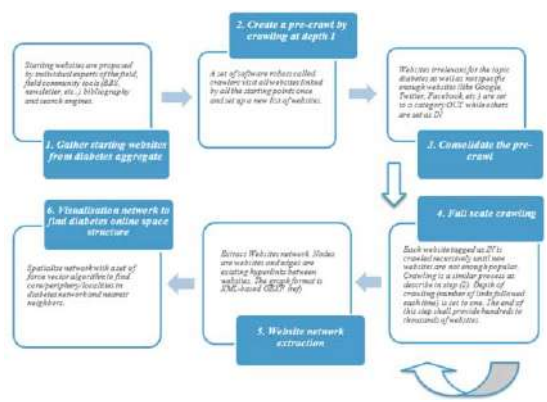

Figure 1– Illustration of the Workflow

These six steps are based on the following decision criteria.

Collection of starting websites: In order to explore an online community consisting of topic related websites, we need to define entry points into the community. These entry points will serve as a gate into the community by following the points links with a robot crawler carefully controlled. As the objective is to

[1] http://hyphe.medialab.sciences-po.fr (accessed on March 28th, 2019)

[2] A web crawler, sometimes called a spider, is an Internet bot that systematically browses the World Wide Web, typically for the purpose of Web indexing.

[3] Sciences-Po is an international research university located in Paris, ranking among the finest institutions in the fields of humanities and social sciences. Médialab is the tenth research center of Sciences-Po to help social sciences and humanities take full advantage of the huge amount of data made available by digitization.

[4] An entity of homogenous content often assimilated to a website hence the use of websites (itself a collection of smaller entities) but not always.

[5] https://gephi.org (accessed on March 28th, 2019)

explore all aspects of the community, the entry points shall reflect different points of view, opinions or topics the community might address so as to make sure to capture enough gates leading to the potential different parts of the final network. To ensure the diversity of entry points we selected a variety of sources starting with (a) two or more experts of the topic suggesting websites (for the diabetes topic, these experts were found in people who are living with diabetes and also working in the diabetes area for several years); (b) using various queries about diabetes on Google to ensure different results and (c) using diabetes community social network pages suggestions.

Choice of depth and the criteria to stop crawling: Once the starting web entities[6] are set, Hyphe offers the possibility to follow their hyperlinks (html markup <a> for anchor) automatically by detecting them in web pages. Hyphe have three depths for crawling, from 1 hyperlink away from the original web entity to 3 hyperlinks away to (3 clicks) depending on how deep the web entities shall be explored. As the web network follows a power law degree distribution, a crawl at depth 3 can potentially gather thousands of websites making it overwhelming for a human to properly assess each and every one of their individual membership to the targeted diabetes community. In this study, to avoid too much noise, we decided to consider only a slower depth level of 1, repeated several times if needed but only for targeted websites whose contribution to the topic is substantial. Moreover, the criteria to stop crawling new web entities depends on how much websites related to diabetes showing up in the final results. If no new diabetes-related entities show up after the crawling, then we considered having reached a local frontier in the diabetes community and proceed with others web entities until no more entities are left to be un-crawled. Then all topic frontiers are discovered. At last, considering the huge numbers of web entities, we did not consider in this first study the entities mentioned only once. It is a web network property that noticeable entities should be linked to by several neighbors. A web entity mentioned only once have little chance to be of importance [12]. We considered a minimum of 3 hyperlinks to an entity which we call it "popular" website for it to be eligible for an additional depth 1 crawling.

Cleaning process to feed each iteration of step 4 with an IN database: To clean the database after each one depth level iteration, we used two ways to make a decision and classify the websites as: IN, OUT or UNDECIDED. In this study, we classified the contents of the web entities strictly related to diabetes as IN; when nothing indicates a potential diabetes-related content, we classified it as OUT[7]; finally, ambiguous websites that mention diabetes among other topics were categorized as UNDECIDED waiting for further in-depth analysis to lift the veil on their classification. The first way to classify the entities is to automatically select in the database the URL string containing the word diabetes and default them as IN. The second way to classify the entities is to select manually the class after a review of the content of each website. This is done by opening its URL in a browser. After the classification, we can filter the database to only retain the IN websites.

Choice of the final pattern in step 6 (Gephi): Once the "pre-crawl" was created by crawling the starting websites at depth 1 and cleaning them, we applied the crawl & clean process again several times to get the full-scale crawling (step 4). Each web entity regarded as IN is crawled recursively until no new websites are popular enough which are cited above 3 times to be included or are all off-topic (OUT or UNDECIDED). The end of this step provides with hundreds of IN websites and their hyperlinks. Then we exported the websites network as a graph in the XML-based GEXF format. In the final network, nodes are websites and edges are existing hyperlinks found between websites (step 5) weighted by count of occurrences. Lastly, we imported the graph to Gephi to visualize the hyperlink structure of diabetes online communities (step 6). In order to do so, after importing the network, we used a force directed "Force Atlas 2" [13] layout well adapted to scale-free networks to spatialize the nodes and their edges. The edges represent hyperlinks only. Therefore, the proximity of the nodes is the result of the force vector-based layout algorithm only and do not demonstrate any physical proximity whatsoever.

Results

As the starting websites were proposed by individual experts of the field, by field community tools (BBS, newsletters, etc.) bibliography and search engines like Google, we combined all the resources and picked up most well-known 15 websites which represent different aspects in the diabetes world as the starting points to feed Hyphe. The following table describes these 15 websites.

Table 1– Starting Websites for Crawling

Different Aspects	Websites
1 portal website	http://www.childrenwithdiabetes.com

After the web crawler Hyphe visited all websites linked by all the starting points once, we set up a new list of websites and

[6] A web entity is a web page (a unique URL leading to a media displayed as a unique page) or a collection of pages relevant for a topic. It can range from a single page to a sub domain of a website to the whole website itself. Website is the web entity by default on Hyphe but this can be tuned to adapt to the web heterogeneity of content structure.

[7] Websites very often provide many links to tools or software or popular social network that are not related to the topic at hand but rather offer another medium opportunity (ex linkedin.com, Instagram.com, google.com, etc.).

use the cleaning process to make sure we only keep the IN websites which are strictly talking about diabetes. Once Hyphe discovers as many web entities as possible and their hyperlinks, we get the final number of the DISCOVERED web pages in Hyphe overview part. Each of the discovered websites then is classified as IN/OUT/UNDECIDED. In the end, we successfully captured 430 IN websites with 6587 hyperlinks, each website contains information about diabetes or some aspects of it together with some basic tags on the nature and content of these websites. Figure 2 is the diabetes hyperlink structure as visualized by Hyphe directly. This graph is messy and while it shows a strong core component, there is no visible underlying structure.

Figure 2– Diabetes Hyperlink Structure with Basic Force Directed Layout

In order to visualize the diabetes online communities in more detail, we created the visualization in Gephi. Then to provide a first view at the sub-communities inside the diabetes community we applied a community detection algorithm aimed at detecting clusters of similarly connected nodes [14]. It does so by maximizing the modularity quality metric in all possible partitions. Modularity measures the difference between the edge density in the partition and a randomized graph with the same number of nodes and the same degree distribution [15]. Then a color map is associated with the 5 discovered communities class resulting in the figure 3.

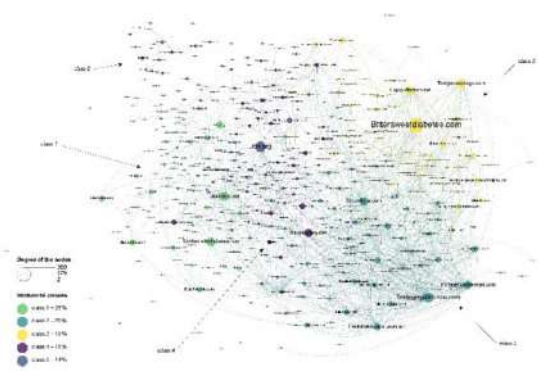

Figure 3– Diabetes Hyperlink Structure with Force Atlas 2 Layout and Communities

The result shows that diabetes online community has its own space and is organized with clusters and distribution of websites of relative importance. More analysis is necessary to show exactly what is the topic but we get a general idea that they don't belong together by chance. It is remarkable that the algorithm working only on node probability highlight these communities that in real life share a common interest when we read their content. If we want to have some general ideas about which community mainly talking about which topic, we need to manually or semantically annotate of websites using terminology of the diabetes fields would be a good way towards explanation the communities' contents. Moreover, we used a degree centrality algorithm [15] which assigns an importance score based on the number of links held by each node to get several central websites in our 430 websites diabetes digital. Node Degree reveals the number of IN and OUT hyperlinks which are from 1 to 303 related to one web entity. Among them:

- bittersweetdiabetes.com is the most popular blog.
- medtronicdiabetes.com, dexcom.com, novonordisk.com, lilly.com, myomnipod.com, tandemdiabetes.com are the main pharmaceutical companies in diabetes industry.
- jdrf.org is the most authoritative association.
- diabetesdaily.com is the mainstream media website talking about diabetes.
- childrenwithdiabetes.com is the largest diabetes online community.
- diabeteseducator.org is the biggest diabetes society.
- integrateddiabetes.com is one consulting institution which offers integrated diabetes consulting services.

Discussion

This approach demonstrates the potential in analyzing and visualizing the diabetes network online. Using Hyphe to extract 430 specific and relative websites, people with diabetes can easily navigate most relevant websites to obtain information and knowledge about their conditions or different aspects of it. Furthermore, such a strong community can offer support from a knowledge and a psychology point of view. Search engine like Google can find global websites by considering their authority in the network such as general organizations like International Diabetes Federation (IDF), American Diabetes Association (ADA), Diabetes Australia, etc. But they cannot offer people with diabetes detailed information to help people manage their diabetes and improve the quality of their lives efficiently. 80% of the iceberg is still under the sea and is difficult to reveal. Hyphe and our methodology is proven reliable to explore the localities, and we were able to find more interesting websites such as personal blogs sharing the stories of the real diabetes daily lives including their struggles to combat diabetes, we can also find different diabetes online communities focusing on the different aspects, nutrition, sports, camping, etc. In addition, some websites are more difficult to detect when they talk about some rare issues, such as diabulimia which is an eating disorder related to type 1 diabetes. However, this study is still limited due to the initial websites where English is solo language to feed hyphe. As a result, it leads to a majority of English-domain websites in the final map despite having some multilingual websites coming from US (using English and Spanish) or Canada (using English and French). Due to the crawler depth limitation and the relatively small number of websites chosen to be presented in the final map, it cannot show the whole world with diabetes but just part of it. A deeper crawl and a more web page lists by reviewing would undoubtedly have more information covered. Future work will focus on the semantic analysis on URLs to indicate to which extend the community is well focused on diabetes topics in general with some underlying trends and identify areas where improvements can be made in the diabetes real world.

Conclusion

We have successfully shown that all stakeholders involved in diabetes have connections on the World Wide Web as an organized world of communities rather than a randomly organized network. In this study, we also provide a replicable practical methodology which combines crawl and visualize tools to analyze a web-based network of diabetes. It is a novel promising way to analyze further chronic disease stakeholders' organizations and communities networking relationships.

Abstract

This study presents an approach for mining structured information from clinical narratives in Electronic Health Records (EHRs) by using Rich Text Formatted (RTF) records. RTF is adopted by many medical information management systems. There is rich structural information in these files which can be extracted and interpreted, yet such information is largely ignored. We investigate multiple types of EHR narratives in the Enterprise Data Warehouse from a multisite large healthcare chain consisting of both, an academic medical center and community hospitals. We focus on the RTF constructs related to tables and sections that are not available in plain text EHR narratives. We show how to parse these RTF constructs, analyze their prevalence and characteristics in the context of multiple types of EHR narratives. Our case study demonstrates the additional utility of the features derived from RTF constructs over plain text oriented NLP.

Keywords:

Electronic Health Records, Natural Language Processing, Information Management

Introduction

Nationwide adoption of Electronic Health Records (EHRs) has given rise to a large amount of digital health data, which can be used for secondary analysis [1]. The data within these records are expected to improve efficiency and overall healthcare. In addition to structured data, a large amount of clinically relevant data remains present in an unstructured free-text format. These narratives are largely variable between institutions and even healthcare professionals within them making it difficult for data extraction. In order to optimize research to improve quality or clinical needs, a systematic representation of EHRs for both structured and unstructured data is necessary. For instance, computational phenotyping has been used to mine or predict both clinically and scientifically significant phenotypes from structured EHR data, unstructured clinical narratives, and their combinations [2]. Computational phenotyping calls for efficient approaches to mine a large volume of clinical narratives for structured information on patient pathophysiology. To this end, natural language processing (NLP) is widely utilized as an effective tool for turning unstructured narratives into structured information [3].

Applications of language processing methods to clinical data in many projects have achieved reasonable success in analyzing various types of biomedical data, including clinical narratives [4, 5]. However, when it comes to EHRs, there is a gap between what data can support and what the method asks for. NLP generally assumes plain text as inputs, but clinical narratives in EHR often possess rich-text format (RTF) such as tables, different fonts, and font sizes. The majority of studies ignore the informative RTF information in EHR narratives. To our knowledge, there are very few, if any, studies that process RTF EHR narratives and utilize the formatting for additional information. When evaluating numerous clinical note repositories for shared task challenges (e.g., challenges from BioNLP [6-8], i2b2 [9, 10], SemEval [11, 12], and BioCreative [13]), there are few RTF EHR narratives.

The task of processing RTF documents is relatively straightforward though non-trivial. Despite the existence of standard packages to parse RTF or convert it to other formats such as HTML, research in the field of biomedical NLP largely ignores RTF and still uses plain-text as their raw input. Typical NLP processes include sentence breaking, word tokenization, part-of-speech tagging, constituency or dependency parsing, named entity detection, semantic role labeling, event frame extraction, etc. These processes largely ignore the formatting information. As a result, EHR databases (e.g., Enterprise Data Warehouse) for medical institutions often additionally store the plain text format of EHR narratives in addition to their RTF counterparts, or simply store in plain text format instead of RTF. Furthermore, information loss can sometimes occur during the conversion of RTF to plain-text formats.

Interestingly, researchers who focus on studying structured data do not treat EHR narratives as structured and often rely on NLP to extract structured pieces out of EHR narratives from plain text. Many studies utilize generic medical NLP systems such as MedLEE [14], MetaMap [15], cTakes [16], or GATE [17]. Other studies take advantage of special purpose NLP systems such as MedEx [18] for medication detection or TEES [19] for medication event frame extraction. Finally, many authors developed their NLP components or even systems to serve specific data mining tasks such as computational phenotyping [20-27].

Our study addresses the gap between structured EHR and clinical NLP research regarding the usage of rich-text formatted EHR narratives. In the current study we demonstrate how to extract the structured pieces (e.g., tables and section headings) from RTF EHR narratives and investigate the prevalence of such structures in EHR narratives. Our objective is to expose the need to start from rich-text formatted EHR narratives, making it suitable for NLP or structured EHR research and demonstrate that this can be done without much hassle. We also perform a case study to show the efficacy of mined structured information in improving computational phenotyping tasks.

Methods

A. Dataset

We constructed multiple rich-text formatted corpora consisting of different types of EHR narratives by querying Northwestern Medicine Enterprise Data Warehouse (NMEDW). The NMEDW is a joint initiative between the Northwestern University Feinberg School of Medicine and Northwestern Memorial HealthCare [28]. The NMEDW is a multi-center data repository with heterogeneous types of data. We constructed multiple patient corpora over a specific period from breast cancer patients. In this study the progress notes were queried, which are records of events during a patient's office visit or hospitalization and can be used to communicate opinions, findings, and plans between healthcare professionals. A well-documented progress note is complete, accurate, and concise for the care delivered, including diagnosis and treatments [29]. We extracted progress notes that were dated between 1 July 2015 and 1 October 2015. In order to test performance evaluation we extracted progress notes for breast cancer patients from a previous study [30], matching their plain text counterparts as a use case.

B. RTF processing

Many word processors as well as many of the medical information management systems support the reading and writing of rich-text format (RTF) files. In this study we found and identified the important RTF structural information from medical narratives, namely tables and section headings. A medical history table may contain several columns with headings stressed in bold, underlined, or inserted as the first line of the table. These tables often summarize important clinical information such as prescriptions, allergies, or medical histories. The format of RTF text is defined by groups, control-words, and delimiters. Groups are enclosed in braces, and control-words start with backslash (\) characters. For example, a 2-by-2 table and the corresponding RTF code is shown in Figure 1.

cell 11	cell 12
cell 21	cell 22

(a)

```
1  code{\rtf1\ansi\deff0
2  \trowd
3  \cellx1000
4  \cellx2000
5  cell 11\intbl\cell
6  cell 12\intbl\cell
7  \row
8  \trowd
9  \cellx1000
10 \cellx2000
11 cell 21\intbl\cell
12 cell 22\intbl\cell
13 \row}
```

(b)

Figure 1: A 2-by-2 table and the corresponding RTF code. (a) A 2-by-2 table defined by the RTF code (b) RTF code snippet that defines a 2-by-2 table.

As illustrated in Figure 1, the codes are within closed braces with control-words in the first line indicating the format and encoding used in this group. Each row in the table begins with a "\trowd" tag and ends with a "\row" tag. Thus, lines 2-7 define the first row and lines 8-13 defines the second row. The "\cellx###" tag declares the position of the right side of a cell and the "\cell" tag denotes the end of a cell. The above code generates a 2-by-2 table with cell widths equal to 1000. Searching for the "\trowd" tag in RTF files allows for table discovery. In addition to "\trowd" tags, many tables in medical notes are also defined by tab-delimited-tables, i.e., cells in a table row are separated by tab characters. To identify these tab characters, RTF uses the "\tab" tag.

Section headings in medical notes often describe the topic of that section. The information within a section is usually cohesive and can easily be interpreted by both NLP programs and manual curation. As a result, the Common Data Model of Observational Medical Outcomes Partnership specifies that the sections be stored as annotations to facilitate portable computational phenotyping (https://github.com/OHDSI/CommonDataModel) [accessed on March 20, 2019]. Section headings tend to share some characteristics such as bold or underlined formatting font. The headings may or may not occupy a whole line and may or may not be capitalized or be followed by a colon. Heading levels are often indicated by indentation. In summary, section headings provide important information and the RTF format allows us to apply specific searching criteria to accurately and efficiently identify section headings and their levels.

However, the syntax of RTF is relatively more obscure and lacks powerful software packages for data parsing compared to more popular formats such as HTML, XML, and LaTex. On the other hand, HTML is a much more commonly used format with many existing tools for parsing and extraction of structured information, such as Python's BeautifulSoup package (https://www.crummy.com/software/BeautifulSoup/bs4/doc/) [accessed on March 20, 2019]. To address this, we convert RTF to HTML using LibreOffice prior to parsing any data and then analyze the structures using Python's BeautifulSoup web scraping package. For regular tables we searched for the HTML <table> tag, and summarized the rows by counting the row tag <tr>. For tab-delimited-tables, we matched them using the regular expression "\S+ *\t *\S+", i.e., two non-space characters separated by a tab and zero or more space characters. The section headings in the documents are usually stressed in bold (HTML tag of <b>) or with an underline (HTML tag of <u>). The stressed phrase occupy a whole line.

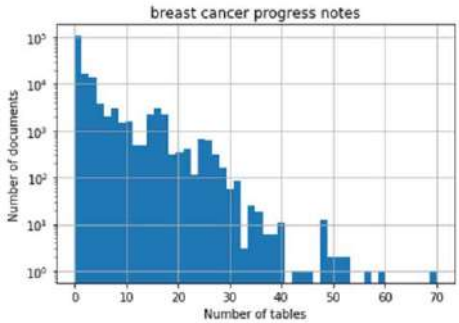
Results

A. Parsing the tables

In our study, we extracted and used 158,948 breast cancer progress notes. Given that column names are often listed in the first row of a table, we also extracted the cells in the first rows to summarize the topic of the tables. The distribution of the number of tables and the most common first rows of these tables are summarized in Figure 2. A Histogram indicating table frequency is shown on the upper panel of the figures. Note that the y-axis is in log-scale. The number of tables in a medical note approximately follows an exponential distribution – the probability decreases by a factor of 10 for roughly every 10 additional tables. The most common first rows are summarized on the lower panel of the figures. Adjacent cells are separated by a comma.

In breast cancer progress notes, the most common first row contains a single cell with the most common terms being "Allergies" and "Past Medical History", making up 16.3% and

16.2% of the notes respectively. The 16.3% of the medical notes have an Allergies table. In addition to these terms, we also identified terms involving lab results, vital information, complaints, current prescriptions, illness history, medication list, and physical exam information (Figure 2). It is evident that the related tables belong to the pre-formatted template.



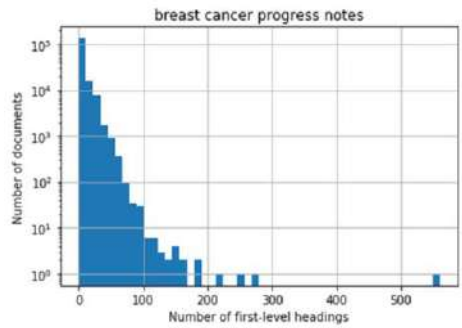
Most common First Rows	Counts	Ratio
Allergies	25855	16.3%
Past Medical History	25750	16.2%
Past Surgical History	20419	12.8%
Lab Results	11444	7.2%
Filed Vitals	11076	7.0%
Chief Complaint	10773	6.8%
Current Outpatient Prescrip-tions	10506	6.6%
History of Present Illness	9671	6.1%
Medication List	9650	6.1%
Physical Exam	9642	6.1%

Figure 2: Histogram of the number of tables and the most common first rows in breast cancer progress notes. The "Ratio" column is the count of the first rows over the total number of notes of this type.

B. Parsing the section headings

Section headings often contain critical information that can be used to identify key features. We searched the section headings in progress notes of patients with breast cancer from the NMEDW. Among the 158,948 breast cancer progress notes we found 46.6% files have first level headings and 2.4% files have higher level headings. Histograms of the number of first-level section headings (section headings with the smallest indentation) in the notes are summarized in Figure 3. The number of headings in a note generally follows an exponential distribution. The lower panel of the figures shows the most common first-level section headings.

In the breast cancer progress notes, we found the most common heading to be "Allergies" similar to the most common first row found in these notes. Interestingly, we also identified headings involving Physical Exams, Lab Results, and Medication Lists, which are also the most common first rows of tables in these notes (Figure 3). These results suggest that section headings are important too. In addition, the structure of a progress note can be better understood by combining data from tables and section headings. Note that the vital signs (which is the first row of a table) are also deemed as the section headings because they are usually emphasized in bold with occupying a whole line.



Most common First Level Headings	Counts	Ratio
Allergies	11599	7.3%
Ref Range	11395	7.2%
Physical Exam	10942	6.9%
Impression and Plan	10829	6.8%
Diagnosis	10725	6.7%
Physical Exam	10712	6.7%
Lab Results	10383	6.5%
History of Present Illness	10018	6.3%
Medication List	9972	6.3%
Chief Complaint	9964	6.3%

Figure 3: Histogram of the number of first-level section headings, and the most common first-level headings in the breast cancer progress notes. Note that the y-axis is in log-scale. The "Ratio" column is the count of headings over the total number of notes of this type.

C. Case study on breast cancer phenotyping

The structured data extracted from the medical notes can be used as features in machine learning models to improve their performances. As a case study, we added the structure information extracted to identify breast cancer patients with contralateral events. The problem was investigated in our previous study [30], with a cohort of 1063 patients who were diagnosed with breast cancer. In the cohort, 33 patients were identified with contralateral events (the case group). We previously identified the breast cancer contralateral events from the cohort using progress notes and counts of pathology reports. In our previous study, the progress notes were treated as plain text; structured information was ignored. This previous study was used as a baseline because it utilized an 8-step, relatively sophisticated NLP system and applied extensive feature engineering (e.g., filtered powerset method) to build the classification model. Thus, our previous system provides competitive plain-text oriented NLP baselines. In this case study, we pulled out the corresponding RTF versions of the same progress notes for the 1063 patients. We extracted the past medical history, past surgical history, and lab test results from the tables in the progress notes and included them as features in the classification model. For lab test results, we used the reference ranges presented in the test result tables to determine whether the measured results are higher or lower than the ranges. We chose common features that occured in at least 10 patients' progress notes, resulting in 37 medical history entries, 33 surgical history entries, and 10 abnormal lab test features. The most common medical/surgical history entries and abnormal lab tests are summarized in Table 1.

We encoded the structured features as whether a patient had a condition in the past medical/surgical history and whether a lab test is below or above the reference range. We adopted the same train-test split (7:3) and the same evaluation metric (AUC) as

in our previous study [30]. We used logistic regression (LR) model and 5-fold cross-validation to tune the regularization factor of LR, and obtained an AUC of 0.89 on the held-out test set. By building an ensemble model that averages the predicted probabilities from the structured-feature model and the NLP-feature model, an AUC of 0.92 was obtained. The model performance was compared with previous results in Table 2. Using much fewer structured features we can achieve a comparable classification performance using unstructured MetaMap CUI features (83 vs. 1285). Combining the two models further improves the classification performance. Note that the pathology report count is essentially a type of structured feature, though not derived from RTF tables [30]. For a fair comparison, the top 3 models in Table 2 (including the 3rd model that was reported as the best model in our previous study [30]) all use the pathology report count. In this case study, including the structured features improved the performance from 0.89 to 0.92. The overall results suggest that structured features extracted from RTF tables can be effective features in computational phenotyping tasks and may work even better when combined with unstructured features extracted by NLP.

Table 1: Most common medical/surgical history entries and abnormal lab tests.

Common Medical History entries (# of occurrences)	Common Surgical History entries (# of occurrences)	Common Abnormal Lab test (# of occurrences)
Breast cancer (313)	Lumpectomy (213)	MCHC low (112)
Hypertension (213)	Right breast (81)	Blood urea nitrogen high (32)
Hyperlipidemia (134)	Colonoscopy (78)	Hemoglobin low (23)
Disorder of refraction and accommodation (77)	Removal of tonsils and adenoids (78)	Albumin low (21)
Hypothyroidism (72)	Left breast (73)	MCH low (20)

Table 2: Comparison of classification performance on the held-out test set using different features. Shaded parts indicate the results from our previous study[30] that treated clinical narratives as plain text.

Model	Number of Features	Test AUC
Combined MetaMap + Structured Features + Pathology Report Count	1365	0.92
Structured Features + Pathology Report Count	83	0.89
Combined MetaMap + Pathology Report Count	1285	0.89
Combined MetaMap	1282	0.68
Pathology Report Count	3	0.67
Full MetaMap without Combination	42	0.30
Bag of Words	55192	0.70

Discussion

This study is a preliminary work that tries to introduce the informatics community to the rich-text formatted EHR narratives but it comes with limitations. First and foremost, we note that different institutions may have different clinical documentation systems, templates, and styles, especially across different healthcare chains on a national scale. Although our study uses multi-site data (a mixture of academic medical center and community hospitals) from regional healthcare chains, we expect challenges may arise when generalizing our study on a national scale. In addition, different healthcare chains may use different EHR systems with possible variations in the prevalence of the rich-text structures. Thus, we plan to expand our study in the future to include more types of EHR narratives, from different EHR systems, and systematically study their variations to better inform the data mining practice for EHR. We will also study the potential impact of rich-text format on improving the interoperability in health information exchange and portable computational phenotyping, as it brings more regularity to the otherwise "free" text.

Conclusion

Electronic Health Records (EHR) narratives are not equivalent to plain text but contain important structural information. One common medical note file format for archived EHR narratives is rich text format (RTF). We have utilized the low-level syntax tags in RTF files to mine the structured information of multiple types of EHR narratives. We ran our parsing systems across RTF clinical narratives from multiple community hospitals and an academic medical center, and successfully extracted tables and section headings from them. The tables contain patient allergies, medical histories, lab test results, prescriptions, vital signs, and even follow-up appointment information. A long EHR narrative may be divided into several sections, with each section containing cohesive information of a perspective and context of a patient's pathophysiologic profile. Properly recognizing the tables and sections is useful to extract structured information from EHR and prevents unnecessary input chunks of text to NLP systems. In addition, targeted NLP algorithms can be further applied to individual sections to extract information more precisely. Our case study on breast cancer phenotyping shows that tasks such as computational phenotyping can benefit from properly extracted structural information (e.g., tables) and more accurate NLP, thanks to the usage of RTF structural information – a hidden and often ignored trove in EHR.

Abstract

Huntington Disease (HD) is a genetic neurodegenerative disease which leads to involuntary movements and impaired balance. These changes have been quantified using footstep pressure sensor mats such as Protokinetics' Zeno Walkway. Drawing from distances between recorded footsteps, patients' disease severity have been measured in terms of high level gait characteristics such as gait width and stride length. However, little attention has been paid to the pressure data collected during formation of individual footsteps. This work investigates the potential of classifying patient disease severity based on individual footstep pressure data using deep learning techniques. Using the Motor Subscale of the Unified HD Rating Scale (UHDRS) as the gold standard, our experiments showed that using VGG16 and similar modules can achieve classification accuracy of 89%. Image pre-processing are key steps for better model performance. This classification accuracy is compared to results based on 3D CNN (82%) and SVM (86.9%).

Keywords:

Huntington Disease, Deep Learning, Diskynesias, Gait Analysis

Introduction

Huntington disease (HD) is a rare genetic neurodegenerative disease in which patients can have different levels of motor impairment and abnormal gait patterns [3]. In this project, deep learning is used to develop a novel evaluation method to classify patients' severity of disease, based on their footstep patterns.

Degeneration of motor function experienced by Huntington disease patients results in impaired balance and involuntary movements, which can be recorded using electronic pressure sensitive channels. All previous studies in this field analyzed high level gait characteristics, such as stride and tempo [9], calculated from the sensor mat based on distances between recorded footsteps. However, no one has studied whether the information contained in the pressure data of individual footsteps can provide a deeper understanding of the nature of the disease. This paper presents a novel approach to classify HD severity based on foot pressure data obtained from Protokinetics' ZenoTM Walkway.

Patients diagnosed with HD were grouped according to their UHDRS motor score, which is currently the gold standard in measuring motor disease severity. A classifier was then developed, and its parameters were optimized using cross-validation. The classifier was trained on the formation of the footprints.

Huntington Disease

Huntington disease is a rare autosomal dominant disease, also known as Huntington's chorea. Patients generally become unwell from middle age and have motor, cognitive, and mental health symptoms. The clinical symptoms of Huntington's disease are complex and variable, but patients invariably worsen over time [4]. The main features are dance-like involuntary movements with a progressive dementia. Huntington Disease is caused by expanded polynucleotide (CAG) repeats on the *Huntingtin* gene, which affect different molecular pathways and ultimately lead to neurological dysfunction and degradation [8].

Clinical Assessment of HD

The Unified Huntington's Disease Rating Scale (UHDRS) was developed as a clinical rating scale to assess four domains of clinical performance and capacity in HD: motor function, cognitive function, behavioral abnormalities, and functional capacity. The motor subscale is currently regarded as the gold standard in motor disease severity assessment, and is used as the endpoint in a number of clinical trials. Other clinical tests commonly used to determine the degree of motor function are the Timed Up and Go (TUG) test, the functional coverage test (FRT) and the Tinetti Performance Oriented Mobility Assessment (POMA) [1].

HD's Impact on Gait

The gait abnormalities in Huntington disease can be summarized as: (1) involuntary movements typically seen as chorea (sudden movements of the hands, feet, and facial muscles), and (2) worsening of balance and voluntary movement control [6]. The latter includes general slowing movements as well as impaired balance and gait.

High level gait charactertistics, such as gait width and stride length, have been extensively studied in HD. As can be seen from the Figure 1, three consecutive footprints form a gait cycle and include information such as stride width, stride length, and step size. These features can be measured and used for classification.

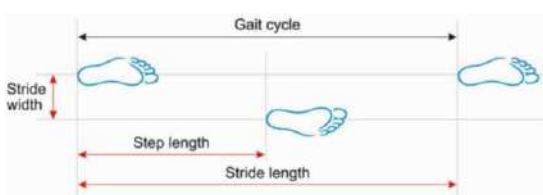

Figure 1 – Gait Cycle[5]

This study proposes to examine the pressure data of individual footsteps for the first time, rather than the high level gait pattern data.

Methods

Hardware for Pressure Data Collection (ProtoKinetics ZenoTM Walkway System)

The ProtoKinetics' ZenoTM walkway system consists of three layers - the pressure sensor and the carpet of the circuit are embedded on top of the protective substrate, hidden beneath the top layer of the linoleum. The pressure sensor grid has a high spatial resolution and is spaced 1.27 cm along the two axes. Due to the protective layered structure, sidewalks are compatible with auxiliary equipment, such as walking sticks and walking racks, without distorting the gait analysis results. The ProtoKinetics Motion Analysis Software (PKMAS) was used to collect and collate footstep pressure data.

Data Acquisition

Subjects and conditions

Participants included individuals who underwent rehabilitation at the Huntington Disease rehabilitation service at St. Joseph's Hospital, Auburn. Each subject has been clinically diagnosed with HD prior to starting the study. All participants gave their informed consent for the HD-FALLS study, which has been approved by the St Vincent's Hospital (Sydney) Human Research Ethics Committee (Reference HREC/13/SVH/378).

Clinical Assessment

Clinical and Zeno Walkway data were collected from participants of HD-FALLS. Although the study collected a broader data, the most relevant to this study is the UHDRS motor score.

Data format and visualization

Patients' pressure data were measured by Zeno Walkway and collected as text files, as indicated below:

Time (sec.);X (sensor number);Y (sensor number);Level

Figure 2 – Pressure Data in Text File

Text files were converted to video using python code. The basic idea of this code was to save the active sensor with the same time information as one frame. All saved frames were then animated as footprint videos. The video speed was 30 fps.

Figure 3 and 4 show the visualization of healthy subject's walking and HD patient's walking.

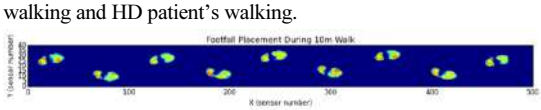

Figure 3 – Visualization of a Healthy Subject's Walk Along the ZenoTM Walkway

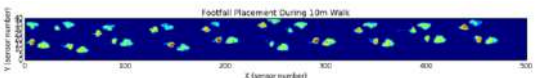

Figure 4 – Visualization of an HD Subject's Walk Along the ZenoTM Walkway

Data Preprocessing

The data preprocessing for novel method is discussed here which included denoise and normalization, and data augmentation. The preprocessing for the other two comparison methods is discussed in corresponding result parts.

Denoise and normalization

Single footprint pictures help better study the formation of the footprint. Four angular coordinates of the footprint were collected, and corresponding images were cut as shown in Figure 5.

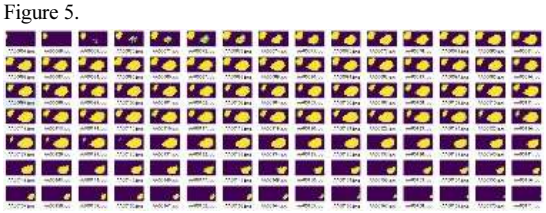

Figure 5 –Collected Footprint

After collecting the footprint, the color image was turned into a grayscale image with a range of pixel values from 0 to 255. To eliminate background noise, the pixel value below 50 was set to 255 to remove the background, but the footprint pixel was saved as original value. The resulting images of individual footprints were concatenated into a large mosaic image as shown in Figure 6.

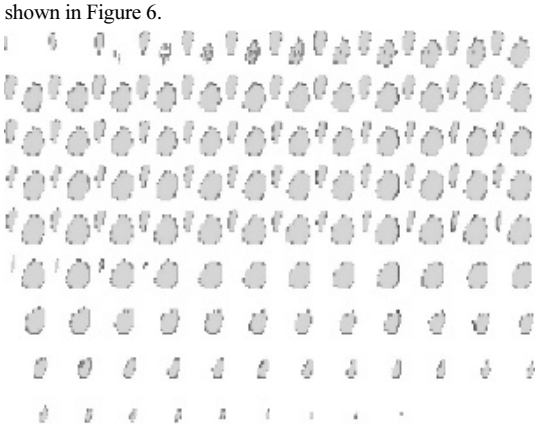

Figure 6 – Footprint Formation Process in Greyscale (Denoised)

The picture shows that the initial touch position (upper left corner) and the last touch (lower right corner). Most grey areas have the same level of pressure, but some dark points on the edges indicate lower pressure levels.

Data augmentation

A cohort of 12 patients included six patients each with low and high severity disease for our best approach. A 6-fold validation was used for model training. To clarify, five patients were randomly picked from one group as training data and 1 patient was left for model validation. 18 footprints were collected from each patient. In total, 180 mosaic images were used for training and 36 images were used for validation.

180 images were still not enough for deep learning training, especially for model with many parameters such as VGG16. However, as a rare disease, it is often hard to obtain many HD patients for research. To enlarge the dataset without collecting new footprint, the built-in function ImageDataGenerator was used. The ImageDataGenerator is a matured function that specializes in data augmentation. There are some parameters to set before it can create new images. In our project, shear range and zoom range were both set at 0.2. Horizontal flip was set as True. A schematic image in Figure 7 shows the basic operation in ImageDataGenerator.

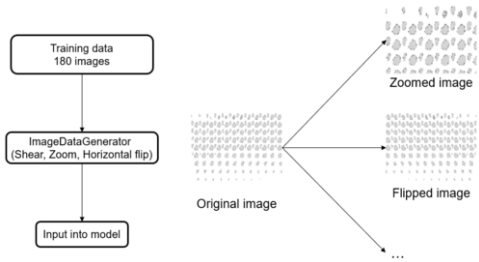

Figure 7 – Workflow for ImageDataGenerator

Modeling

The model for the pressure data of individual footsteps was easy and simple but models for control methods were advanced. It showed that pressure data of individual footsteps have rich features and can achieve good performance even without combining high level features.

For our novel method, a pretrained VGG16 was used for the purpose of feature extraction. VGG16 is a convolutional neural network architecture named after the Visual Geometry Group developed by Oxford University. It was used to win the 2014 ILSVR (ImageNet) competition [7]. So far, it is still considered as an excellent visual model and has outperformed more advancements in some areas, such as Inception and ResNet [2]. Since we have a small training data set, too many parameters can lead to overfitting. Compared to Inception and ResNet, VGG16 has fewer parameters and shorter training time.

A 3D convolution neural network was trained on the same patients data for comparing performance. The 3D convolution calculates features from spatial and temporal dimensions. 3D convolution is achieved by convolving a 3D kernel to a cube formed by stacking multiple consecutive frames together. With this configuration, the feature map in the convolutional layer is connected to consecutive frames in the previous layer, thereby capturing gait information.

3D Convolution neural network is designed to analyse videos or consecutive frames. In this project, normal pressure images were captured at 10Hz from patients' gait pressure video.

The inputs consisted of three types of images: Footprint pressure images, x gradient and y gradient images (Figure 9).

The x and y gradient images were obtained from normal images using the Prewitt operator. 30 contiguous frames were used as an input unit for each type of image group.

$$G_x = \begin{bmatrix} 1 & 0 & -1 \\ 1 & 0 & -1 \\ 1 & 0 & -1 \end{bmatrix} \quad G_y = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & -1 \end{bmatrix}$$

Figure 8 – Prewitt Operator for (x,y) Gradient

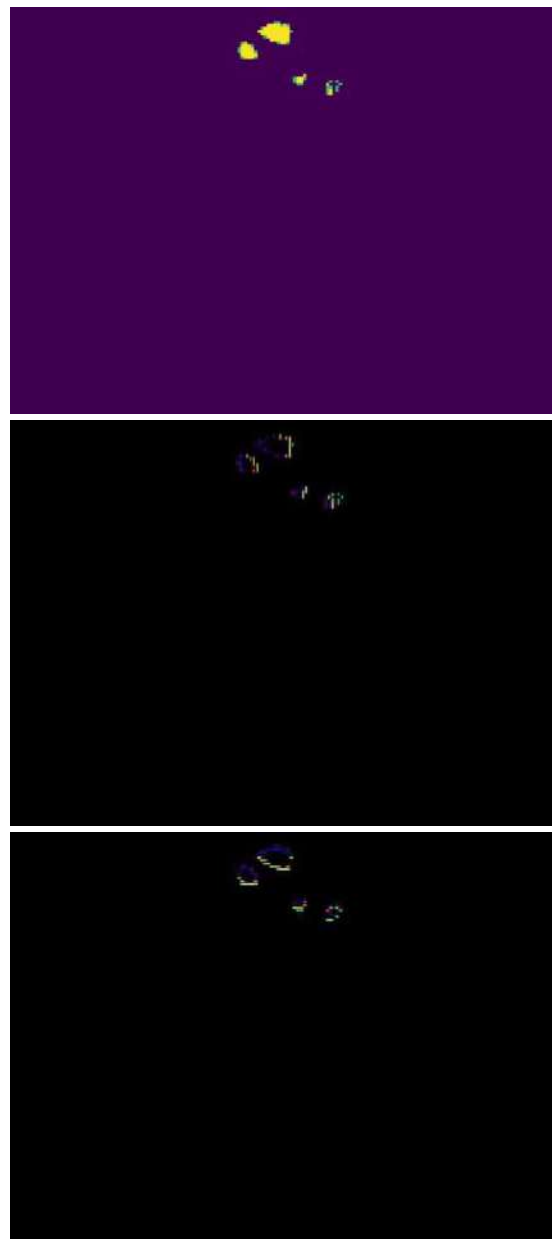

Figure 9 – Normal Pressure Image, (x,y) Gradients

SVM was also used for comparison. The SVM learning algorithm has several parameters that include the kernel function (used to transform the dataset into a higher dimensional feature space), the kernel parameters (which depend on the choice of kernel), and the margin parameter. The values of these parameters can significantly impact classification accuracy and thus they need to be tuned to develop the optimal model for a given problem. A grid search was therefore undertaken to optimize the combination of values for these three parameters.

The datasets used for SVM were pressure pattern feature set and gait pattern feature set (Figure 10). The pressure pattern feature set represented the footfall over a 30 cm x 20 cm area within a 3 second duration. These features, which represented the temporal variation in footfall pressure distribution for each step,

comprised the feature set that shall hereby be referred to as the pressure pattern feature set.

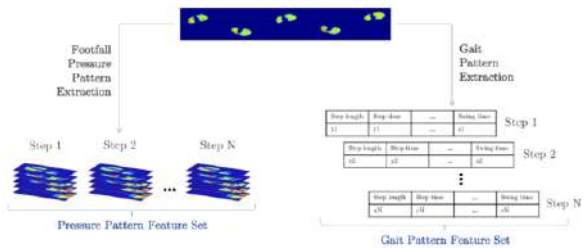

Figure 10 – Overview of SVM Data Preprocessing Approach

The gait pattern feature set that included only the features affected by the symptoms of HD were extracted, as partly listed in Table 1.

Table 1 – Spatiotemporal Features Extracted by PKMAS That Comprise the Gait Pattern Feature Set

Feature	Definition
Step length	Distance between heel contacts of consecutive footfalls.
Absolute step length	Diagonal distance between heel contacts of consecutive footfalls.
Stride length	Distance between heel contacts of the same foot (equivalent to the summation of consecutive step lengths)
Stride width	Distance between consecutive heel contacts, taken perpendicularly to the direction of gait.
Step time	The period of time taken between the first contacts of consecutive footfalls.
Stride velocity	Equal to stride length divided by stride time.
Stance time	The period of time during which the foot is in contact with the ground.

Results

Result of Novel Method

The formation of the footprint was used as an input to the experiment. The model used had two parts. The first part was VGG16, which was used to extract features such as edges and corners from the image. The second part worked as a weighting matrix, and different weights can be arranged for different types of features. The final output was the severity level (high or low).

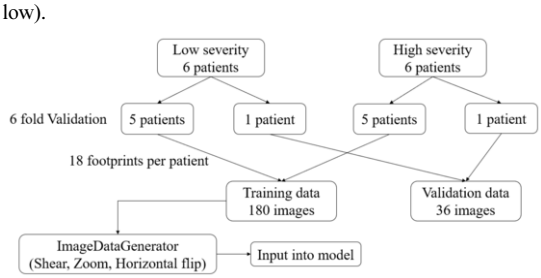

Figure 11 –Work flow for Footprints Formation Model

The grouping method and data structure are shown in Figure 11. With 6-fold validation, the classification accuracy was 89%. To avoid the problem of small sample size, we used ImageDataGenerator to create larger data sets based on the formation of footprints, data augmentation, and cross-validation to achieve accuracy.

Result of 3D CNN Method

18 patients' walking pressure videos were used for model training including 9 low severity patients and 9 high severity petients. 9-fold validation was used to evaluate our model on a limited data sample. The size of captured frames was 2700x200 and rearranged as 800x600. 3D convolution parts shown in Figure 12 were of the same architecture. The features were extracted and concatenated followed by classification layer. Our 3D CNN model achieved a classification accuracy of 82%.

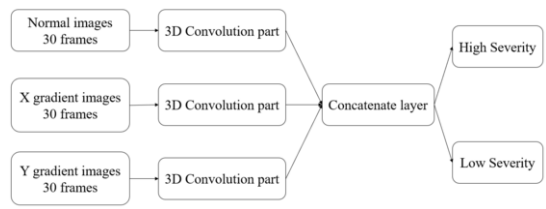

Figure 12 –Work flow for 3D CNN Model

Result of SVM Method

For comparision, two SVM classifiers were developed; one trained on raw footfall pressure data and the other on high-level gait features (computed by the Protokinetics' Movement Analysis Software package) for each footstep recorded for 65 subjects diagnosed with HD. The objective was to classify HD severity as either `high' or `low', which was compared against the Unified Huntington's Disease Rating Scale score of the HD patient to whom the step belonged.

The SVM trained on only the footfall pressure data achieved a classification accuracy of 76.9% (while that trained only on high-level gait features classified HD severity with an accuracy of 82.4%). When the predictions of both the classifiers were combined using an optimized weighting system, classification accuracy increased to 86.9%.

Discussion

Although deep learning method seems to be a blackbox to researchers, we can find clues by comparing different data input and model configurations.

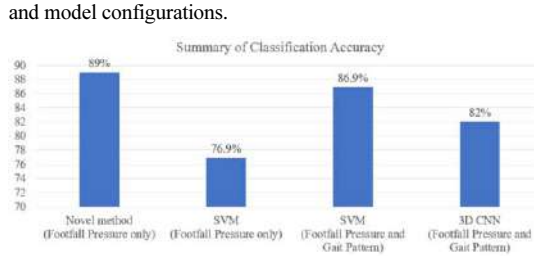

Figure 13 – Classification Accuracy of Four Methods

Our novel method used the pressure data of individual footstep formation process as temporal feature. Compared to 3D CNN which has a strong spatial information input and a designed structure for temporal information input, the novel method has a better performance. It shows that focusing on formation of individual footprint gives more representative features for model training.

During our work with 3D CNN, we found that including x,y gradient of images helps to boost the performance. Convolution layers were capable of extracting features such as edges or corners, but when edges became important factors in our project, it was better to extract them before providing input into the model.

Footprint pressure frames were not working properly with SVM as its accuracy ranked the last but these frames work well with 3D CNN model. When the results of the 3D CNN and the SVM trained on high level features were compared, we found that 3D CNN seemed to rely on footprint's local area but failed to get high level features. High level features (stride length, stride width, step length) were more recognizable and useful for the SVM model based on the performance results.

A combined SVM model ranked second in our performance summary showing that an optimized weighting system of deep learning model for footprint images and the SVM for high level features might be able to achieve better performance.

We managed to achieve a classsification accuracy at 89% in this research by using only objective pressure data without considering the widely used gait pattern data.

Limitations

Being the first study to examine individual footprint pressure data, our study has a number of limitations. First, the preprocessing module can be further optimized. Footprints were processed individually. However, this approach did not consider whether the steps involved were from left or right foot. Analyzing the left and right foot separately may improve our results since HD may affect gait asymmetrically. Additional measures should be taken in future processing to ensure that the left and right foot are equally represented. Second, in terms of category labels, separating the UHDRS motor score into "low" and "high" severity could be a simplification. Third, the number of patients in this study was limited and did not include any healthy subjects as controls. Models derived from small samples may have biases that can be overcome with larger data sets.

Conclusions

This study uses an innovative perspective to explore the nature of Huntington Disease and its impact on motor function. By analyzing individual foot pressure data obtained from a pressure sensor mat, we found that the formation of footprint and temporal change in foot pressure is potentially a feasible classifier for HD motor disease severity.

Future work

Gait features

For the first time, we have demonstrated the feasibility of classifying disease severity using individual footprint pressure data. After further verification, we will explore how this approach can be integrated with exisiting gait measures (such as gait width and stride length) to improve classification accuracy.

Deep learning method

The novel model only includes convolutional layers that cannot extract features between two consecutive footprints. Although 3D CNN model can work with consecutive frames, the feature extracted seem to be less representative which leads to worse performance compared to novel model result. An idea is to combine advantages of both models. First, we will design a new model structure with input portals for x, y gradient images. Second, the inputs will not only include the current existing footprint formation, but also the relationship between the high-level features and the low-level features of the footprint.

Identifying Cardiomegaly in ChestX-ray8 Using Transfer Learning

Sicheng Zhou[a], Xinyuan Zhang[b], Rui Zhang[a,c]

[a] *Institute for Health Informatics, University of Minnesota Twin Cities, Minneapolis, Minnesota, USA*

Abstract

Recently, the National Institutes of Health (NIH) published a chest X-ray image database named "ChestX-ray8", which contains 108,948 X-ray images that are labeled with eight types of diseases. Identifying the pathologies from the clinical images is a challenging task even for human experts, and to develop computer-aided diagnosis systems to help humans identify the pathologies from images is an urgent need. In this study, we applied the deep learning methods to identify the cardiomegaly from the X-ray images. We tested our algorithms on a dataset containing 600 images, and obtained the best performance with an area under the curve (AUC) of 0.87 using the transfer learning method. This result indicates the feasibility of developing computer-aided diagnosis systems for different pathologies from X-rays using deep learning techniques.

Keywords:

X-rays, Cardiomegaly, Machine Learning

Introduction

Cardiomegaly is a medical condition that indicates the enlarged heart. It can be an important sign of potentially severe heart diseases, such as high blood pressure, heart valve disease, heart muscle disease, pericardial effusion, and heart attack. Also, the cardiomegaly can increase the risks of several heart diseases, including the heart failure, cardiac arrest, blood clots in heart, and heart murmur [1]. It is estimated that there are more than 200,000 new cases of cardiomegaly every year in the US, which is an important health issue for the middle-aged and senior population. The cardiomegaly is easier to treat if detected early, thus its early diagnosis is important. The chest X-ray, as one of the most frequently used examination in radiology, has been applied for several decades to detect and visualize the abnormalities of body organs [2-3]. It has been proven to be an effective diagnostic tool for pathological alterations, with additional advantages due to its noninvasive and low-cost characteristics [4]. Also, the X-ray is an important clinical diagnosis method for cardiomegaly [5].

Distinguishing the different types of pathologies from the X-ray is a challenging and tedious task even for domain experts [6]. Figure 1 shows the examples of X-rays in healthy and cardiomegaly condition. Only trivial differences exist between the two images. Thus, it is meaningful to develop a computer-aided detection method to facilitate the clinicians to accurately identify the X-ray images with cardiomegaly. Many related works have been done in developing such techniques in pathology detection field. Traditional image classification models have been applied in medical image classification and achieved satisfying performances. For instance, the Local Binary Patterns (LBP) [7-8] and the Bag-of-Visual-Words (BoVW) [9; 10] are two models widely applied to retrieve or classify the radiology images. In the LBP model, the images are usually divided into small cells of pixels, then the values of pixels in each cell are binarized. Next, the LBP histograms over each cell can be calculated as features passed to the classifier [10]. The BoVW is also called dictionary learning, it was proposed to mimic the visual processing by the human's brain [10]. The BoVW is similar to the bag-of-words representation of text, it regards an image as a distribution of local descriptors. Those local patch descriptors can be color, texture, shape, and the most popular descriptor is the scale-invariant feature transform (SIFT) [9-10].

Figure 1–(a)X-ray Images for Patients without Cardiomegaly. (b) X-ray Images for Patients with Cardiomegaly.

The deep neural networks have been widely applied in image processing area due to the development of new variant convolutional neural networks (CNNs) models [11-12] and modern hardware [13]. These models have reached promising performances for image classification tasks for the ImageNet Large Scale Visual Recognition Competition (ILSVRC) [14]. Also, these methods have been successfully applied in the processing of the medical images, including the detection of pleural effusion assessment on chest radiography, the lymph node detection on CT, brain segmentation, and assessing diabetic retinopathy [15]. Thus, our study explores the feasibility of using deep learning methods to identify the cardiomegaly from the X-ray images.

The deep learning methods are most effective when applied on large data sets, however, such large datasets are often not available in the medical field due to privacy issues [13]. Recently, the National Institutes of Health (NIH) published a new chest X-ray database called "ChestX-ray8", which contains 108,948 frontal view X-ray images taken from 32,717 unique patients. Natural language processing (NLP) techniques were used to annotate each image with eight disease labels from the associated radiological reports. The disease labels include atelectasis, cardiomegaly, effusion, infiltration, mass, nodule, pneumonia, and pneumothorax [16]. This annotated large dataset provided opportunities to developing computer-aided diagnosis (CAD) systems based on the deep learning methods. Initial experiments of image classification were conducted using this dataset [16]. They built a Deep Convolutional Neural Network (DCNN) architectures that used different ImageNet pre-trained models, i.e., AlexNet [11], GoogLeNet [12], VGGNet-16 [17] and ResNet-50 [18]. It is found that using the ResNet-50 pre-trained model achieved the best results in identifying the cardiomegaly from the X-rays (AUC = 0.814).

There are three pre-trained models we will use in this study, including the ResNet-50, InceptionV3, and Xception [19]. The ResNet-50 is a type of CNN model, and it was proposed to solve the problem that when the traditional CNN model has deeper layers, the performance would decrease in training and test set but not due to overfitting. Basically, ResNet-50 is a residual net with 50 layers. It can allow the model to go deeper, and enable smooth propagation and optimization [18]. This model won the first place on the ImageNet detection challenge. Compared to the traditional CNN models, the InceptionV3 has advantages that it can improve the overfitting problems of complex neural networks and reduce the parameters of the neural networks to reduce the computing cost. The core idea of InceptionV3 is to use convolution kernels with different sizes to extract features with different granularities from the images [12]. Xception was developed based on the InceptionV3 model, the depthwise separable convolution was introduced into the Xception model, which can process the spatial dimension and channel dimension of the image separately. Xception has roughly the same number of parameters as InceptionV3 and obtained better results on classification dataset consisting of 350 million images and over 17,000 classes [19]. In this work, we tried to identify the cardiomegaly from X-rays by combing three above-mentioned state-of-art pre-trained models based on ImageNet. We implemented the transfer learning method to integrate the three pre-trained models for identifying the cardiomegaly from X-rays.

Methods

Data Sources

We used the "ChestX-ray8" database described previously. It comprises 108,948 frontal-view X-ray images from the year 1992 to 2015. In this project, we selected 21,966 images in total. In 767 of the images they were labeled as "cardiomegaly" and the others were labeled as "healthy". The whole dataset was divided into a training and a testing set. The training set contains 467 images labeled with "cardiomegaly" and 20,899 images labeled with "healthy". The testing set contains 300 images for both "cardiomegaly" and "healthy" categories. We split the training and testing set in this way due to the limited number of images labeled with "cardiomegaly".

Image Pre-processing

Three groups of images were used in our experiments. The first group contains the original image set. For the second group, two steps were implemented to preprocess the original image set. The first step is to crop the image based on the characteristics of cardiomegaly. Since cardiomegaly is closely related to the shapes and sizes of heart and breastbone. We tried to crop the unnecessary background to highlight the heart area. The dimension of the original image is 1024 × 1024. We crop all the images into the dimension of 800 × 800. The second step is to do the histogram equalization for all images [20]. Histogram equalization is a frequently used method for image contrast enhancement. It uses the cumulative distribution function to map the original image histogram to a new image histogram. It stretches the grayscale of the image by normalization. For the third group of images, we transformed the second group of images that contain three color channels into gray-scale images with one color channel.

Transfer Learning

We implemented transfer learning for the image classification task. It is usually unpractical to train the CNN from the beginning because of the insufficient data size and computing power. Thus, the transfer learning becomes an effective method in the image processing domain that could take the advantages of the well-developed models to solve new tasks [21]. Transfer learning mainly has two types when dealing with imaging processing problems. First, a pre-trained model can be used as the feature extractor for the new dataset. Once the features are extracted, a linear classifier can be trained for the new task. The second type is to retrain the fully-connected layer on top of the CNN on the new dataset while to fine-tune the weights of the pre-trained network through backpropagation. Considering the limited computing power and the size of our dataset, we used the first method in our study. Three models with weights pre-trained on ImageNet, including the InceptionV3 [10], ResNet50 [12] and Xception [19], were applied to extract the features from the training set of X-ray images and trained a classifier based on the different combinations of the features. The pipeline of our experiment was shown in Figure 2. Basically, for each experiment group,

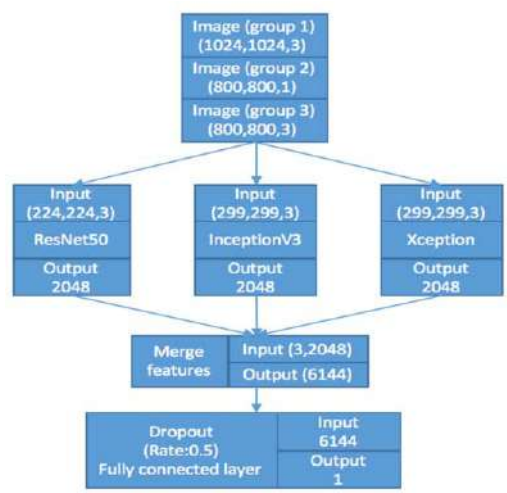

Figure 2–The Experiment Pipeline for Transfer Learning.

we used the three pre-trained models to extract the features, and trained the classifiers based on features extracted by one

model, different combinations of two models and the combination of three models.

Evaluation

We evaluated the performances of the trained classifiers using different combinations of features extracted by the pre-trained models as illustrated in Figure 2. We also tested the scaled and non-scaled features as the comparison. We used the accuracy, F-1 score and the area under the curve (AUC) to evaluate the classification results using the test set mentioned previously.

Results

Images after Pre-processing

Examples of images labeled healthy and cardiomegaly from three experiment groups are shown in Figure 3. The original images, cropped images that focus on the heart area, images after histogram equalization based on cropped images, and one-channel gray-scale image based on all the previous operations are shown in order. After cropping, many unrelated areas could be removed. The histogram equalization highlights the heart area, which could help the following image classification task.

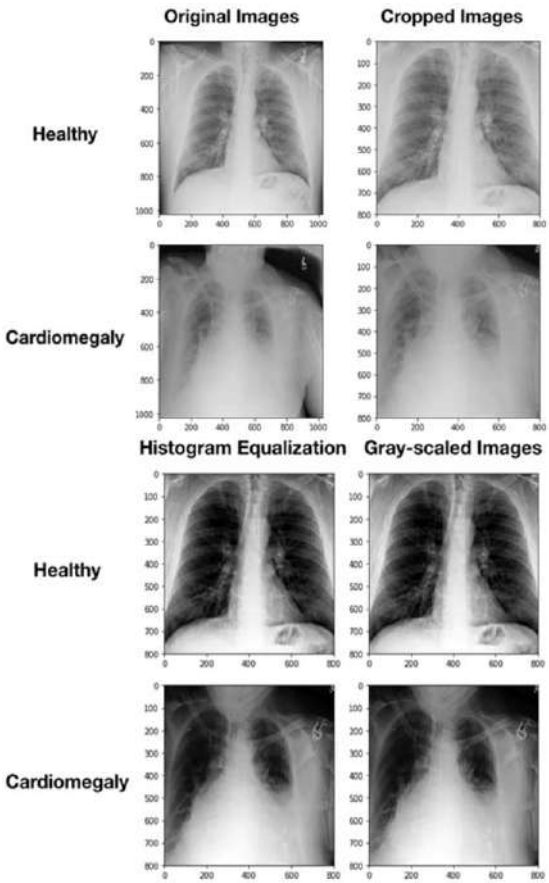

Figure 3– X-ray Images after Cropping and Histogram Equalization.

Classification Results Using Different Pre-trained Models

The results for identifying cardiomegaly from X-ray images are shown in table 1-3. For each experiment group, the results using separate and combined pre-trained models are listed. The scaled features were compared with non-scaled features.

Table 1– Image Classification Results for Group 1

Model	Accuracy	F-1 Score	Scaled-feature
InceptionV3	0.725	0.720	Yes
InceptionV3	0.792	**0.790**	No
ResNet-50	0.695	0.690	Yes
ResNet-50	0.747	0.740	No
Xception	0.673	0.670	Yes
Xception	0.712	0.700	No
InceptionV3 &ResNet-50	0.750	0.750	Yes
InceptionV3 &ResNet-50	0.778	0.780	No
InceptionV3 &ResNet-50 &Xception	0.735	0.730	Yes
InceptionV3 &ResNet-50 &Xception	0.782	0.780	No

Table 2– Image Classification Results for Group 2

Model	Accuracy	F-1 Score	Scaled-feature
InceptionV3	0.723	0.720	Yes
InceptionV3	0.795	0.790	No
ResNet-50	0.693	0.690	Yes
ResNet-50	0.765	0.760	No
Xception	0.655	0.650	Yes
Xception	0.708	0.700	No
InceptionV3 &ResNet-50	0.737	0.740	Yes
InceptionV3 &ResNet-50	0.797	**0.800**	No
InceptionV3 &ResNet-50 &Xception	0.726	0.720	Yes
InceptionV3 &ResNet-50 &Xception	0.792	0.790	No

After initial experiments, we found that the Xception model always had the worst performances and did not improve the performances in combined features. Thus, we stopped using Xception model separately in group 3.

Table 3– Image Classification Results for Group 3

Model	Accuracy	F-1 Score	Scaled-feature
InceptionV3	0.715	0.710	Yes
InceptionV3	0.782	0.780	No
InceptionV3 &ResNet-50	0.748	0.750	Yes
InceptionV3 &ResNet-50	0.793	**0.790**	No
InceptionV3 &ResNet-50 &Xception	0.715	0.710	Yes
InceptionV3 &ResNet-50 &Xception	0.790	**0.790**	No

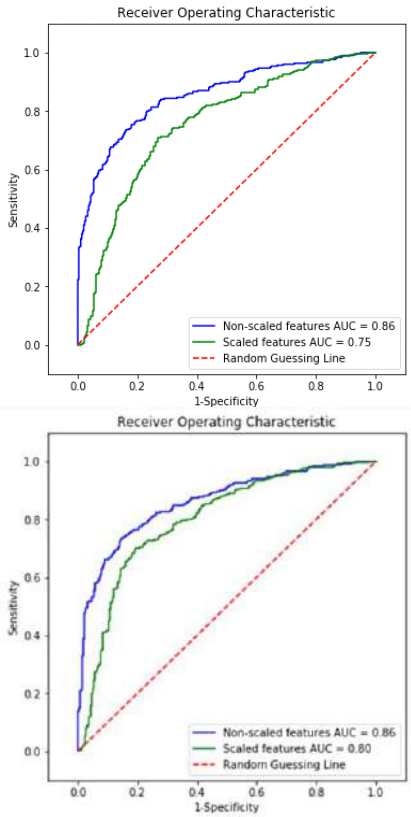

Figure 4–The Selected Best ROC Curves in Experiments.

The group 1 used original images, the features extracted by the combination of InceptionV3obtained the best results (F-1 = 0.79). The images in group 2 were cropped and stretched through histogram equalization. The combination of InceptionV3 and ResNet-50 models obtained the best results (F-1 = 0.800). The group 3 used gray-scale image with only one color channel. The combination of InceptionV3 and ResNet-50 models and the combination of InceptionV3, ResNet-50, and X-ception both reached the best results (F-1 = 0.790).

The selected best ROC curves are shown in Figure 4. The upper figure shows the ROC curve for using the only InceptionV3 model in group 3, and the lower figure shows the ROC curve for using the combination of InceptionV3 and ResNet-50 models in group 2. Our best performing experiment obtains the AUC = 0.860. Both the individual InceptionV3 model and the combination of InceptionV3 and ResNet-50 models reach the best results. The performances of experiments using the Xception model are not ideal, usually with F-1 around 0.700.

Discussion

This study explores the feasibility of applying transfer learning methods to identify the cardiomegaly from X-ray images. We used the pre-trained CNN models based on the ImageNet to extract the features from the X-ray images and obtained promising results (AUC = 0.860). In Wang's et al. work [16], they used the ResNet-50 model and tried to finish the similar task. They obtained the best result with AUC = 0.814 for identifying the cardiomegaly disease from X-ray images. Our method out-performed their results. Although the experimental scenarios are not identical, our task is binary classification while their task is multi-classification.

The three pre-trained CNN models in our study are InceptionV3, ResNet-50, and Xception. When using the model separately, the features extracted by the InceptionV3 obtained the best performances in all experiment groups, while the Xception is not proper for the X-ray images compared to others. The combination of InceptionV3 and ResNet-50 models slightly improve the performances. The best F-1 score is 0.800 and AUC is 0.860 using the combination of the two models. However, using the combined features does not mean better results. In group 1, the InceptionV3 itself has the highest accuracy than other combined models.

We used three experiment groups in the study, each group has images with different pre-processing methods. All the pre-processing steps used classic methods and obtained better images visually. However, the results show that compared with the average accuracy and F-1 score, there's no much difference among three groups, which indicates the pre-trained CNN models extract the features in a way that not influence by the image pre-processing process used in the study. Considering the property of X-ray images and the cardiomegaly disease, we also tried other pre-processing methods. For instance, to highlight the edges of the images, however, due to the unstable qualities of the images, the method cannot apply to all the images. Figure 5 shows the effect of the edge detection, the upper images show successful examples of pre-processing to highlight the breastbone and heart area, while the lower images show the bad examples. Since the quality of the X-ray images varies a lot, more powerful image pre-processing methods would be necessary to improve the results in future studies. Besides, the normalization of extracted features was conducted in all experiment groups. Usually, the feature normalization would improve the performances of neural networks in image classification, since it could reduce the noise of the images by bringing the intensity values to the normal distribution. We used the 0-1 normalization in the study, however, it has side-effects and harms the performances of the model.

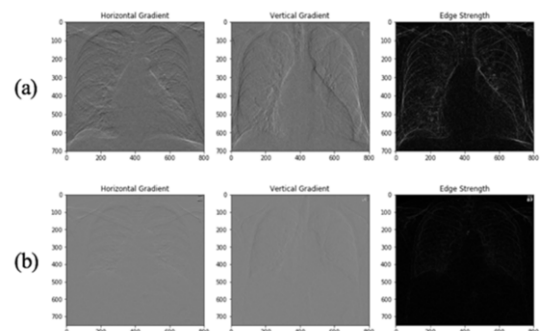

Figure 5–Successful and Failed Edge Detection Examples.

Limitations & Future Work

There are mainly two limitations for the study. First, is the unbalanced dataset. We have 767 X-ray images labeled with "cardiomegaly" and 20,899 images labeled with "healthy". Considering the difficulty of obtaining the annotated X-ray images, it is already the most comprehensive dataset we could obtain. The second limitation is related to the transfer learning method. We used the pre-trained CNN models based on the

ImageNet. Theoretically, these models only work best when our dataset is similar to ImageNet data. The ImageNet data contains over 14 million images in our daily life, but the X-ray image is a special type of image. Currently, there's no pre-trained model based on X-ray images. In the future, we will try to improve the performance by retraining the Inception V3 model. Also, we plan to work with the clinical department to evaluate if our method could improve the efficiency of manual review of X-Rays in clinical settings.

Conclusions

In this study, we applied the transfer learning method to identify the cardiomegaly from X-ray images. We obtained the best performance using the combination of InceptionV3 and ResNet-50 pre-trained models, with AUC of 0.860 that surpass the state-of-the-art results in related work. This result shows the feasibility of using transfer learning methods to develop the CAD system for X-rays.

Acknowledgments

The authors declare that they have no competing interest. Thanks Dr. Luca Giancardo for preparing the image dataset.

Abstract

According to the latest statistics of the China National Health Protection Commission, the prevalence of adult diabetics in China has reached 11.6%, and the number of patients has exceeded 114 million. Understanding the needs of diabetics and what kind of problems they are anxious about are crucial for doctors, hospitals and other health care providers, which can be used to ameliorate patient education services and help patients to improve their disease management skills. Hence we have conducted a study to analyze the questions about diabetes collected from a Chinese health website; the number of which is 151,589. We have divided these questions into 9 categories using a convolutional neural network. The shocking results showed that the questions about prevention only account for 1.23%. And a Chinese patented drug Xiaoke pill, the main component of which is glibenclamide, ranks fourth among the drugs the user cares most about due to the cheap price. However, patients know very little about its side effects.

Diabetes Mellitus, Machine Learning, Natural Language Processing

Introduction

According to the China Internet Network Information Center, the number of Internet users in China reached 802 million in 2018, and the Internet penetration rate was 57.7% [1]. The Internet has become an important carrier for consumers to express their health information needs and search for health information. Furthermore, patients with chronic diseases are more willing to share experiences and seek help via the Internet [2]. In order to meet the needs of the market, there are dozens of companies in China that started offering online disease counseling services for patients, by constructing a connection between patients and doctors through the internet. As a result, these sites have accumulated a large number of disease-related questions, from which we can mine valuable information about what the patients are concerned. Health providers like hospitals can make use of these questions raised by patients to improve their services such as patient health education, and patient follow-up to consumers.

In 2000, the International Diabetes Federation (IDF) predicted that the number of diabetics worldwide would reach 366 million by 2030 [3]. But just 10 years later, in 2011, diabetes data released by IDF showed that the number of people with diabetes worldwide had increased to 366 million [4]. The spread of diabetes is faster than expected. Moreover the number of patients with diabetes in China has ranked first in the world [5].

Nevertheless, people with diabetes usually have no medical background. It's natural for them to feel overwhelmed and scared when faced with diabetes, which is incurable. Hence studying their needs and analyzing their anxieties are fundamental to health care providers to comprehend their needs, which can break the information gap between the patients and health care providers. As a result, health care providers can provide better patient education services and improve self-management ability of diabetics. In order to achieve this goal, we have chosen to study diabetes-related questions on the internet to analyze the needs of diabetics.

In previous studies, Haihong Guo et al. analyzed hypertension-related questions, which studied a very limited amount of data of 2000 questions [6]; Zongcheng Jia et el. studied cancer-related questions with a data of 1000 questions [7]. As far as we are concerned, there is occasionality in the distribution of such a small amount of data, which in general cannot represent the reality. And with the development of artificial intelligence, some traditional machine learning algorithms like support vector machines (SVMs) and Naive Bayesian have been used to classify questions by feeding some features as Bag of Words (BOW) or TF-IDF extracted from the dataset into the algorithm [8], which is not using state of the art technology, meaning that better models can be used to improve the performance.

To analyze the diabetes-related questions, we used a Convolutional Neural Network to classify these questions, which is capable of capturing semantic level information. Based on the results of the classifier, we have further explored the hidden information in the data. This method can be generalized to analyze other chronic diseases by means of feeding labeled data to our model.

Methods

Data Collection

In order to reflect the real distribution of the diabetes-related questions, we designed a spider specific for a Chinese health website (http://www.39.net/) to crawl all the diabetes-related questions without any selection or filter, of which the total number is 151,589. With such a large amount of data, we believe that the results obtained are highly convincing.

Since these questions are all raised by patients, most of which don't have a medical background, these questions about diabetes are very colloquial and there are a lot of misspellings. For instance, Many patients may type "二甲双胍"(metformin) as "二甲双瓜"(metformin). And some consumers may merge several questions into one single question like "Do I have diabetes? Is it necessary to take medicine? Which treatment is better?". The diversity and complexity of the dataset is also a huge challenge for us, which put forward higher requirements for the robustness of our model.

Classification Schema

According to the classification schema of the references [6,9], combined with the specific characteristics of diabetes itself, all diabetes-related questions are classified into 9 categories: diagnosis, treatment, lifestyle, complication, maternity related, prognosis, health provider choosing, prevention, and others. The "others" category represents some description irrelevant to disease. Using such a schema, each question can be classified into one of the classifiers.

Word2vec

Word2vec is an efficient model for learning high-quality, distributed vector representations that capture a large number of precise syntactic and semantic word relationships [10]. Unlike traditional Bag of Words representations, words are projected from a sparse, 1-of-V encoding using one-hot encoding (here V is the vocabulary size) onto a lower and dense dimensional vector space via a hidden layer. In general, the dimensions of vectors are set between 100 and 500. In such dense representations, semantically close words are likewise close in Euclidean or Cosine Distance in the lower dimensional vector space. Since Word2vec uses the unsupervised learning method, it's very efficient and easy to use.

It has been shown that performance can be improved by training the Word2vec model using domain-specific data before training a downstream neural network [11]. To train our own word2vec model, we fed a large corpus of text into the model, including all the diabetes-related questions and a lot of other medical-related documents. In our model, the dimension of the vector is set at 300.

As a result, each word can be represented in a distributed vector, containing syntactic and semantic information. Therefore, we can calculated the similarity that can be represented by the cosine similarity between the 2 vectors correspondent. Here are some interesting results:

Table 1. Word Similarity

Word1	Word2	Similarity
糖尿病 (diabetes)	高血压 (hypertension)	0.62
糖尿病 (diabetes)	苹果 (apple)	0.18
糖尿病 (diabetes)	水果 (fruit)	0.17
糖尿病 (diabetes)	蔬菜 (vegetable)	0.12
水果 (fruit)	高血压 (hypertension)	0.14
水果 (fruit)	苹果 (apple)	0.63
水果 (fruit)	蔬菜 (vegetable)	0.87

As is shown in the table above, the semantic information is well captured by the model trained. Such a well-trained model can improve the performance of our neural network model.

Convolutional Neural Network

There are two, main deep, neural network architectures in NLP (natural language processing): convolutional neural network (CNN) and recurrent neural network (RNN). Generally speaking, CNN is mainly used for classification tasks like sentiment classification since sentiment is usually determined by some key phrases; RNNs is mainly used for a sequence modeling task like language modeling as it requires flexible modeling of context dependencies [12]. Since our task is to classify questions, CNN is chosen as our basic network architecture.

Convolutional neural network, originally invented for computer vision tasks, which uses convolving filters to extract local features from images, have also been shown to perform well in natural language processing. With the help of the Word2vec model, sentences can be embedded in a matrix. After that, sentences can be treated just as an image which is originally represented by a matrix.

In this study, we used a multi-channel CNN which is largely used in our other classification tasks, and have also been proven to achieve excellent results. The main model architecture is shown in Figure 1.

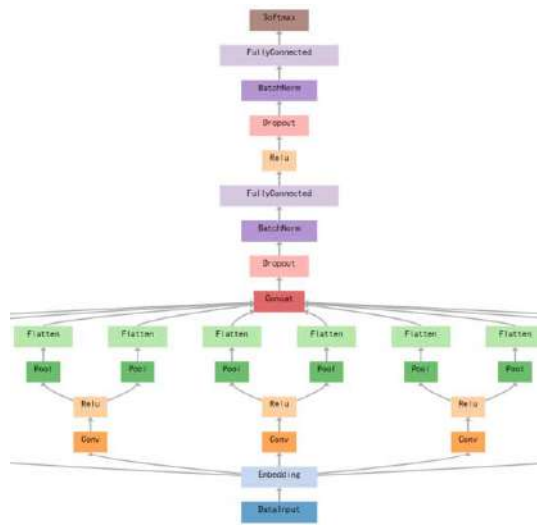

Figure 1. Main Model Architecture

Note: Each "Conv"(convolutional) module in this graph represents a convolving filter with different kernel size. Due to limitations of image size, not all the "Conv" module are presented in the figure. Max Pooling layer and Average Pool layer are used at the same time, represented by "Pool" module in the graph. To avoid overfitting problem, 0.5 is set as the dropout rate in the "Dropout" module.

Annotation and Training Procedure

To train a deep neural network, it's essential to feed labeled data into the deep model. We manually annotated 1000 questions, randomly selected from the dataset in the first place. Using such a small amount of data, we have been able to train a model that performs not very well but can already identify certain patterns according to the limited training data.

What we did next was to use the convolutional neural network to predict these unlabeled data and use the results as references to help us speed up the annotation process. The output of the model represents the probabilities that one sentence is classified into each category. Those sentences with low probabilities mean that the model fails to identify the patterns in the questions, which in most cases, represents that there is no similar pattern in the labeled data. So we need to annotate more data with new patterns for the model to learn. In this study, we defined the uncaptured pattern threshold at 0.7, and the captured pattern threshold at 0.95, meaning that if prediction probability of a question is below 0.7, we judge that the pattern of this sentence cannot be recognized by the model. In contrast, the prediction probability of a question above 0.95 means the sentence is well recognized.

Next, we manually annotated another 500 questions, randomly selected from the unrecognized questions. By repeating the training and annotation process above 4 times, we were able to train a well performing convolutional neural network.

Results

Neural Network Performance

We have annotated 3000 questions in total by means of the annotation and training strategy mentioned in the method section. All labeled data is divided into 2 sets, the training set occupying 80% for training our model, and the test set occupying 20% for evaluating our model, which is invisible to the model. The accuracy of our neural network has reached 96.7% in the test set, representing the performance of our convolutional model.

Using such an annotation and training strategy, we avoided annotating the same patterns all the time and were able to feed more new patterns to our neural network, which can largely improve the performance and robustness. Here is an example of the classification result to prove the robustness of our deep neural network:

- Question without misspelling:
  - 长期吃二甲双胍对健康都有些什么副作用？(What are the side effects of long-term consumption of metformin on health?)
- Question with misspelling:
  - 长期服用二甲双瓜有什么副作用(What are the side effects of taking metformin for a long time?)

Both questions are properly classified into the same class: treatment. The classifier works fine even if there is a spelling mistake in the sentence.

Classification Result

The classification result of the number of 151,189 questions is presented in Figure 2. We can conclude that the most concerned aspects of diabetics are diagnosis, lifestyle, and treatment. However, little attention has been paid to how to prevent diabetes, occupying just 1.23 percent, suggesting that patients rarely care about diabetes before actually getting diabetes.

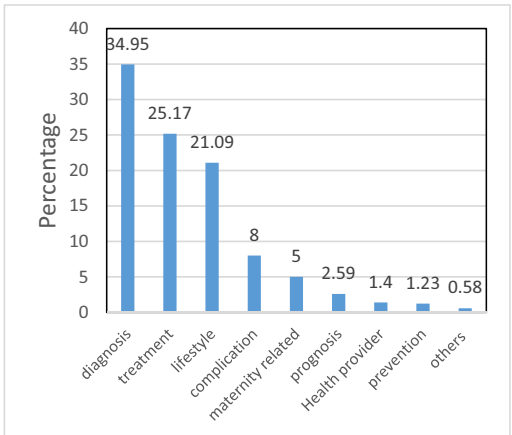

Figure 2. Classification Results

Study of Prevention Class

We carefully studied the questions of diabetes prevention. What we have found is that under most circumstances, people will start asking questions about how to prevent diabetes only when a relative or a friend has diabetes, here are some typical examples:

- 我的几个好朋友都得了糖尿病。怎么样才能预防糖尿病呢？(Several friends of mine have got diabetes. How can I prevent diabetes?)
- 身边有不少的亲戚朋友得了糖尿病，他们都很痛苦。所以我心里很担心，也很害怕。请问我该怎样预防糖尿病？(There are quite a few friends and relatives around me who suffer a lot from diabetes. So I am distressed and scared. How can I prevent diabetes?)

On the basis of the result, education about diabetes prevention needs to be spread to more people to help everyone recognize the importance of diabetes prevention.

Study of Lifestyle Class

Comparing questions before 2010 and after 2010 in Figure 3, the proportion of patients' questions about lifestyle increased from 13.71% to 22.59%, which shows a significant increase. A reasonable explication is that consumers are now more aware that lifestyle plays a very import role in diabetes.

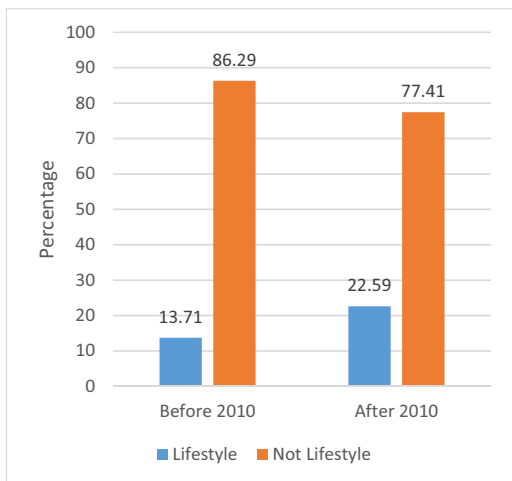

Figure 3. Comparison of Lifestyle Related Questions Before and After 2010

Knowing that diet plays a crucial role in diabetes, we conducted a further study about the most cited food by diabetics in the lifestyle class, shown in Figure 4. As for Chinese, eating has always been one of the most important things in daily life. Medical professionals can provide a better dietary recommendation for patients as a reference by means of the results obtained.

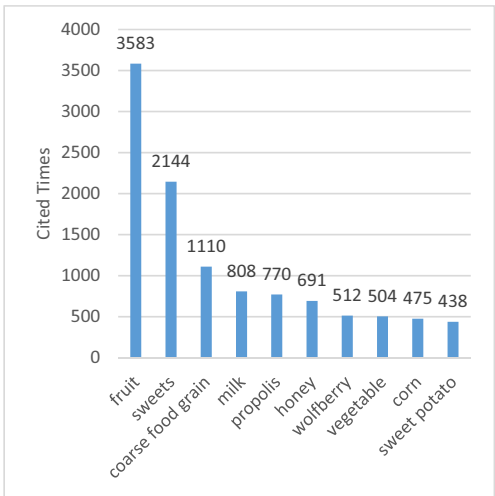

Figure 4. Top 10 Cited Foods

Study of Different Age Groups

It is also fundamental to analyze the different needs of patients of different ages, the result of which is presented in Figure 5. We can see significant differences in the aspects that people of different ages are concerned about.

Young people are more concerned about maternity-related issues, who are at an age suitable for childbearing. They may worry about problems like whether diabetes will be passed on to children or whether people with diabetes have fertility.

While older people are more concerned about complications and lifestyle to alleviate the impact of diabetes on life. Many people at this age are using oral medication or insulin therapy. They are more eager to know the drug usage, efficacy and adverse reactions.

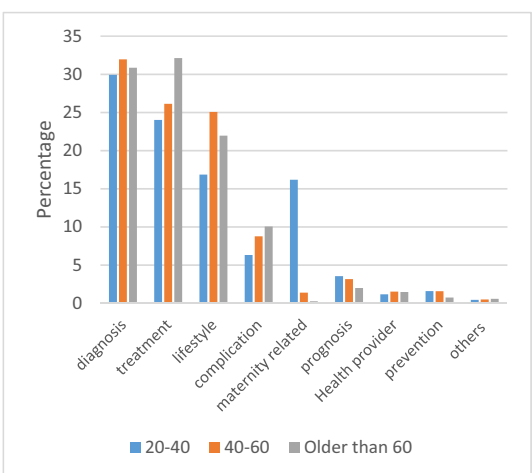

Figure 5. Classifcation Results of Different Age Groups

Study of Drugs

About the medication for diabetes, consumers raised more questions about insulin, metformin, gliclazide, and the Xiaoke Pill. Despite the import role of insulin in blood sugar control, the application of insulin is far from sufficient. Many diabetics, even medical staff, especially non-endocrinologists, have a variety of concerns and hesitation about the use of insulin, which suggests that diabetes professionals should teach patients and relevant medical staff more knowledge of insulin, improve their attitude towards diabetes.

The questioning rate of metformin is high, and that may be related to metformin being recommended as the first choice for diabetes treatment.

Xiaoke Pill is a kind of Chinese patent medicine, which is favored by many consumers because of the cheap price. Also, in China, many patients believe that Chinese traditional medicine has fewer side effects than western medicine, which may also be a reason why Xiaoke Pills are very popular in China. However, Xiaoke Pill contains glibenclamide, which can cause severe hypoglycemia and may lead to liver and kidney damage with a long-term application. Therefore, medical professionals should fully explain to consumers the side effects of Xiaoke Pills, and guide consumers to abandon the use of this drug.

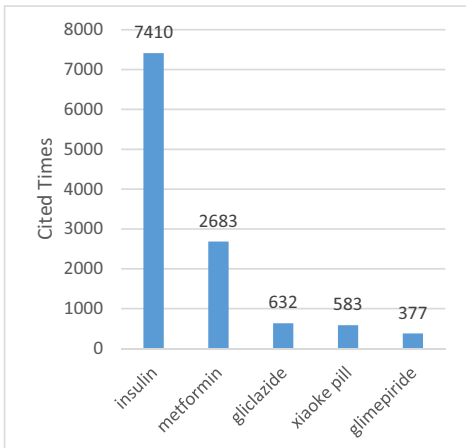

Figure 6. Top 5 Cited Drugs

Discussion

In this study, we have applied Word2vec and a state of art convolutional neural network to classify diabetes questions. In addition, we have used a more advanced annotating strategy, which can feed more patterns to the deep neural network to improve the performance. To achieve the same performance using the normal annotating strategy without pattern selection, we need a larger amount of annotated data.

Compared to the previous works presented in the introduction section, which tried to classify and analyze disease-related questions, the results of our work is more convincing. At the same time, we further explored more hidden information based on the results of the classifier.

Doctors, hospitals, and government medical institution can use the results of this analysis to better understand the needs of diabetics and discover the aspects in need of improvement.

For example, there are only a few problems related to the prevention of diabetes, meaning that people are not paying enough attention to the prevention of diabetes, which may be a reasonable cause of the growing number of diabetics in China.

There are also many shortcomings in our research. First, we have annotated 3,000 diabetes-related questions, which requires extensive work and takes a long time. Our model cannot be directly generalized to other diseases. To do a similar analysis of another disease, we have to redesign the

classification schema and annotate the new data. The classification schema we used is not perfect. For example, questions about sport, diet, and living habit are classified into the same class: lifestyle.

In the future, we should aim at improving the limitations of our work. Some more advanced deep neural networks like ELMO [13] and BERT [14] have achieved state of the art performance in many NLP tasks. Maybe these networks can be used to improve the annotating and training process. And, we can redesign a better classification schema that can be easily generalized to another chronic disease. We hope that more advanced natural language processing technologies can be applied to the medical domain.

Conclusions

In this study, we identified the diabetes information needs for consumers by analyzing a large amount of data. We have developed a classification schema for diabetes-related questions and used a convolutional neural network to classify the questions according to the schema designed. And, we found that the prevention of diabetes has not received enough attention in China and the popularity of Xiaoke Pill in China also needs to be reviewed.

Challenges and Opportunities in Changing Data Structures of Clinical Document Archives from HL7-V2 to FHIR-Based Archive Solutions

Jochen Zohner [a], Kurt Marquardt[a], Henning Schneider[a], Achim Michel Backofen[a]

[a] *Department of Medical Informatics, Justus Liebig University, Giessen, Hesse, Germany*

Abstract

In 2018, a major replacement of clinical applications took place at the University Hospital of Giessen. One key part was the clinical document archive containing a vast collection of clinical data from the last 30 years. The aim of this sub-project was to move all data to a new system without any loss, while maintaining all functionality and all communication interfaces. This project successively resulted in a complete paradigm change in document storage. While the legacy clinical data repository (LCDR) was designed according to HL7-V2 principles, the replacement resulted in an HL7-FHIR implementation. The aim of this work is to discuss the differences between both approaches, the obstacles that appeared during migration, but also the opportunities resulting from the new philosophy, especially as far as the impact on the use of scientific data is concerned.

Keywords:

Information Storage and Retrieval**;** Database Management Systems**;** Electronic Health Records

Introduction

In current clinical network infrastructures, a central document archive has become more and more essential to prevent medical staff from spending too much time seeking relevant patient information. The resulting data aggregation not only leads to more efficient clinical workflows but produces new opportunities for data analysis, ranging from user optimized cumulative data views, to support for accounting information generation, to diagnosis prediction and assistance on scientific studies. The University Hospital of Giessen has a long tradition in the use of clinical document archives, resulting in a vast collection of data, starting with lab values in the late 1980s today, offering a spectrum of more than 50 data sources and a volume of about 300 million datasets. To cope with these large amounts of data, the HL7-V2 standard was consequently used not only for data transmission, but also for storing the data in databases using the HL7-segment structures as table definitions. The outcome was a standardized Entity-Attribute-Value (EAV) model [1,2], which has served clinical demands well during the last decades.

The emerging requirements for mass data storage, data security and protection, as well as legal requirements, forced the University Hospital of Giessen to replace the proprietary LCDR with a modern commercial clinical document archive solution by Synedra, an information technologies company. Synedra's approach hereby entirely differs from the LCDRs EAV-model, since all data is stored as monolithic data in database BLOBs, compensating for the disadvantages of this approach by using the HL7-FHIR [3] standard in JSON-format.

Fundamental Concepts and Data Types

The principal purpose of a clinical document archive (CDA) comprises data collection, storage, and display. Additionally, the CDA has to provide stored information for various medical subsystems, especially for the clinical information system (CIS) itself. The export of anonymized data for the support of clinical studies is another purpose that a CDA has to satisfy. In all of these cases, the CDA acts as a uniform abstraction layer for data originating from a broad range of different medical subsystems, like laboratory information systems (LIS), radiology information systems (RIS), or department specific information systems like for cardiology, pneumonology, etc. For different sources of information, the structure of the corresponding data is also different. Basically, we can distinguish the following classes of data, each requiring entirely different treatment:

1. **Monolithic documents**, which are most often stored as PDF or image formats like JPEG;
2. **Plain text** or formatted text (like HTML), which are transmitted inside an HL7-ORU message;
3. **Structured data** with multiple observation values;
4. **Reference pointers** to documents or web pages stored in medical subsystems;
5. **DICOM** references from the PACS; and
6. Additional data from **clinical studies** most often stored in Excel spreadsheets.

The LCDR was principally designed for presentation and as a broker server without the demand of storing all data inside its own database, but leaving monolithic data, webpages, and DICOM data on external databases of the originating subsystems and referring to them via web linkage. According to this, the preferred data type of the LCDR was structured data, having the advantage of flexible display and the best usability for statistical evaluation. In contradiction, the new Synedra archive is intended to store all information in its own database, for the sake of data persistence, and treats all information like monolithic data.

Therefore, Synedra creates a HL7-FHIR resource containing all the structured information and metadata concerning the clinical finding. These data are stored in JSON format into a Postgres database, making it reasonably searchable by creating appropriate indices, as well as in XML format, to the file system for display purposes. This closes a major gap between the functionality of the LCDR and the Synedra archive and enables Synedra to provide customized data presentation

layers, like cumulative lab display and selective access to structured data. Also, Synedra uses the XML resources to deliver entire documents via RESTful web services, allowing the CIS and other subsystems to participate in the data stored in the Synedra archive on demand.

Another improvement provided by the Synedra archive is the complete integration of DICOM data. Since 1996, Giessen was lucky to successfully manage the linkage between DICOM images and corresponding radiological findings by transmission of study instance UIDs within HL7-ORU messages. However, the information from DICOM image tags was not searchable in the LCDR because it only possessed a display link to the DICOM series but not the images themselves. This problem is fixed in the Synedra archive by receiving all DICOM series from the PACS. Similarly, the monolithic PDF documents and links to external web interfaces, which could not be searched by the LCDR, became searchable by Synedra by importing its contents into its database. Finally, data spreadsheets provided by clinical studies, including questionnaire responses or observations, were able to be imported and stored in the Synedra archive as appropriate FHIR resources [3].

Methods and Results

Challenges during Data Migration

It turned out that the migration of data from the LCDR to the Synedra archive was even more demanding than expected. The very first approach, to generate download lists with all the metadata of the documents and have Synedra download all the documents using the usual web interface of the LCDR, led to an undefinable set of crippled data due to the complexity of the data landscape and the many subsystems involved, making appropriate exception handling impossible. Therefore the transmission via HL7-MDM using the Orchestra communication server as middleware was considered. This resulted in a vast range of different errors, depending on the data's document classes (as mentioned in the section above), requiring individual adjustment.

Structured data

The Synedra archive was not intended for the use of structured data, initially. When the question arose, how to handle these data, maintaining both the original presentation of the data and the structured information itself, the idea of using the HL7-FHIR standard was born. Since a FHIR resource is suggested to not only contain patient information and observation result sets but an HTML representation of the data for display purposes [3], this format turned out to exactly fit the existing requirements.

Monolithic documents

The architecture of the Synedra archive was primarily designed for storing documents without caring about their inner structure. These documents are most often stored with a fixed representation like PDF. The transport of such documents can be performed either by storing the data to a shared folder and transmitting a reference to the document's storage location or transmitting the document within the corresponding HL7-message. The latter approach allows the distribution of documents to several recipients without interference and so was preferred by Synedra. This approach impacted on the Orchestra communication server like inflating its log files to exceed the file system's limits and overburden the debugging tools whenever errors occurred, and so was abandoned.

The most common errors with these data were due to subsystems deleting or changing the documents without notifying the LCDR of the changes. These problems also were solved by Synedra's storage philosophy for the future.

Plain text

The LCDR behaved rather fault tolerant. When transmitting plain text data in HL7-OBX segments, special characters, wrong coding information and misused HL7-escape-characters spoiled quite a few data transmissions either when passing through the Orchestra communication server or when received by Synedra. These errors had to be fixed in the LCDR data stock one by one.

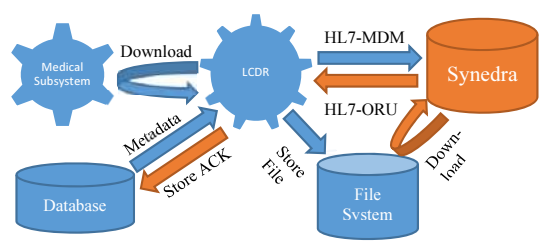
Reference pointers

Synedra stores all data persistently in their database and does not hold references to external resources. The LCDR held several references to different subsystems, some of them providing interactive web pages that display data only after a user action was performed. These resources could not be downloaded like usual documents and needed to be rebuilt or exported in different ways, directly from the source of information. Another obstacle arose by access control using tokens with time limitations.

Communication Approaches

The remedy for the latter problem led us to the general approach of making the LCDR download the documents, store them to a shared folder and send an HL7-MDM notification for each one to the Synedra archive. Since the Synedra archive always sends HL7-ORU messages with reference pointers to access recently stored documents along with the original document identifiers to the communication server after successful storage, we used this mechanism like an "acknowledge with regard to contents" notification and stored these response messages along with the original data into the LCDRs database. This procedure made the export status completely transparent (*Figure 1*) (*Table 1*).

Figure 1 – Document Export



Another problem proved to be the timely manner. Data export would take longer than acceptable due to performance limitations of the LCDR. On the other hand, one could not expect the clinical staff to search two archives for the documents. To solve this, an additional process, which we called "export on demand," was established. Whenever a patient visits the hospital, an HL7-ADT message is released by the CIS. This message, received by the LCDR, triggers an export mechanism for all documents concerning this patient (*Figure 2*).

Table 1 – Sample Data from the LCDR including Links to Notification for and Acknowledgement Messages from Synedra

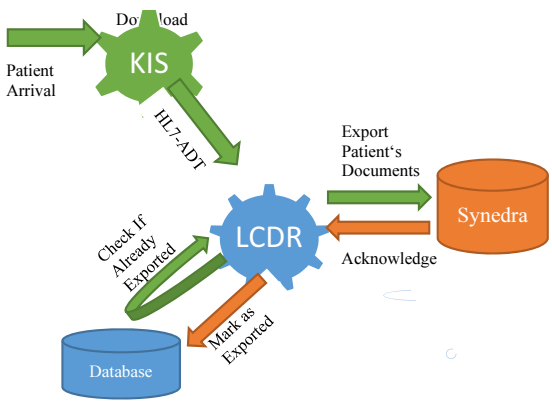
Thus, instantly all of a patient's documents seemed to be present in the Synedra archive to the clinical users, although the very last transmission took place almost one year after the production startup of Synedra.

Figure 2 – Export on Demand



Used HL7-FHIR Resources and Versions

HL7-FHIR is a standard currently evolving at a rapid pace. FHIR consists of several resources, each one designed for appropriate clinical demands. Hereby, both the set of resources and the structure of the individual resource itself depend on the version of FHIR used. At the project's start, FHIR version "STU3", the current version at that time, was used. In December 2018, "R4" was officially released [3]. The Synedra CDA today supports both versions, STU3 and R4, as far as the interfaces are concerned, but stores new data according to version R4 and successively migrates legacy data from STU3 to R4.

Concerning the FHIR resources, "DiagnosticReport" and "Observation," supported by "Patient", "Organization" and "Practitioner," were the first to be implemented. Further resources like "MedicationAdministration", "Condition", "Procedure", "Claim", "AllegyIntolerance", "FamilyMemberHistory", "Immunization" and "QuestionaireResponse" [3] were drafted and are currently being implemented. The latter resources especially play an important role for the use of scientific data.

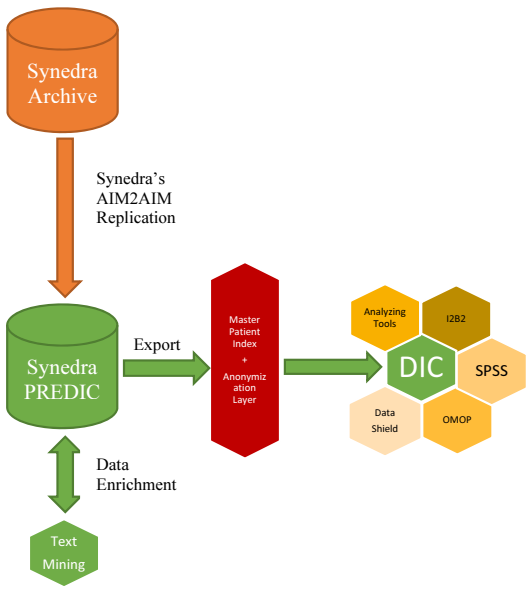
The FHIR standard allows the implementation of extensions, offering the possibility of storing additional information not covered by the standard, if necessary. For the Synedra CDA, the standard proved to be sufficient except for one single extension of the "DiagnosticReport," which holds the original HL7-ORU message for the sake of reproducibility of the "HL7-V2 to FHIR" conversion step. While no major problems occurred using FHIR, it may be noteworthy to mention that the flexibility of FHIR, like the substantial number of optional elements and the extensibility, makes the beginning steps with FHIR easy but leads to a lot of work later on.

Impact on Scientific Data Use

A significant benefit from centralized CDAs is the possibility to use a broad range of clinical data for the purpose of clinical research. The LCDR supported such attempts by providing a number of searching facilities based on the selection of patients having some observations exceeding user-specified values. Of course this only worked with structured data and so was mostly limited to lab values and some similar data sources. Along with the Synedra archive's architecture and its capabilities, the idea was raised to also use the archive in a more extensive way to support clinical research. As we have already seen, Synedra made not only structured data but all data searchable, including even monolithic and DICOM data. This allows us to specifically export selected anonymized data to be stored into a so-called data integration center (DIC) [6], which can in turn be used afterwards with analyzing tools like SPSS, OMOP [7] or I2B2 [4,5].

For non-structured data, the use of text-mining tools becomes sensible and allows us to include a much broader range of data than ever before, accompanied by the possibility to add the so-gained structured information to the original document. In order to avoid confusing the clinical data with scientific analysis data, a second instance of the Synedra archive was implemented, acting like a preprocessing facility for the DIC and therefore being called PREDIC. By Synedra's event-based replication capabilities, the Synedra PREDIC becomes a complete mirror of the data collected in the Synedra archive for the sake of scientific evaluation (*Figure 3*), expanded by study data, additional subsystems database contents, and document-related analysis results. Therefore, again Synedra's HL7-FHIR interface is used for injecting the additional information. These features open the door to standardized data export of patient-related medical observation data, surpassing the rudimentary possibilities of the LCDR by far.

Figure 3 – PREDIC Architecture



Discussion

The replacement of an old system by a new one can either be regarded from the perspective of the old system or from the new one. After two decades of the LCDR running in this manner, its replacement at first was planned like a one-to-one exchange of one archive for the other. Thus, the first replacement approaches were based very much on the LCDR structures, like using the abstraction layer of the LCDR for downloading all data sets in a uniform way. The power of this abstraction layer in disguising the documents' origin and the delivery method turned out to be more appropriate for human usage than for archiving purposes. Even taking random samples is not an adequate method for discovering problems that appear in some thousands of 300 million cases. One has to face all possible exceptions and errors that the legacy system tolerates. The generic approach with trial and error results not only in delays but in vague states, forcing data exports to be repeated several times. On the other hand, the method of storing acknowledgement messages directly related to the original document (*Table 1*) slows down the export process for every single document, but proves to accelerate the entire operation, since it makes selective resending of failed data possible without exploiting log files or performing manual corrections. This procedure also made it possible to establish the export on-demand function, instantly eliminating the user's need to fall back to the use of the LCDR for legacy documents.

When considering the functionality of the new CDA, the opposite mistake was made in the beginning. The view of the present Synedra archive dominated, reducing the expectations to simply store and display monolithic documents. The emerging need for dealing with structured data augmented the view and merged the pure archive with the repository approach by involving the HL7-FHIR standard.

Conclusions

The original attempt of renewing a clinical document archive primarily designed to maintain the status quo became a mutual process of enhancement. While the data transfer became a rather complex task, the Synedra archive evolved into a versatile platform including solutions for all the repository capabilities of the LCDR by the use of HL7-FHIR, accompanied by a remarkable expansion of Synedra's archive functionalities. We not only saved 30 years of precious clinical data, we even gained an overall solution for both clinical document archiving and a universal support of clinical studies.

Abstract

Improving communication among healthcare providers is one of the critical components of safe and quality patient care. The study objective is to examine how occupation and training of health professionals in Riyadh, Saudi Arabia influence professionals' perception of the role of electronic health records (EHRs) in improving communication between healthcare providers in primary healthcare centres. A survey-based study method employing a descriptive, cross-sectional design was used. Health professionals' occupation and training were found to influence their perception of the role of the EHR in improving interprofessional communication. Physicians and professionals with training on EHRs had the highest rating for the system's role in improving communication between healthcare professionals. All healthcare providers should embrace EHR systems in their practice to promote interprofessional communication and collaboration in the patient care process.

Keywords:
Electronic health records, Primary health care, Health personnel

Introduction

Effective communication among health professionals is crucial for the improvement of patient safety, and outcomes with ineffective communication noted to result in several adverse events such as medical errors that put patient's life at risk [1]. Electronic health records (EHRs) have been demonstrated to be useful systems for improving communication not only among the healthcare providers themselves but also between patients and their caregivers [2-5]. In promoting the exchange of patient's health information among providers, the EHR creates an opportunity for care coordination between health professionals and medical departments that enhances the provision of safe and quality patient care marked with reduced medical errors and other adverse events [6].

Despite the implementation of EHR systems resulting in these benefits due to improved communication, it has been established that sufficient communication among healthcare providers is still a challenge in the healthcare system with much focus having been placed on provider-patient interaction more than in communication between physician and professional colleagues [7]. The challenge is even bigger in Saudi Arabia where English is a second language but considered the official language used in communication in Saudi healthcare organisations. In addition, the Saudi healthcare organisations have health professionals from all around the world with different backgrounds and of course different mother tongue languages. Most of the research on the EHR role in improving healthcare outcomes has also only been reported in western countries with little evidence in the Saudi context. This could be due to the low adoption of EHR systems in Saudi Arabia due to various factors such as lack of perceived usefulness by the health professionals and hospital size [8]. To the best of the authors' knowledge, there are no previous studies that have discussed the role of the EHR in improving communication in Saudi Arabia especially from the perceptions of health professionals in primary health care (PHC). Factors influencing the use of EHRs by healthcare providers in these settings have also not been adequately investigated. Therefore, this study aimed to evaluate the perceptions of health professionals in relation to their occupation and training on the role of EHRs in improving communication among healthcare providers for better patient care in primary health care centers (PHCCs) in Riyadh, Saudi Arabia. In so doing, the study had three specific objectives: 1) to investigate the healthcare professionals' perception towards the EHR role in improving communication between healthcare providers, 2) to investigate the correlation between the occupation of health professionals and perception of use of EHRs in improving communication between health professionals, and 3) to investigate the relationship between training on EHRs and perception of use to improve communication between health professionals.

It was hypothesized that several factors could influence the users' perception and use of the EHR to facilitate communication with colleagues. In this study, the occupation of the healthcare professionals in Saudi primary care and training on EHR systems were expected to influence the professionals' perception of the role of the EHR in improving communication among health practitioners.

Methods

This cross-sectional study was designed to investigate the perception of healthcare professionals working in PHCCs in Riyadh city on the role of EHRs in improving communication among health professionals leading to high-quality and safe healthcare in relation to the professionals' occupation and training on EHRs.

Study setting and sample

The study was conducted in Riyadh City which has the highest number of PHCCs since it is the capital of Saudi Arabia. The region has 1710 healthcare professionals comprising physicians,

nurses, pharmacists, laboratory technicians and those from allied health professions such as physiotherapists working in PHCCs [9]. Therefore, a survey involving all the healthcare professionals was undertaken to evaluate their perceptions on the role of EHRs in regards to the quality of service provision. This population was chosen because they interact with EHR on a daily basis and are considered to be in the best position to gauge the application of these tools in the provision of care. Other employees in the primary health care sector in Riyadh falling in various categories such as clerks, drivers, office assistants, administrative personnel, and any other group of supporting staff were not included in the study.

Instruments

The data collection instrument was an online-based questionnaire using Research Electronic Data Capture (REDCap) to ensure the participants' convenience. The questionnaire included both closed and open-ended questions. It was adapted from the survey tool developed by Secginli and peers to evaluate the perception of Turkish healthcare professionals towards the EHR in Family Health Centres (FHCs) which are primary health care settings [10]. The tool had 14 statements related to EHR benefits of which "improves communication between health professionals" was one of them. In addition, it had 9 items for perceived obstacles to implementing the EHR in PHCCs and 10 related to the quality of healthcare services due to the use of EHR in PHCCs. The measurements were based on a Likert scale of 1 to 5 representing strongly disagree to strongly agree. The survey tool was tested for reliability and validity using a pilot study done online in the same way it was to be used in the actual study. This pilot test involved 23 participants drawn from the same population with the sample illustrating a normal distribution with Cronbach's alpha of 0.828 and 0.969 for the combined 23 items for perceived benefits and obstacles, and 10 items for quality of health services respectively compared to the total population as shown in Table 1. The validity of the results was enhanced by including the entire population in the study which improves the response rate. For clarity, the questions in the questionnaire were carefully worded and properly ordered to eliminate any form of ambiguity or bias.

Table 1 – Reliability Tests

Dimension	Cronbach's alpha	No of items
EHR benefits and obstacles to implementation	0.828	23
Quality impact on healthcare services	0.969	10

Data collection procedures and ethical issues

The data was collected for a period of two months, that is between 30th November 2017 and 30th January 2018. All the healthcare professionals working in PHCCs in Riyadh City were invited, through the General Directorate of Health Affairs in Riyadh Region and Human Resource (HR) departments in each of the PHCCs, to complete the survey that was made available in an online format using REDCap for the participants' convenience. The participation was entirely voluntary and by completing the survey, one was considered to have given informed consent. After completing the survey, the data was retrieved from the database for analysis. The study was approved by the University of Tasmania Social Science Human Research Ethics Committee and the Ministry of Health of Saudi Arabia.

Data analysis procedure

The Statistical Packages for Social Sciences (SPSS) (version 20) was used for data analysis. Descriptive statistics were mainly calculated for demographics and overall responses, and they included frequencies, percentages and means. A chi-square test of independence was used to determine the relationship between the healthcare professionals' perceptions of EHR benefit in improving inter-professional communication with respect to their occupation or previous training on EHR. The p-value was set at 0.05.

Results

Participants' characteristics

Out of the 1710 questionnaires distributed, 1127 were returned and found to be eligible for analysis. This represents a response rate of 66%. Most of the respondents were nurses representing 32.6% of the sample. Majority of the respondents (72%) were Saudi nationals. Female health professionals also comprised more than half of the health professionals representing 55.4%. The majority were 20 – 34 years old and had worked for less than 10 years or less in PHCCs in Riyadh. Moreover, almost 60% had no previous experience outside Saudi Arabia, training on EHR and experience on EHR in primary healthcare. This data is presented in Table 2.

Table 2 – Demographic Data of the Whole Population (n = 1710) and the Respondents (n = 1127)

Demographic characteristics		All (N = 1710) n (%)	Respondents (N = 1127) n (%)	Response rate per demographic (%)
Occupation	Physician	369 (21.5)	209 (18.5)	56.6
	Nurse	543 (31.7)	367 (32.6)	67.6
	Pharmacist	256 (14.9)	208 (18.5)	81.3
	Technician	368 (21.5)	228 (20.2)	62.0

Gender	Male	795 (46.5)	503 (44.6)	63.3
	Female	915 (53.5)	624 (55.4)	68.2
Nationality	Saudi	1103 (64.5)	811 (72.0)	73.5
	Non-Saudi	607 (35.5)	316 (28.0)	52.0
Age	20 - 34	803 (47.0)	608 (53.9)	75.7
	35 – 49	665 (38.9)	471 (41.8)	70.8
	50+	242 (14.2)	48 (4.3)	19.8
Length of working years in PHCCs in Riyadh	0 – 10	1065 (62.2)	870 (77.2)	81.7
	11-20	420 (24.6)	226 (20.1)	53.8
	21+	225 (13.2)	31 (2.8)	13.8
Previous health experience outside Saudi Arabia	No	978 (57.2)	686 (60.9)	70.1
	Yes	732 (42.8)	441 (39.1)	60.4
Previous training on EHR in primary healthcare	No	966 (56.5)	674 (59.8)	69.8
	Yes	744 (43.5)	453 (40.2)	60.9
Previous EHR experience in primary healthcare	No	978 (57.2)	686 (60.9)	70.1
	Yes	732 (42.8)	441 (39.1)	60.2

Perceptions of healthcare providers about the benefits of EHR systems

The majority of healthcare providers perceived EHR systems to be useful in improving communication between health professionals with the statement having a high agreement level of 73.6% as shown in both Tables 3 and 4. On an average scale, the statement had a mean agreement level of 2.65 (Standard deviation = 0.63, range: 2.61 - 2.69) at 95% confidence level.

Correlation between perceptions of EHR role in improving communication and health professional's occupation

There was a significant difference between health professional's perception of EHR role in improving communication between health professionals and other benefits in general ($p<0.0001$). Physicians had the highest agreement level of 83.7% with EHR benefit in improving communication between healthcare providers compared to other professionals. They were followed by pharmacists, nurses, other professions and lastly technicians with an agreement level of 63.2%. This data is presented in Table 3.

Table 3 – Correlation between Perceptions of EHR Benefits and Occupation Categories

Reduces medical errors	63.5	73.7	65.5	63.0	54.4	58.3	<0.05

Correlation between perceptions of EHR role in improving communication between health professionals and training

A significant difference was found in the perception of the EHR role in improving communication between healthcare professionals with training on the EHR and those without. Approximately 81% of the health professionals with previous training on the EHR and its benefits agreed that the EHR improves communication among healthcare providers compared to about 69% who did not have any previous training as shown in Table 4.

Table 4 – Correlation between Perceptions of EHR Role in Improving Communication and Health Professionals' Training in EHRs

Discussion

The aim of this study was to investigate the influence of health professionals' occupation and training in EHRs on the perceived role of EHR systems in improving communication between health professionals in Saudi PHCCs.

The findings suggest that healthcare providers consider EHRs to play a key role in the provision of healthcare in primary healthcare. Moreover, the study shows that the occupation of healthcare providers as well as their training in the EHR determine how they perceive EHR benefits including improving communication among healthcare professionals.

In general, the majority of all healthcare providers agreed that EHRs have benefits in improving communication among healthcare teams. Previous studies have also shown that the majority of the health care providers perceive the EHR to be useful in improving provider-provider interactions [3; 6]. This might be due to their experience in interacting with EHR systems at different levels of care including diagnosis, posting lab results, ordering and issuing of prescriptions. However, it could also be a common belief that such systems are effective in improving communication due to their interlinked nature of different departments in a hospital or organisational setting that allows sharing of patient's medical information. EHRs could be critical in these scenarios by providing the patient's medical and treatment history where a particular intervention is required [4]. It has been observed that EHRs serve as an important platform for sharing of patient information to guide the provision of better care that could significantly improve the efficiency and safety of health care and result in cost savings [11]. Gordon and colleagues also asserted that there is a need for effective communication among members of a healthcare team to not only improve the quality of patient care but also to reduce costs of treatment as well as improve patient experience [2; 12].

The benefits of EHRs in improving communication among health professionals were perceived most by physicians, pharmacists, and nurses. This could be explained by the close working relationships of these three categories of professions. They usually interact in many areas of patient care including diagnosis of diseases and prescription by the physician, drug selection and monitoring by the pharmacist, and administration and monitoring by the nurse. Hence, the need for constant communication. Vitari and Ologeanu-Taddei similarly showed in their study that the intent of use of EHRs varied among three categories of clinical staff including physicians, paraprofessionals, and administrative staff with physicians having a higher intent mainly due to professional autonomy and medical responsibility [13]. Another study involving health workers in Central Malawi similarly found that job title influenced EHR usage; however, its finding showing that about two-thirds of the clinicians preferred paper-based records to electronic ones was surprising [14].

Those who have training in EHRs in Saudi PHCCs agreed that the EHR plays a major role in improving communication among healthcare providers. A possible explanation for this result is that training improves understanding of the benefits of EHRs including improved communication among health professionals. Another study also observed that training of staff about EHRs significantly improved their use of the systems in the provision of healthcare services [15]. It had also been established that EHR training resulted in more usage of the system possibly due to increased user confidence [14]. For instance, a literature review by Wang and colleagues established that team training is one of the effective strategies that could, to some extent, improve communication between intensive care unit physicians and nurses [16]. It could, therefore, be argued that effective use of the system should go beyond the training to involve implementation where communication among healthcare providers remain key to achieve the desired patient outcomes.

Strengths and limitations of the study

A major strength of this study is that it is the first available published study in Saudi Arabia and covers a large geographical area making it generalisable to a large population in similar settings. However, the study also had some limitations. First, the findings could be biased as the study was based on participants' reports about their feeling of the impact of EHR systems in improving communication between health professionals. The target population was also not representative of health professionals working in Saudi public hospitals because the survey was done in only PHCCs. The population was also limited to healthcare professionals, but it could be extended to include other healthcare personnel such as administration staff. Furthermore, it did not include other facilities that are privately owned, managed by non-governmental organisations (NGOs) or other health service providers. It was not established whether other factors such as level of education of the participants might have an influence on their perception of the role of EHRs on improving provider-provider communication as there is evidence suggesting that these factors could influence electronic systems usage [14]. Lastly, the research mainly reports the findings from primary healthcare centres in an urban setting with well-equipped facilities that may not be generalisable to other geographical areas.

Implications for practice

The study impacts the current practice by highlighting the need for increased implementation and awareness of EHRs and their roles in healthcare among Saudi healthcare providers in PHCCs. In particular, it emphasizes the need to embrace the use of EHRs to facilitate communication among health professionals in the process of providing patient care. Considering this is the first point of care for the majority of patients, it would reduce the potential medical errors and harm to the patient thus ensuring the provision of cost-effective treatments to achieve the best outcomes. The staff should be regularly trained in the use of EHRs to improve their knowledge, skills, and confidence in using the systems so as to facilitate communication. However, the implementation of EHRs in the Saudi context should take into consideration the potential hindrance factors such as the language of communication. The working of the systems is mainly based on English, which is a second language to a large Saudi national population. This highlights the need for further training not only in using the EHR systems but also the language of communication.

Implications for research

The influence of occupation and training of health professionals on their perception of the EHRs' role on improving communication among healthcare providers should be investigated further in a larger population from urban, peri-urban, and rural areas as the geographical location may affect the results. Moreover, future studies should target all Saudi hospitals as this study targeted healthcare professionals in only PHCCs. The study also implies that other factors other than occupation and training that could influence EHR implementation in primary healthcare settings should be explored.

Implications for education

Training on EHRs should be included in teaching curriculum for all students undertaking health courses to improve their

knowledge about these systems and their role in facilitating communication for better patient care. Saudi hospital organisations should also conduct regular training of their health workers on EHRs and their benefits.

Conclusions

The study demonstrates that the occupation of Saudi healthcare providers plays a significant role in the providers' perception of the EHR role in improving communication between health professionals covering a wide range of issues related to patient care such as diagnosis, medications, and follow-up among others. However, the finding that the role of EHRs in improving communication among health professionals among other benefits varies across professions is a call for effective strategies that ensure that all healthcare providers embrace EHR systems for improved healthcare delivery. Training on EHR systems similarly influenced this providers' perception implying the tremendous benefit of training.

In this view, the study highlights the need for all PHCCs in Saudi Arabia and beyond to have EHR systems to facilitate effective communication. This is necessary to prevent errors, harms, and adverse events that may arise from ineffective communication. Moreover, all healthcare providers irrespective of occupation should be encouraged to use EHRs. This could be achieved through training that ensures that they are equipped with the necessary skills and knowledge to use them effectively.

Acknowledgements

The authors highly appreciate the healthcare professionals working in PHCCs in Riyadh city for their precious responses. We are also grateful to the University of Tasmania and the Ministry of Health of Saudi Arabia for its support.

Abstract

The aim of this study was to investigate hospital professionals' experience and attitude with patients accessing their own electronic health records. The study was conducted one year after service establishment. Data was collected through an online survey. In total, 457 replies were received. The results revealed a quarter of the administrative staff received feedback from patients or relatives regarding mistakes or missing information in their EHR. In addition, 67.5% of health professionals expected more patients to have basic knowledge of their health status in the future, and 21.4% found patients already gained better knowledge about diagnosis, treatment, or follow-up. The results also revealed some challenges with the service, especially for health professionals working in psychiatry, with some scepticism on whether the service is suitable for the sickest and most vulnerable patients.

Electronic Health Records, Patient Access to Records, Telemedicine

Introduction

Patient-accessible electronic health records (PAEHR) are developing in many countries, including Norway [1]. In Norway, the Electronic Health Record (EHR) has been fully established for many years now, and the patient is both the object and the owner of the health record. Patients have, since 2001, had the right by law to access their health record [2] and, in 2013, a White Paper stated patients should have digital access [3]. In accordance with the Norwegian Patient Right Act § 5.1 [2], health professionals can deny patients' access to either the full record or to specific documents in the journal if it is "necessary to avoid endangering the patient's life or serious damage to the patient's health", or if access to the information is inadvisable for persons close to the patients.

Currently, two of four health regions in Norway offer patients ages 16 or older, and parents of children under the age of 12, digital access to their hospital's EHR via the national health portal Helsenorge.no. Northern Norway was the first health region that offered all patients in the region digital access to their own EHR. In general, all documents available in digital format, including psychiatry reports, are made available for the patient as soon as they are approved/signed by health professionals, unless health professionals decide to deny access. In addition, a log list, showing those who accessed the record was made available to the patient at the time of this survey.

Before PAEHR was established, the University Hospital North Norway (UNN) sent their patients epicrisis by post after each consultation or hospitalisation. The other hospitals only sent it to the patient by request. In general, access to full or specific parts of the health record was given upon request where print or CD was sent via ordinary mail.

Patients reported to be generally satisfied with the PAEHR, recommended it to others, and generally understood the content [4]. At the same time, as the patients received this new service, a variety of tasks previously performed by secretaries or other support staff were transferred to the doctors [5]. Media claimed the time Norwegian doctors could use to direct patient care declined from about 60% in 2004 to less than 43% in 2012 [6]. It is not known whether PAEHR will increase the health professionals' workload and impact their work practice [7], create a different impact between health professionals (e.g. doctors and nurses) [8], and differ between somatic care and psychiatry, as others have been reluctant to provide open access to psychiatric records, considering it too sensitive [8].

The primary aim of this study was to investigate hospital health professionals' experiences and attitudes with patients accessing their own EHRs. The secondary aim was to explore whether there were differences in experiences and attitudes based on the implemented practices between hospitals, between doctors and nurses, and between psychiatry and somatic care.

The study was carried out in collaboration with the Northern Norway Regional Health Authority and the Norwegian Directorate of eHealth.

Methods

Data collection was performed through an online survey by sending a link via e-mail. The survey was distributed to all employees through a common e-mail list for the four hospitals in Northern Norway. The study was conducted in December 2016, after one year of experience with the service.

The respondents received different questions based on their professional background. The questionnaire to the health professionals and the administrative staff consisted of 25 and 14 items, respectively, including background variables such as job position, employment fraction, hospital, main working field (somatic/psychiatry/both), duration of practice, gender, and age. The questionnaire comprised of a combination of multiple choice questions, follow-up questions depending on the choices, and free text fields. Questions and quotes have been translated from Norwegian to English.

The questionnaire was anonymous. A questionnaire used in a pilot study was used as a template for the survey development. The questionnaire was pilot-tested by four researchers several times until no suggestion for modification came up.

No questionnaires were excluded from the analysis due to incomplete answers. The research objectives were investigated by descriptive statistical analyses using the statistical program R, version 3.4.2. For calculating the mean, the questions "Not applicable" and "I do not know" were omitted, and the response options were assumed to be at the interval level. A two-sample Student's t-test was used to test whether the differences in attitudes between health professionals from somatic care and psychiatry were statistically significant.

When presenting frequencies in the Results section, the "Totally agree" and "Quite agree" categories were merged into "Agree", and the "Yes, sometimes" and "Yes, quite often" categories were merged to "Yes". When comparing experiences and attitudes between doctors and nurses, both psychiatrists, psychologists, and physicians were included under the term doctor.

The free text responses were subjected to a content analysis aimed at identifying dominant themes related to the specific questions. Responses from health professionals within psychiatry and somatic fields were analyzed separately.

Some overall results from this study have been previously reported in Norwegian via oral presentations or the web.

Results

Demographics

In total, 457 replies were received. The responses were divided among the four hospitals as follows: 212 from UNN, 194 from Nordland Hospital (NH), 39 from Finnmark Hospital, and 12 responses from Helgeland Hospital.

As many as 77.7% of the respondents were female, and 80.7% of the respondents had a full-time position. The age distribution was quite uniform: 29.3% between 50 and 59 years old, 24.3% between 40 and 49, 24.1% between 30 and 39, 10.7% younger than 30, and 11.6% older than 59.

Most of the respondents worked in the somatic field (65.2%), while 27.4 worked in the psychiatry field, 3.5% in both fields, and 3.9% in other fields. Among respondents there were nurses (29.5%), doctors or psychiatrists (17.9%), other clinical positions (13.6%), psychologists (5.5%), social workers (2.2%), physiotherapists (1.8%), ergotherapists (1.3%), and radiographers (0.9%) in addition to administrative positions (27.4 %).

General Experiences Among Health Professionals and Administrative Staff

There were 332 responses from health professionals, and 125 responses from administrative staff members.

The main finding was that more than a quarter of the administrative staff received feedback from patients and/or their relatives regarding mistakes or missing information in their EHR (25.6%).

More than one third of both clinical (36.4%) and administrative (36.8%) staff received questions from the patients and/or their relatives related to use of the PAEHR. The same number of administrative staff forwarded requests from patients and/or their relatives to responsible health personnel (36.8%). Among health professionals, 15.4% received feedback from patients and/or their relatives regarding mistakes or missing information in their EHR. 72.8% of clinicians and 54.3% of administrative staff knew where to find information about the service.

Health Professionals' Experiences

The main finding was that 67.5% of the health professionals expected more patients to have a basic knowledge of their health status in the future, and 21.4% found patients were better informed about diagnosis, treatment, or follow-up than before (Table 1).

In addition, 28.3% experienced that the patients or their relatives referred to information from their EHR, and 19.6% of the health professionals planned to use the PAEHR in future follow-ups, for example, by adding more information in the EHR. 26.5% of the health professionals reported they had changed their way of writing in the EHR, while 71.4% meant that they should, in principle, complete the EHR documentation earlier, regardless of the patient's access. More results are presented in Table 1 below.

Table 1 - Health Professionals' Experience with PAEHR N=332

Do you agree with the following statements?	Yes[a]	No[a]
I expect that more patients will have basic knowledge of their health status in the future.	67.5	17.2
I find that patients are better informed about diagnosis, treatment, or follow-up than before.	21.4	36.8
I experience that patients/relatives refer to information they have found in their EHR.	28.3	69.6
I receive requests where I think: "Patients could easily find this information in their EHR, if they access it through the service".	26.8	69.9
I would use the patient's access in the follow-up, for example by adding more information to the patient in the EHR.	19.6	38.3
I changed my way of writing in the EHR.	26.5	61.8
In principle, I mean that we should write the EHR documentation earlier, regardless of the patient's access.	71.4	17.7
I inform patients that they can read their own EHR and check their referrals through the service.	50.8	38.3
I am worried that I need to spend a lot of time explaining journal content.	17.5	56.9
I am worried that I need to spend a lot of time reassuring patients because they have read their EHR.	26.5	46.4
During the past year, I discussed with colleagues whether there is a basis for denying a patient access to their EHR.	26.2	64.5

[a] "Yes" and "No" is presented in %. The "I do not know" category is not included in the table.

Differences in Practices Among Hospitals

The quantitative results showed no significant difference in attitude and experience between UNN (the only hospital that for several years sent epicrisis to the patients by mail after a consultation) and the other hospitals. However, by limiting the results to the psychiatry field, only, for the two hospitals with the most responses, 47.4% of the respondents from NH claimed they changed their way of writing in the EHR, while the corresponding figure for UNN was 30.8% (less than 40 clinicians responded at both institutions, p=0.139).

Differences in Experiences and Attitude Between Health Professionals in Psychiatry and Somatic Care

The results showed statistically significant differences in experiences and attitude between health professionals in psychiatry and somatic care regarding the use of PAEHR (Table 2).

The main finding was that as many as 43.9% of the health professionals in psychiatry reported they changed the way they wrote in the EHR after the service was established, compared to 23.6% from the somatic field. On the other hand, 77.4% of health professionals from psychiatry and 83.0% from somatic care expressed they should, in principle, write the EHR documentation earlier, regardless of whether the patient has online access or not.

In general, 27.2% of health professionals had discussed with a colleague whether to deny a patient access to information in their EHR or not. The problem was much more relevant in psychiatry, where as many as 60%, compared to 15.2% in somatic care, discussed this issue.

There was also a small difference between psychiatry and somatic care with regard to how often patients refer to information they find in their journal (18.4% vs. 25.4%).

Table 2 - Differences in Experiences Between Psychiatry and Somatic Care, 95% KI, p<0.05

Related to Use of the PAEHR-Service:	Somatic Care	Psychiatry	p
I experience that patients/relatives refer to information they have found in their EHR[a]	1.25 (1.20 - 1.31)	1.43 (1.28 - 1.48)	0.013
I changed my way of writing in the EHR[b]	3.24 (3.11 - 3.36)	2.70 (2.49 - 2.90)	<0.000
In principle, I mean that we should write the EHR documentation earlier, regardless of patient's access[b]	1.82 (1.70 - 1.94)	2.06 (1.88 - 2.24)	0.028
I discussed with colleagues whether there is a basis for denying a patient access to their EHR[a]	1.17 (1.12-1.23)	1.72 (1.58 - 1.86)	<0.000

[a] 1-no, 2-yes, sometimes, 3-yes-often
[b] 1-totally agree, 2-quite agree, 3-quite disagree, 4-totally disagree

Differences in Experiences and Attitude Between Doctors and Nurses

While 37.8% of the doctors were worried they would have to spend a lot of time reassuring patients or their relatives after reading their EHR, only 15.1% of the nurses expressed the same concerns (p<0.000).

While 37.8% of the doctors claimed they changed the way they wrote in the EHR, only 24.8% of the nurses changed their practice (p=0.045).

Qualitative Feedback on the Service

A total of 99 respondents provided additional comments in the open text field. There were 58 comments from health professionals from somatic care and 38 comments from health professionals in psychiatry, while three were categorised as both/other. From the somatic field, 39 comments came from UNN, 14 from NH, and five from the other hospitals. Of the 38 comments from psychiatry, 17 came from UNN, 15 from NH, and six from the other hospitals. Some comments included both support and criticism of the service, while others raised several concerns. Comments that did not contribute any specific experience with the service were categorized as neutral (Table 3).

Table 3 - Comments from the Respondent

Comments	Psychiatry			Somatic		
	UNN	NH	F	UNN	NH	F
Number of comments	17	15	6	39	14	5
Neutral	3			17	8	1
Positive	5[a]		2	6[a]	1	4
Critical	11	15	4	20	5	
Content of critical[b] comments regarding the PAEHR service						
Not suitable for any mentally ill patients	2	1	1			
Not suitable for all patient groups	8	5	1	1		
Patients should only be able to access parts of the EHR		2			2	
Patients might misunderstand		1		7	2	
Need to deny access	3	2	1			
Omit information	1	4		1		
Write a hidden journal	1	2				
Suggest delaying the information		2	1	1		
Complicates their work	2	4	3	8	2	
Worry for their own security		1		1		
Skeptical of the new logging functionality	1	2		1	1	
Other comments	1			7		

[a] Two of these also include critical comments, [b] Some critical comments raised several concerns

The positive comments from both fields mainly support the establishment of the PAEHR as a service.

The frequency of comments from psychiatry (38/125=0.304) was higher than that from the somatic field (58/298=0.195). In addition, 79% (30/38) of the comments from psychiatry were critical, compared to only 43% (25/58) from somatic care. Looking at the content of the critical comments, we also found more concerns were raised from psychiatry, compared to the somatic field (52 vs. 34).

The respondents' main concern was that PAEHR was not considered suitable for mentally ill patients (4), while 14 respondents considered it unsuitable for all patient groups in psychiatry. Examples of unsuitable patient groups were the sickest patients with psychosis, delusions, unrest, and utterance, where reading the EHR could worsen the situation. In addition, concern was raised towards vulnerable children with parents accessing the EHR on their behalf. Parents in a conflict situation, or if the child is a victim of abuse, could cause further

problems to the child. Vulnerable adult patients could also be threatened to show their EPR to others.

Some respondents commented patients should not be able to read the whole EHR, but maybe only the epicrisis. They worried patients with severe illness might misunderstand information, especially in the middle of a therapy period. Respondents referred to experiences where patients refused to speak with health professionals based on what they had read in the journal.

Some health professionals denied access to information they worried might harm the patient or their relationship with the patient. However, some pointed out that the functionality for denying access to information was complicated to use and little known. Other respondents reported they omitted some information from the EHR, and a few others reported they wrote a "hidden" journal containing the information they did not want the patient to read. Other suggested to delay displaying the journal documents, for example, until after the therapy period in psychiatry was completed. A number of respondents, from both fields, commented that PAEHR complicated their work, caused more work, and worsened the treatment. They felt they had to spend more time to evaluate what they should write or not. They had to write in a manner that the patient would not find offensive, and had to consider who they wrote to, a young person, old person, or a very sick person. If they decided to deny access to information, this could harm the patient-therapist relationship, as the patient might become suspicious and mistrustful. The service could also make it complicated to reflect on patients' symptoms through documenting "suspected" illness. Other comments focused on the difficulty to use the service for elderly patients, who might not receive any information from the hospital unless the epicrisis is sent by ordinary post as before.

Some of the respondents worried about the new functionality which provides patients with a log list of those who access their EHR. The respondents worried the service could complicate their work and patients could question their motives since they often accessed other journals to look for similar symptoms, used them as a template, or used them for teaching purposes.

A doctor working in psychiatry stated the PAEHR *"<…>complicates my work and worsens the treatment and alliance I will build with the patients*". Another said: "*I think it is not right that patients in psychiatry should have access to their journal. In fear of writing something "offensive" I think many therapists unfortunately have to do double-journal entries. Which again is vulnerable to getting lost. I deny the access when I know it's information that can be a trigger for the patient, but frankly, within psychiatry, there's a lot to be offended by, especially if you're mentally ill, and it could be impossible to predict what someone sometimes can take offence at".*

Discussion

The results of this online survey demonstrates several positive effects of the PAEHR. The fact that administrative staff received feedback from patients or relatives regarding mistakes or missing information in their EHR might improve the quality and correctness of the journal content and hence ensure patient safety and quality of the health service. This is very important for the patient in order to receive a correct diagnosis and a correct treatment. Two of three health professionals expected patients to gain more knowledge of their health status in the future, and more than one fifth found patients were already better informed about diagnosis, treatment, or follow-up than before. Despite some questions may be interpreted to cover more than the PAEHR, we believe the results of this survey demonstrate the potential clinical relevance of this service.

More than one fourth of the health professionals reported they changed their way of documenting in the EHR, as reported in other studies [8], while more than two thirds reported that, in principle, they should write the EHR documentation earlier. Future studies might explore potential changes over time, for instance, if more health professionals will alter their way of documenting due to the patients' access.

The results showed no significant difference in attitude and experience between UNN, the only hospital that for several years had sent the patients epicrisis by post after the consultation, and the other hospitals. However, looking at the psychiatry field, health professionals from NH claimed to have changed their way of writing to a greater extent than the health professionals from UNN. The results were not statistically significant, but supported by the comments from the two hospitals. There were more positive and neutral comments, and less critical comments from UNN compared to NH, where all the comments were critical (Table 3). These comments might support that UNN's earlier practice of sending out the epicrisis making the transition to the PAEHR service easier for their employees working in the psychiatry field.

The results revealed some challenges with using or adapting to the service, especially for health professionals working in psychiatry. Almost twice as many respondents from psychiatry than from somatic care reported they have changed the way they write in the journal, and nearly four times as many health professionals from psychiatry compared to somatic care have discussed with their colleagues whether to deny patients access or not. When comparing the frequency and content of the text comments, the PAEHR might have put an additional burden on some health professionals, especially those dealing with psychiatric patients. Many respondents questioned if the service was actually suitable for the sickest and most vulnerable patients. The health professionals could deny patients' access, but some respondents commented they did not have a strong enough reason to hide information, while others found the functionality to hide the information not user-friendly. Health professionals could benefit from information on, and continuous training on, how and when to deny patients' access to journal records.

Health professionals in the somatic filed received more questions from the patients regarding information in the EHR than health professionals in the psychiatry field (25.4% vs. 18.4%). There is therefore little reason to believe that higher levels of patient demand was the reason why health professionals within psychiatry seemed to raise more concerns towards the PAEHR.

More doctors than nurses claimed they changed their way of reporting, and twice as many doctors than nurses worried that they will have to spend more time reassuring patients, or their relatives, after they read their journal. This finding has probably more to do with the fact that the doctors who diagnose the patient, and have extensive knowledge, also have the overall responsibility for the patient, thus implying a stronger relationship. This might lead to a more negative attitude to the PAEHR as they feel a greater threat to their autonomy [9,10].

Norway and Sweden have comparable healthcare systems, and comparable PAEHR solutions in the way that patients have access to mainly all the information in the EHR system. Patients reported they are satisfied with the service [4,11], and the service fills important needs for them [11]. In Sweden, criticism has been raised from the clinical professions, and mainly from

physicians [8,9,12,13]. Physicians are mainly negative toward patients reading their health record online, while nurses are mostly positive, and nurses with some experience from patients using this service are more positive than nurses with no experience [9]. Physicians who used the PAEHR for themselves, as a patient, had a more positive attitude compared to physicians without such an experience [9]. Physicians were concerned patients could misunderstand the information in the EHR, something that would affect their work process and workload in a negative way [9,10]. A systematic review of studies from primary care indicated patients increased convenience and satisfaction, while health professionals were concerned about impact on workload and that the information would cause worry for the patient [7]. No changes in health outcomes were reported, but medical errors were detected, which may improve patient safety, and uptake of prevented care improved [7]. Several studies reported concern over increased workload, while only some demonstrated an actual increase in workload, and then in e-mail or online messaging, with face-to-face contact staying the same or falling [7]. In another study including 105 General Practitioners (GPs) and 13,564 patients, the GPs expected to increase their workload, while no significant increase in workload was showed after one year of experience. At the same time, patients reported an increased sense of control, better understanding of their medical issues, and they felt better prepared for future visits, in addition to improved adherence to medications [14].

Today, the PAEHR is well integrated in the two health care regions, and we believe that the positive benefits will compensate for the possible additional workload for health professionals. However, the issues raised by the health professionals from psychiatry should be followed up.

There are some limitations with this study which should be acknowledged. The online survey was sent to all employees through a third party (the IT-support organisation), using a common e-mail list, regardless if they had journal access or not. As a consequence, it was impossible to calculate an accurate response rate. However, the response rate was relatively low. We acknowledge that this type of recruitment for research easily leads to responses from people with strong opinions, very positive or very negative, more often than those who have not made an opinion. It is therefore important to be aware that the data material may be subject to this bias in the interpretation of the results.

More knowledge on how the service will influence both patients and health professionals in the future is necessary through further studies.

Conclusions

Health professionals' experiences and attitude with patients accessing their own EHRs was investigated through an online survey. The results revealed several positive findings, including patients identifying mistakes in the EHR and being better informed about diagnosis, treatment, or follow-up than before. The results indicate minor differences in experiences and attitudes based on the different practices existing at the different hospitals, and between doctors and nurses. On the other hand, major differences in experience and attitude were found between psychiatric and somatic care.

Health professionals working in psychiatry questioned if the service was suitable for the sickest and most vulnerable patients. Some adaptions, instructions, or training might be necessary to make the service more suitable for the psychiatry field.

Acknowledgements

This study has been partly funded by the Northern Norway Regional Health Authority and the Norwegian Centre for E-health Research. We would like to thank all the respondents for their contribution, and Helse Nord IKT and the hospitals for distributing the online survey by e-mail.

Service-Oriented Device Connectivity: Device Specialisations for Interoperability

Björn Andersen, Simon Baumhof, Josef Ingenerf

Institute of Medical Informatics, University of Lübeck, Lübeck, Schleswig-Holstein, Germany

Abstract

There are IEEE 11073 standards for foundational, structural, and semantic point-of-care medical device interoperability, but the first devices with this interface have yet to enter the market. One of the missing pieces for implementation and approval are Device Specialisations that specify how to use information and service models to represent a specific type of device on the network. Required and optional metrics need to be standardised as well as nomenclature terms, units of measure, and extension points. Finally, device-to-device interaction at runtime has to be defined for automatic verification during testing and approval. Applications include C-arm fluoroscopes used in different clinical settings.

Keywords:

Health Information Interoperability; Reference Standards; Computer Communication Networks

Introduction

Modern, sophisticated medical devices still lack the ability to exchange data with devices from different manufacturers despite the increasing demand from clinicians and operators [1]. Until recently, the options for integration were indeed limited: Next to proprietary solutions, the only open alternative was the *ISO/IEEE 11073 Point-of-Care Medical Device (PoCD) Communication Standard* that enabled simple point-to-point interaction between an agent and a manager. The requirement for a loosely-coupled system of networked medical devices, however, was only met by the introduction of the ISO/*IEEE 11073 Service-Oriented Device Connectivity (SDC)* sub-series of standards. Driven by the research project OR.NET [2], this series now provides point-of-care medical and surgical devices with a contemporary communication protocol based on web service technology.

In SDC, the information exchange is based on the *IEEE 11073-20702-2016 Standard for Medical Devices Communication Profile for Web Services (MDPWS)* that defines safety, streaming, and compression features on top of previously existing web service standards. In addition, the *IEEE 11073-10207-2017 Standard for Domain Information & Service Model for Service-Oriented Point-of-Care Medical Device Communication* specifies a participant model, which allows for the structured network representation of a medical device's capabilities, and a message model, which defines communication endpoints for these capabilities. Both models are represented in XML Schema (XSD), whereas a device capability description must be expressed in eXtensible Markup Language (XML). This allows for the validation of a device's description against the standardised model.

The endpoints defined therein are bound to MDPWS through the *IEEE 11073-20701-2018 Standard for Service-oriented Medical Device Exchange Architecture & Protocol Binding* [3]. For semantic interoperability, every item of a device description is annotated with a code from the IEEE 11073-1010X series of nomenclature standards. Furthermore, the SDC standards provide mechanisms for authentication, authorisation, and encryption in order to maintain the confidentiality of personal and associated medical data [3].

Whereas the components of a device description are well-defined, different manufacturers may yet model their functionally equivalent devices differently. For personal health devices (PHD), the introduction of *Device Specialisations* facilitated interchangeability of devices from different manufacturers in the patient's home environment. These formal definitions of device types specify the structure of the hierarchical *containment tree* that constitutes the capability description.

Device Specialisations are also necessary for SDC devices, but the specifications must allow for a wider range of applications than their PHD counterparts. In addition to the mostly static containment tree, it is necessary to describe the dynamic interaction and the requirements towards communication partners to allow for automated testing and validation procedures, which are currently under development within the scope of the research project *Modular Validation Environment for Medical Device Networks (MoVE)* [4]. These Device Specialisations will not only be required for regulatory issues and type approval, but also for actual plug-and-play of medical devices.

Methods

Requirements Analysis

The most important difference between PHD and SDC is the device-to-device interaction and remote control that is one of the key benefits of device interoperability at the point-of-care. For patient safety, it is paramount to describe the underlying interaction patterns in a way that allows for automatic verification. This includes the definition of non-trivial safe states and fall-back mechanisms in case of a communication error or breakdown.

Furthermore, medical devices may need other network participants in order to provide their own functionality. A universal foot switch, for example, requires some device that can be controlled. Deploying a component within a medical device network can be assisted by automatic assessment of

compatibility by validating the functionality that is offered by a system of medical devices against the required capabilities.

Device Specialisations for Service-Oriented Device Connectivity

An SDC Device Specialisation combines knowledge of the composition and usage of a medical/surgical device with expertise in device modelling. Manufacturers of a certain type of device agree on a containment tree structure that is then brought into a machine-readable representation using XSD. This enables the validation of a device's description not only against the standardised data model but also against this schema in order to determine the correctness of the device model and the compliance with the standard.

However, the underlying semantics of the device description are of equal if not greater importance. Therefore, besides the semantic information that is conveyed implicitly through the structure of the containment tree, every description and state element is annotated with a *type* using standardised nomenclature codes, the same applies for units of measure. These codes are either taken from the preferred IEEE 11073-1010X series of nomenclature standards or from other controlled vocabularies that can be referenced by the device description. Which term(s) to use is either strictly defined by the Device Specialisation or can be chosen from a limited set for a specific metric.

Whereas items that are defined in a Device Specialisation cannot be omitted in a device that is to fulfil the standard, adding specific functionality is allowed. It is thus possible to integrate manufacturer-exclusive innovations into the network representation or to fulfil more than one Device Specialisation at a time. For example, a complex patient monitor may serve as an electrocardiograph *and* a pulse oximeter *and* a blood pressure monitor.

Oftentimes, elements of the containment tree depend on one another, e.g. the dose area product (DAP) calculated by a C-arm fluoroscope depends on settings such as tube voltage, current, and exposure time. These dependent metrics are expressed in the specification as well as (safety) requirements towards devices that exercise remote control. In this example, a controlling device that modifies critical parameters of the fluoroscope may have to visualise the estimated DAP to the human operator for confirmation. In the same way, quality-of-service (QoS) parameter boundaries or technical infrastructure requirements can be expressed.

Finally, the dynamic interaction of a medical device with other devices and components needs to be defined and verified. Therefore, the runtime behaviour of the device is specified in a machine-readable way. The MoVE project currently explores the usage of *Testing and Test Control Notation version 3 (TTCN-3)* [5] for this purpose. It allows for the definition of simple and complex test cases involving an arbitrary number of participants including the device-under-test (DUT).

Regulatory Issues and Type Approval

SDC Device Specialisations simplify the development and testing process for medical device manufacturers, but they also play an important role in type approval. In addition to conformance testing against the IEEE 11073 SDC communication protocol, Notified Bodies are also expected to validate the functionality of a device against the Device Specialisation for its type. This kind of integration testing involves interoperability with other (simulated) devices as well as *intraoperability* – the correct representation of the actual (physical) device state on the network [6].

Ultimately, medical devices that perform a given task as part of an ensemble of components will need to obtain certification for the precise role they play in the ensemble. This role and the interaction capabilities thus need to be explicitly stated in the intended use description of the device and may modify the classification of the device if it is, for example, intended to control a device of a higher class [6]. Referring to roles and capabilities that have been standardised in the form of a Device Specialisation significantly simplifies this procedure for both the manufacturer and the Notified Body.

These benefits have also been identified by the U.S. Food and Drug Administration (FDA) in a guidance document on interoperable medical devices [7]. Whereas the European Union's 2017 Medical Device Regulation (MDR) [8] also offers a definition of interoperability, it remains vague with regard to its regulatory impact and the benefits of communication standards.

Results

In this section, we present how specifying the characteristics of a C-arm fluoroscope facilitates device interchangeability in two example use cases. Figure 1 shows a simplified containment tree with channels for the operational parameters of the fluoroscope, dosage information, and the motion of the C-arm.

Surgical Navigation: Collision Avoidance

For this use case, consider the task of collision avoidance, for example in the operating room: For intraoperative radiography or fluoroscopy, a C-arm is often used as it can move around the operating table to acquire image data. Obviously, this motion should not cause a collision with the table. Through the provision of positional data from the C-arm, a surgical navigation system could warn the user before a collision occurs or could even remotely stop the repositioning completely. In addition to the containment tree, the interaction pattern for this control operation is also part of a Device Specialisation.

Synchronisation of Fluoroscopy and Ventilation

Another use case that greatly benefits from standardised devices is the synchronised fluoroscopy. It would allow this procedure to be carried out with any two devices from different manufacturers. The fluoroscopy can be synchronised with the breathing cycle of a patient who is connected to a ventilator if both devices provide the respective data. For projectional radiography, it would also be possible to stop the ventilator for the duration of the X-ray image acquisition in order to minimise motion artefacts and continue the breathing cycle afterwards.

Note that ventilators at the point-of-care (e.g. in the ICU or for anaesthesia) require a different Device Specialisation than a Home Healthcare Environment Ventilator from the PHD domain. The latter, which is under development as IEEE P11073-10426, targets a different device category and is not expected to include device-to-device interaction or remote control capabilities.

Discussion

The benefit of a standardised medical device communication protocol in general and an SDC Device Specialisation in particular lies in facilitating real-world applications. The manufacturer-independent interchangeability reflects the clinical reality of heterogeneous devices that need to interoperate.

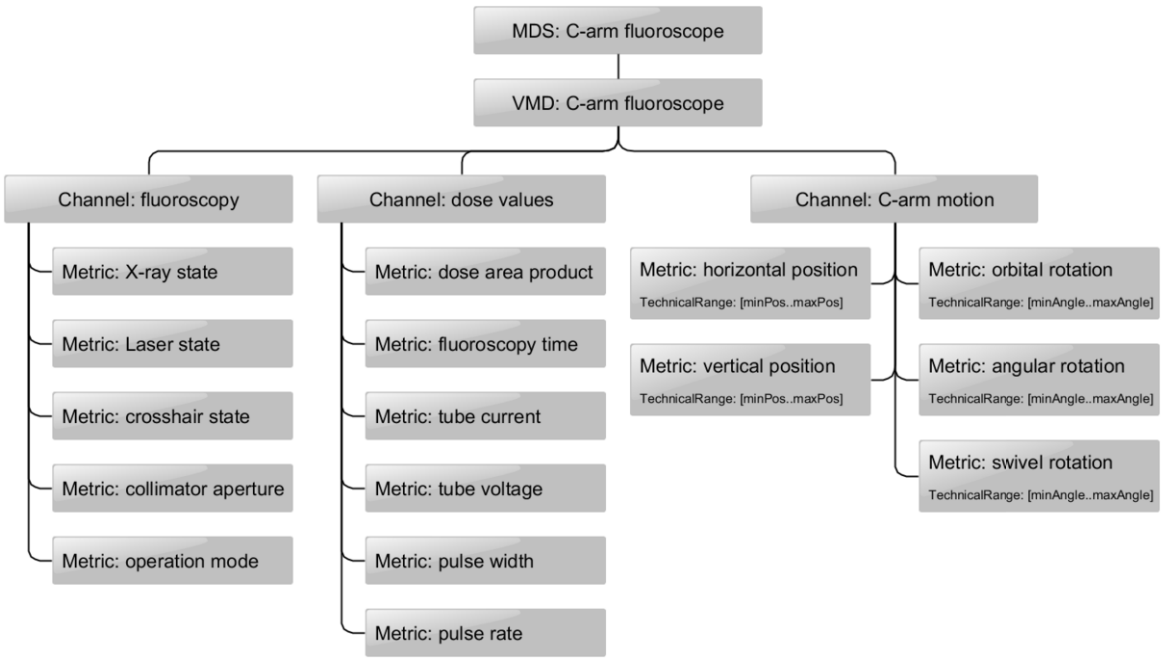

Figure 1 - Simplified model of a C-arm fluoroscope as a hierarchical containment tree; operations, contextual information, and alerts are omitted for brevity.

Whereas the PoC Device Specialisations currently under development refer to the SDC series and are going to be standardised within the new IEEE 11073-107XX sub-series, the payload of all IEEE 11073 communications is semantically described using the same vocabulary. Therefore, physiological measurements and other data can be combined from multiple sources, e.g. the home environment and the clinical workplace.

Conclusions

The standardisation of SDC Device Specialisations will further the implementation of open communication interfaces into actual medical devices, support the approval process, and facilitate plug-and-play. Devices that are interconnected using SDC will provide their operators with better assistance, perform more complex tasks in an ensemble, and ultimately increase patient safety.

Abstract

Medicine has evolved considerably in recent decades in part thanks to information and communication technologies in health (ICTs). However, face-to-face consultations continue to be the predominant model, since alternatives such as telemedicine are still the subject of debate. On the other hand, in some very specific specialties, centralization is relevant, mainly due to the low frequency and prevalence of diseases, as well as the need to have highly specialized professionals, causing problems in terms of accessibility and costs for the health system. In this study we have analyzed the first consultations to an orthopedics oncology service at a tertiary institution and performed an analysis of economic costs was carried out between 2 possible scenarios: face-to-face consultations versus telemedicine. Analyzing the 2 scenarios, there would be a cost-benefit in the use of telemedicine leading to a decrease in healthcare cost between 12.2% and 72%.

Telemedicine, Cost Analysis, Personal Health Records

Introduction

Medicine has evolved considerably in the last decades, mainly based on advances in technology [1; 2]. Some examples include imaging studies that have increases significantly in terms of definition and accuracy [3; 4]. Regarding the field of Surgery, advances have also been remarkable, including navigation-assisted surgery for oncologic musculoskeletal tumors [5-8]. However, the way to perform medical appointments, has not changed in the last decades. Personal interviews continue to be the prevalent model and although new alternatives have been proposed, such as telemedicine, its benefits and acceptance by the medical community continue to be debated.

For very specific medical specialties, centralization is relevant, mainly due to the low frequency and prevalence of the diseases as well as the need to have highly specialized professionals [9; 10]. However, in large countries, centralization can be a problem in terms of distance, transfer and healthcare costs.

Tele-orthopedics involves the provision of specialized services in orthopedics remotely. This, according to the taxonomy of telemedicine regarding the participants of the consultation, is usually carried out between an orthopedic surgeon and a patient [11]. Benefits have been reported regarding the use of tele-orthopedics services such as: significant savings in travel time; reduction of work times and increase in patient satisfaction regarding postoperative care compared to traditional methods [12].

The equipment used for telemedicine improves quickly as technology evolves in terms of quality, costs and ease of use. However, it is important to evaluate the quality and safety of the care provided, including patient satisfaction and its economic impact in detecting and reducing events before using this type of technology in medical care. Some studies suggest that telemedicine can be used as an alternative to face to face consultations for orthopedics patients in an outpatient setting. It was also proven that the use of videoconferencing systems was adequate to provide orthopedic care in rural areas, but most but most studies lack adequate assessment methods and cost-benefit analysis [13].

We analyzed first-time appointments for appointments of orthopedic oncology patients at a tertiary complexity centre and carried out an economic cost analysis between two possible scenarios: face-to-face appointments vs. telemedicine consultations. We attempted to determine if the use of telemedicine for first-time patients could save costs to the healthcare system.

Methods

Setting

Hospital Italiano de Buenos Aires (HIBA) is a non-profit organization with 165 years of history in Argentina. Its healthcare network includes a Universitary hospital of high complexity that covers health care for outpatients, inpatients, emergencies, critical care, home care, chronic care and medical and surgical specialties. It has its own medical insurance service (health maintenance organization), with more than 160,000 affiliates, and provides health services to 1,500,000 people with other health insurances. Annually, more than 45,000 patients are admitted to their hospitals, and 45,000 surgical procedures and 3,000,000 outpatient visits take place.

Since 1998, the HIBA has its own health information system (in-house) that includes the management of clinical and administrative information. Its Electronic Health Record (EHR) is an integrated, modular, problem-oriented and patient-centered system, used in the different clinical scenarios (ambulatory, hospitalization, emergency center and home care) [14; 15].

As part of the information system, an integrated Personal Health Records (PHR) called POPES is available to all outpatients since 2007. PHR allows patients receiving medical care in the hospital network to access and verify clinical and administrative information, and to interact with the health system. Among its main functionalities, the PHR allows users to update their personal information, share information, manage scheduled appointments, view test results, check, order and buy prescribed medication, to consult with the healthcare team through Telemedicine tools, and it has a messaging service for

communication with the general practitioner". At present, POPES has approximately 400,000 registered users [16].

Design

We carried out a prospective study. All the patients attended at an outpatient clinic by the orthopedics oncology team during the period of time between January and June of 2018 were analyzed. Relevant information of each patient was collected in a structured form in the EHR, which was completed by each professional. A total of 4 orthopedic oncology surgeons participated in the research. Only first-time appointments were analyzed.

An estimated economic cost analysis was carried out, considering: a) transfer cost b) face to face appoint cost c) telemedicine cost. For transfer costs, we took as reference a round trip airplane ticket for patients who lived at least 400 kilometers away from our hospital. The national airline (Aerolineas Argentinas) was used as reference for price and always the cheapest option was chosen. The cost of the face-to-face appointment according to our Hospital data was 49 U.S. dollars. The cost of the telemedicine appointment was set by our institution in US $80. Accommodation and travel expenses were not considered in the analysis. For patients under 18 years old, an extra flight ticket was added for cost analysis because they must be accompanied by an adult. The objective of the study was to determine whether the use of telemedicine for first-time consultations in orthopedics oncology would reduce the costs to the health system.

Results

A total of 1,224 consecutive appointments for orthopedic oncology were analyzed, of which 207 (17%) were first-time patients (see figure 1).

108 out of the 207 first-time patients (52%) were male and the mean age was 48 years (range 2-90).

The mean time between referral and face-to-face appointment in our institution with an orthopedic oncology specialist was 1.6 weeks (range 0-11). In 107 patients (52%), the diagnosis was made at the first-time appointment without the need of medical treatment, thus solving the problem with a single appointment.

36 patients out of 207 patients of 207 (18%) had to travel at least 400 km to access the hospital (table 1). These patients came from 14 different provinces (figure 2).

Estimated cost analysis

The equivalent cost for telemedicine for the 207 first-time patients would have been US $16,560. The estimated cost of transportation for this group of patients was $8,572 and the cost of the regular face-to-face consultation US $10,143 (total value: 18,715). This represents a mean value of US $90 per first time patient. Analyzing both scenarios, there would be a cost-benefit in the use of telemedicine for first-time patients at our orthopedic oncology unit, which would lead to a decrease in healthcare costs of 12.2%.

For the select group of patients (n = 36) who had to travel at least 400 km for the appointment, the economic benefit increases significantly, (US $2,880 vs US $10,336), representing a 72% reduction in costs.

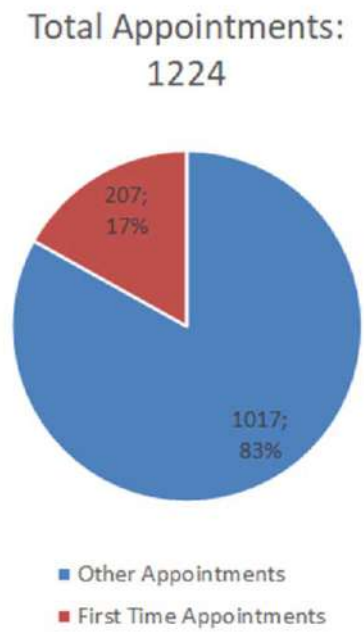

Figure 1: Total Appointments and First Time Appointments

Discussion

The present study, through a cost analysis, seeks to demonstrate potential savings with the use of telemedicine for first-time appointments to orthopedic oncology specialists for patients with suspected bone tumors.

Bone tumors are of low prevalence, with a wide variety of lesions that have a high risk of local recurrence and metastases, which is why timely diagnosis by a team of specialists has a direct impact on patient outcomes. However, the diagnosis is not a simple task and is often delayed due to the insidious presentation and high diagnostic error rate, since there are similar lesions that simulate these tumors [17]. In all cases, the formulation of differential diagnoses must be made with the integration of clinical signs and symptoms and diagnostic images. Based on differential diagnoses and staging studies, it is determined how and where to perform a biopsy.

Table 1: Characteristics of Patients in First Time Appointments

Variable	Value
Patients	107
Age average (yo)	48 (2-90)
Female	48% (N=99)
Male	52% (N=108)
Distance > 400 km.	18% (N=36)
Diagnosis in First Time Appointment	52% (N=107)
Mean waiting time from referral	1.6 Weeks

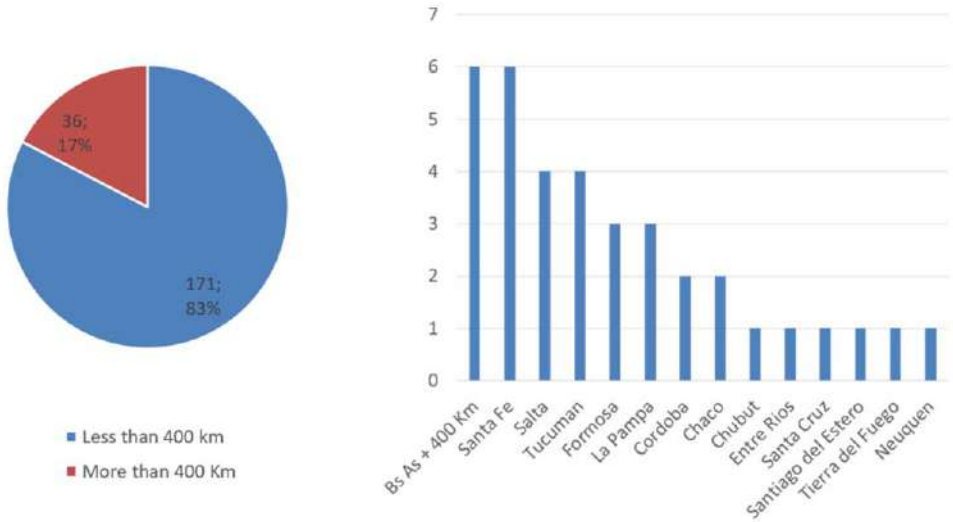

Figure 2: Patients' precedence

The average delay for an appointment with a specialist can be up to 10 months, and sometimes patients are attended by up to 5 medical teams with 30% of inadequate procedures carried out [17]. In the United Kingdom delayed diagnosis is the main cause of sarcoma litigation [18].

The wide geographical distribution of the patients that are treated the Hospital Italiano de Buenos Aires means that the use of Telemedicine has an enormous potential when it comes to improving accessibility and healthcare costs, since 50% of consultations can be solved in the first appointment. This first appointment is usually centered in the review of patients' medical records and all their tests and studies. This information is sent asynchronously, reviewed and analyzed by the professional team and then a synchronous meeting with the patient is scheduled for notification of the resolution of the team in each case, and to schedule the steps to follow (either the need of referral to perform more studies or schedule long-term controls).

The present study was limited to comparing estimated costs for the healthcare system, establishing a standardized cost of travel ticket and cost of care, without taking into account the real costs according to the distance for each case, nor the cost derived from the need to repeat studies, as well as the loss of profit of patients and their families. Additionally, we did not consider differential costs according to patient age, despite pediatric and elderly patients could have higher costs given the need of a companion.

At the end of this study, we did not find evidence of a cost analysis for these patients. However, there is plenty of evidence for other groups. For example, a study that evaluated the impact of electronic consultation on a Canadian tertiary care pediatric specialty referral system concluded that similar to what happens with adults, electronic consultations improves primary care physician access and timeliness to elective pediatric specialist advice and influences their care decisions, while reporting high end-user satisfaction [18].

A study that evaluated the cost of a speech pathology synchronous telepractice service for patients with head and neck cancer concluded that such telepractice service provides cost-efficiency over standard care through the provision of a remote specialist [19]. Another group that studied the use of telemedicine for the same pathologies reported that this service allows timely access to surgical care along with considerable savings for patients with head and neck cancer [20].

The main limitation of our study is the estimated costs methodology: it is not an analysis of real costs, since we used the same value for transfer costs for all patients. Another limitation was that other variables that can influence costs were not taken into account.

In future lines we intend to make qualitative evaluations to patients whose diagnosis were negative in the first consultation to make a long-term follow-up of the final diagnosis and an adequate calculation of costs taking into account all the variables, so we can account for the real cost-effectiveness of the system.

Conclusions

In our experience with the implementation of a telemedicine tool for first-time appointments with orthopedic oncology specialists, the estimation of costs in a limited period of time suggests that this intervention may reduce costs to the healthcare system.

Acknowledgements

This work was carried out with the collaboration of the Institute of Orthopedics and the Department of Health Informatics of Hospital Italiano de Buenos Aires. We thank the entire interdisciplinary team (doctors, nurses, designers and developers) and the patients who trusted us and made their consultations at a distance.

Abstract

The Primary Health Care strategy is based on organization of interdisciplinary teams and comprehensive approach to health, disease and health care processes. To strengthen information systems so that they represent primary health care complexities, participatory meetings were held with primary care practitioners from the public health care system of Buenos Aires City. Terms for the record tool and its components were chosen using consensus methodologies. This process involved 300 practitioners from 49 centers, and submission of 21 proposals. It was decided to change the term "Electronic Medical Record" with "Comprehensive Health Record." It was also agreed that, apart from "Reason for Consultation," the field "Problem Situation" would be added, that "Care Service" would be replaced with "Care Act," and that a new module "Health Team Management and Education Activities" would be included to document practitioners team activities.

Keywords:

Public health informatics, primary health care, electronic health record

Introduction to this Article

Use of information technologies (IT) in complex adaptative health care systems remain a challenge for design, development, implementation, and evaluation of interventions. The comprehensive socio-technical model proposed by Dean F. Sittig [1] provides useful analysis framework for considering complex interaction between social and technical factors coming into play in any implementation.

An electronic record system was implemented following 2016-2019 Health Plan for the public health care system of Buenos Aires City, which included a digital health strategy. As the system failed to reflect specific characteristics of primary care work processes and primary health care (PHC) strategy [2,3], it encountered practitioners' resistance, dissatisfaction, and dissent.

It is well-known that users' involvement and engagement in design of health information systems is key to software adjustment to work processes, lower resistance to use, tool adoption, and successful implementation [4-6]. This approach proves to be even more significant with in-house development capabilities. However, achieving meaningful participatory processes in health care organizations remains a challenge. The case under study is molded by characteristics of work processes in the primary health care strategy, whose foundational principles include interdisciplinary teamwork and comprehensive community-based approach to health, disease, and health care processes [7-10].

In this context, the question is how to introduce adjustments into the record system in a participatory way, given characteristics of primary health care practice and PHC strategy in public health care system of Buenos Aires City. The objective of this paper is to present consensus-based experience and participatory decision-making employed to develop record tools representative of characteristics of primary health care.

Background

Primary health care professionals are responsible for all actions and services delivered in basic specialties and outpatient modalities. Primary health care centers are people's main entry point to and follow-up area in health care networks. Primary health care centers are organized around the PHC strategy. According to WHO, this strategy is based on certain essential elements, such as universal health care access and coverage, comprehensive and integrated care, emphasis on health promotion and disease prevention, family, and community guidance, active participation mechanisms, organization of multidisciplinary teamwork, territory-based approaches, among others [11].

Implementation of electronic information systems in Buenos Aires City started June 2016 in primary health care setting. Its first phase was completed in 2017. This implementation phase included system based on three modules: patient identification, appointments, and simple-format electronic medical record (EMR) for documenting health consultations between patients and practitioners. The EMR had two mandatory fields: free text progress report and reason for consultation using terminology service whereby list of patient problems is generated [2,12]. Figure 1 shows EMR components used to document a medical act.

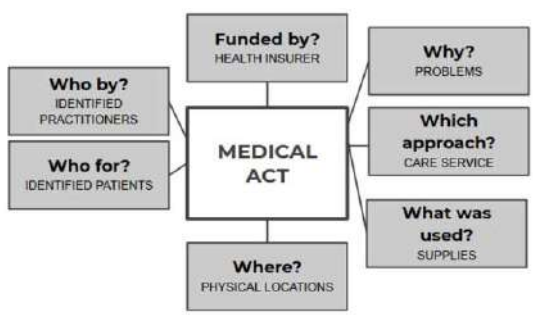

Figure 1-Medical Act Components in the EMR

Given that it is crucial to monitor how the system is used at early implementation stages in order to ensure immediate

response to users' comments and requests [9], in November and December 2017, a Health Information Systems Office team conducted a survey to make qualitative assessment of users´ perceptions. Group interviews were carried out with 130 system users in 11 primary health care centers with at least a 6-month system implementation. Results concerning EMR design and format revealed difficulty in documenting some primary care practices, such as interdisciplinary health care and community activities. Some limitations were also observed in trying to represent complexity of health, disease, and health care processes with available terminology services, particularly in connection with social determinants of health as described in literature [13].

In early 2018, based on results of this assessment, the entire terminology used in the EMR was examined. It was observed that over 50% of total documented terms (n=39,492) were not health-related problems, but referred to other components and processes that the system was not adequately capturing. Furthermore, medical act structure was duly adjusted to primary care documentation needs. Figure 2 shows results of this analysis. The care act, not only medical act is central, and components that need to be represented in the system have been added. These components include different care modalities, other physical locations, other types of care provision, and terminology for comprehensive health care.

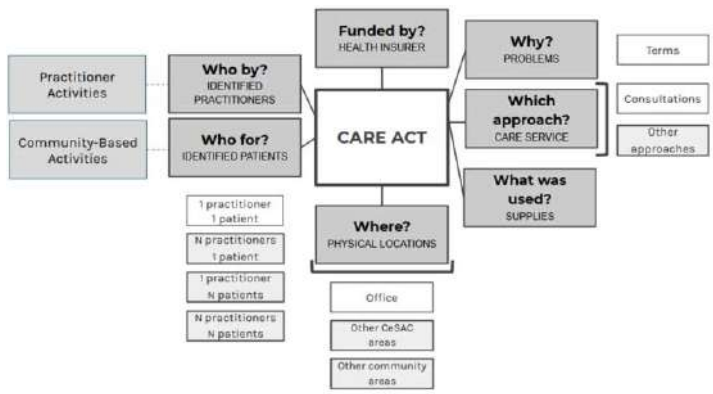

Figure 2-Care Act Components in Primary Health Care

Methods

Setting

Buenos Aires City healthcare network is composed of Ministry of Health, 35 Hospitals, 74 Primary Care Centers (CESAC, CMB), 1 Ambulatory Reference Medical Facility (CEMAR), 2 children´s dental centers, and 2 mental health centers. It is structured into 12 geographical areas to organize health care delivery. The health system employs a total of 41,000 people. Since June 2016, Electronic Medical Record (EMR) has been gradually implemented in outpatient settings [2]. By October 2018, 60 healthcare facilities were using EMRs, over 1 million EMRs had been opened, and 2.5 million clinical notes registered.

Experience Systematization

An interdisciplinary team of medical practitioners, psychologists, educators, anthropologists, and communicators was created in order to plan the strategy. Starting point was a number of meetings convened by the organizing team. It was decided that the objective of systematization was to document the process of reaching participatory consensus and its ensuing agreements. All records and documents produced during planning and development were collected and analyzed, their history being traced (see *Meeting Methodology*). *Results* were systematized, and subsequently all information was examined and organized according to predetermined structuring component, to eventually arrive at critical interpretation of the whole process (see *Discussion*). Finally, *conclusions* and lessons were drawn and documented in writing.

Meeting Methodology

Design of system evincing complexity of PHC strategy, as in care act structure, required thorough reflection by its users. First, organizing team reached their own conceptual agreements, consulted literature on consensus methodologies [10], and decided to hold participatory meetings with end users for tool design as first step in a series of iterative cycles of interaction and agreements. Agenda of these first sessions was to find: a) most appropriate denomination for patients' individual health record tool, commonly referred to as Electronic Medical Record, b) appropriate denomination for each of the care services provided, c) how to organize and denominate problems and reasons for consultation, and d) how to organize and denominate professionals´ activities which do not entail direct contact with patients. Four activities were planned, and work proposals were pilot tested before implementation with a team consisting of 6 primary care practitioners. Meeting development was supported by active strategy of communication with end-users.

First On-Site Meeting

Primary health care centers´ heads and practitioners comprising maximum 4 people per institution were invited. It was suggested attendees should represent different disciplines. Invitation was made via official communication, e-mail, and telephone calls. Previous registration was also requested using structured form with mandatory fields including institution, full name, discipline, contact information, and available time for attendance. The first meeting aimed at introducing some concepts about information systems based on care act structure and work on components that needed to be represented. Work was organized in small groups of about 6 people from different

disciplines and institutions. These groups were previously formed by the organizing team. Each group was given a list of 100 terms frequently used in the EMR. These terms had been previously selected out of the total terminology (n=39,492) to collect a purposive sample representing term heterogeneity. Sample was made of 300 terms divided in 3 groups of 100 terms. Each team was asked to analyze and divide terms into categories, choosing a name for each of them and determining their scope. These ideas were visually represented in a map and shared among all attendees. Findings were pooled, similarities and differences identified. At end of the meeting, working materials were handed over to each institution, so that activities be replicated locally with rest of the team and new proposals generated. A virtual semi-structured template was developed for motions to be submitted. Structured fields had to contain suggested terms for each component, and free text fields for rationale, comments, and so on.

Local Work

Each institution was allowed to work on its own or with the organizing team. New proposals were presented within 3 weeks, as established. Organizing team systematized information in a comparative chart. Structured data were collected, eliminating duplicates. Data in free text format were examined based upon conceptual recurrence.

Second On-Site Meeting – Panel of Representatives

Two representatives of each institution were invited. Proposals resulting from local work instances and their analysis were shared. By means of scoring system, all attendees on one hand agreed on alternatives to be excluded and, on the other, accepted those to be submitted to open voting. Conceptual definitions were discussed, agreed on, and put in writing. In addition, lists of practitioners willing to participate in later work cycles were drafted.

Open Virtual Voting

The consensus-based options were submitted to voting using web platform known as *Portal APS en Red*, used by primary health care institutions for news, instructions, and system access. Voting was open for 3 weeks.

Results

First On-Site Meeting

Meeting was attended by 120 users from different disciplines (see Table 1), representing 49 primary health care institutions. At debriefing, following initial consensus was made:

1. Having common information system helps institutions perceive themselves as part of an integrated network.
2. The way of representing population´s health problems is heterogeneous across institutions.
3. It is necessary to work together in order to enrich terminology services, particularly in connection with social determinants of health.
4. It is vital for the system to represent interdisciplinary activities.
5. Care acts may be health care-related, disease preventive, health promotional, or educational. They may also be individual or group/community-based.
6. Care acts may take place either in health care institutions or outside them, that is, in community institutions.
7. Reasons for consultations are not always health-related problems.
8. Information documented in the system may be epidemiological or administrative, for planning and management purposes.
9. The EMR is a tool for documenting people's health. It is necessary to count on other tools to document practitioner education and management activities.

Local Work

Twenty-one proposals were received. The organizing team was called in by 3 institutions. Structured data systematization resulted in following alternative names for each component: a) EMR: Single Comprehensive Health Record, Comprehensive Health Record, Health Care Electronic Record Instrument (IRES, by its Spanish acronym), Health Record, Electronic Health Record, Diagnostic Summary, Medical Practice Record, Health Practice Record, Personal Health Record, and Comprehensive Health Record. b) Care service: Provision, Intervention, Approach, Care Act, Team Practice and Response. c) Problems: Problems, Problem Situation, and Reason for Consultation. d) Practitioner activities: Special Practitioner Activities, Professional Interventions, Health Team Management and Education Activities, Practitioner Activities, PHC Team Professional Activity.

Analysis of free text showed no new findings and reinforced some of the initial agreements reached during first on-site meeting, particularly need to differentiate reasons for consultations from health problems, and existence of different types of care acts.

Second On-Site Meeting – Panel of Representatives

Meeting was attended by 32 practitioners from 21 institutions and different disciplines (see Table 1). The consensus-based voting options were: a) EMR: Comprehensive Health Record and Health Record; b) Care Service: Care Act and Intervention; c) Problems: it was unanimously decided not to submit it to voting and resort to a different record for Reasons for Consultation and Problem Situations; and d) Practitioner Activities: Health Team Management and Education Activities and Practitioner Activities. The definitions for each component were agreed in writing (see Table 2).

Table 1-Disciplines of On-Site Meeting Attendees

Discipline	Meeting 1	Meeting 2
Medicine/Dentistry	55%	43.74%
Social work	10%	21.87%
Psychology/Educational Psychology	6.66%	15.72%
Speech therapy	2.5%	-
Administration	4.17%	-
Nutrition	4.17%	9.37%
Nursing	1.67%	-
Obstetrics	1.67%	-
Anthropology	0.83%	-
Unspecified	11.67%	9.37%

Open Virtual Voting

Total of 153 voters participated. Results were as follows: a) EMR: Comprehensive Health Record (81.05%), b) Care Service: Care Act (52.24%), c) Reason for Consultation and Problem Situation was unanimously agreed on during on-site meetings and, d) Practitioner Activities: Health Team Management and Education Activities (79.58%).

Discussion

The complexity of primary health care in public health care system of Buenos Aires City was evidenced in the number of health care centers participating in the meetings, multiplicity of disciplines involved, and heterogeneity of terms used to refer to the population's health problems. In this context, reflecting

upon design of information systems which capture this complexity turned out to be quite challenging [8].

Table 2-Consensus-based Definitions for Voting

Component	Consensus-based Definitions
Electronic Medical Record	Mandatory, unified, personal, electronic record, documenting all actions performed on individuals by health care professionals and teams (Law 26.529/09 and Law 5.669/16). It was agreed that the denomination of Health Record to be used across whole network should be representative of complexity of the health, disease and health care processes.
Care Service	Every act performed by health care professionals or teams (Law 5.669/16). This refers to every contact between the health care team and individuals in the community, be it individually or in groups, and for care, prevention, or promotion purposes. It may adopt different modalities, such as consultation, advice, recreation, workshops, talks, and so on.
Problems	Reason for consultation: Everything patients express as reasons for presenting to, visiting or contacting a health care professional, this being their subjective perception and including the way they express themselves. Problem situation: Everything that triggers action by the health care professional, both in terms of education, promotion, and prevention, as well as for diagnosis, treatment, and rehabilitation purposes. These are assessments and findings based on professional expertise and knowledge of patients. It may be individual or family-related, and it may be a social or environmental determinant.
Practitioner Activities	Individual or group activities carried out by health care professionals without direct contact with community or patients including education, planning, evaluation, team meetings, case reviews, supervisions, and so on.

Design and implementation of information systems are impacted by technical aspects. However, social and cultural dimensions within institutions play fundamental role [1]. In primary health care, it was necessary to engage in in-depth discussion as to how health, disease, and health care processes are understood and how work processes are represented within the framework of PHC strategy. The consensus methodology used during meetings paved way to conceptual agreements, which are necessary starting points. These overall agreements were attained owing to the fact that participants got involved in the process and effort was made to set transparent rules [6,10].

At onset of implementation in primary health care, the information system was resisted by users. With time, different opportunities for interaction and joint work facilitated progressive appropriation of the tools by users, which was apparent in increased meeting participation. Once certain degree of system maturity was gained, it was a paramount goal to convene meetings to enable users make thorough assessment which might lead to ideas for real improvement.

Considering characteristics of health care organizations, two fundamental challenges arise when trying to manage change: striking adequate balance between practitioners' autonomy and clear definition of responsibilities; and at same time, implement change smoothly and strategically whilst coping with resistance [14,15]. Thus, it was key to promote opportunities for practitioners to work autonomously, with probable support of organizing team, open communication and interaction channels, clear goals and scope when managing meetings, and to underscore shared responsibility for introducing tool improvement motions as well.

The blended on-site and virtual strategy was instrumental in offering participation opportunities flexible enough for virtual participation of all practitioners, which allowed for organized work in smaller groups at on-site meetings.

Proposal to reflect on design of record tool shared by all institutions and practitioners helped show that information is crosscutting and also to envisage prospect of integrated health network favoring continuity of care.

Among conceptual agreements resulting from meetings, mention should be made of comprehensive view of health embodied in replacement of electronic medical record with comprehensive electronic health record; interdisciplinary approach and different types of care provision, reflected in substitution of care act for medical act; complex representation of multiple situations that may result in contact between practitioners and people in the community, captured by agreement to distinguish between reasons for consultation and problem situations; and significance of documenting practitioner activities that add quality to care act, such as education, team meetings, and activity planning.

The magnitude of these agreements is not only seen in change of terms used in the system, as with the EMR, a main tool in health information systems. Agreements also exhibit perspective which is not only medical/clinical and focused on health problems, but also comprehensive, interdisciplinary, and care-oriented.

Even though meetings aimed at defining terms for some of the record tool components, process complexity showed that, beyond terms, the way things are named bears highly symbolical and conceptual impact.

Based on achievement of conceptual agreements and term changes, in future, specific working groups will have to be organized for participatory design of functionalities representing primary care work flows.

As to limitations of these meetings, even when call was open and there was active participation, few practitioners were not challenged by the agenda and did not attend.

Conclusions

The experience derived from our meetings unambiguously stresses user participation in design of representative information tools as well as reaching conceptual agreements conducive to denominating health, disease, and health care processes recorded in the information system.

Implementation of these results will be carried out throughout 2018 and 2019, starting with change of term "Electronic Medical Record" to "Comprehensive Health Record," since other components demand software engineering.

Abstract

Complex prescribed medicine regimens require extensive self-management. Handling multiple pills can be confusing; using a pillbox organiser is a common strategy. A smart Medication Coach Intelligent Agent (MCIA) can support patients in handling medicine. The aim of this research was to evaluate the feasibility and acceptability of the MCIA. A prototype was tested with 15 participants, age 17-76, filled a pillbox according to prescription assisted by the MCIA implemented in a Microsoft HoloLens. A quantitative method using questionnaires was applied. Results showed that using the MCIA implemented in an AR-headset, to assist people with prescribed polypharmacy regimen in filling a pillbox, was feasible and acceptable. There was a difference related to age regarding people's willingness to use an AR-headset for medication self-management. People older than 65 felt less comfortable using the technology and were also more hesitant to use the technology than those under 65.

Keywords:

Self-Management, Artificial Intelligence, Polypharmacy

Introduction

For people with chronic disease and multiple prescribed medications, self-management is considered an essential component [1]. Self-management requires an active role of the patient, including managing symptoms and medical treatment on a daily basis [2]. Using multiple medicines is commonly referred to as polypharmacy and is more common among older people [3]. On average persons older than 65 years have three chronic conditions, and more than 70% take five or more drugs every day. For patients with coexisting conditions, who take multiple prescribed medications distributed throughout the day adherence can be particularly challenging [4, 5].

Adherence to medication regimens is key to achieving better health outcomes for patients. Nonadherence to prescribed medication affects both the quality and length of life for patients [6]; it also places a significant cost burden on healthcare systems [7].

Common strategies used by older people to improve adherence to polypharmacy treatment is to associate medications with specific daily routines, such as meals, and using a pillbox [2, 8]. Instead of taking pills from multiple packages at different times throughout the day, the pillbox is filled up for a week at the time. A pillbox commonly has 28 compartments, distributed as seven horizontal compartments labeled Monday to Sunday, with four vertical slots for each day. The vertical compartments have labels suitable for the most common times to take pills during a day, such as morning, noon, evening, and bed.

Handling one's pills and filling the pillbox is part of medication self-management. Complexity in treatment regimens can lead to difficulties for people to continue self-management related to taking medicine and filling the pillbox. Medicine pills that look similar and use of generic medications can cause confusion and insecurity which in turn may be the trigger point for why people are unable to continue self-management and instead need to apply for health care services and help from a nurse to fill the pillbox for them. With this situation, patients lose their independence. It also puts a strain on society and health care systems, as there in many countries is a growing shortage of nurses and other health care professionals.

Based on the augmented reality (AR)-paradigm and intelligent coaching systems, a novel solution has been introduced. A smart mHealth application that can support patients with common problems related to the management of their medication makes it possible to provide patients with assistance and give advice when filling a pillbox, thus enabling continuous self-management and delay or minimize the need for nurse intervention [9, 10]. This smart mHealth application is designed and implemented as a Medication Coach Intelligent Agent (MCIA). By Intelligent Agent, we mean a software program able to be reactive, proactive, autonomous, and social. Autonomy plays a critical role in the behavior of an intelligent agent since it is expected to take decisions on its own. Hence, the MCIA has to manage different types of information such as medication plan (medication regime) of the patients, medication restrictions, as well as the patient's preferences and sensor input data from an AR-headset. It has proactive and reactive behavior in order to support patients in medication management. The MCIA is implemented in an AR headset and has autonomous reasoning capabilities that allows it to lead with long term goals in the settings of medication plans [11].

An augmented reality (AR)-headset makes it possible to have the mobility of a mobile device and still establish a social and friendly relationship with the user in hands-free interaction. Through holograms, it is possible to augment the users' field of view with an avatar. With a digital avatar, there are more possibilities regarding looks and appearances compared with a physical robot, which might have more effect on the intentions of the users. An AR headset, such as Microsoft HoloLens[1], makes it possible to be more aware of the environment and user activities because of its many sensors.

The main difference between classic smart pillboxes and the MCIA is that the technologies provide support in different stages of the medication self-management process. Classic

[1] https://www.microsoft.com/en-us/hololens

smart pillboxes and smartphone apps generally target patient groups who need help with reminders of when to take medicine, supporting the patient at the time when the patient is to put the pill in his or her mouth. The MCIA may be used for this purpose. However, it can also support individuals at an earlier stage of the medication process, when they are filling up weekly pillboxes with pills from prescribed cartons.

The aim of this research was to conduct a pilot study to evaluate the feasibility and acceptability of the proof-of-concept prototype of the Medication Coach Intelligent Agent (MCIA), implemented in an AR headset. The prototype was tested in a living lab context where participating individuals filled a pillbox according to a prescribed polypharmacy medicine regimen, assisted by the MCIA implemented in a Microsoft HoloLens. We aimed to answer the following questions: a) Is there a difference, related to age, regarding if people are willing to use an AR headset for medication self-management? and b) Is there a difference, related to the experience of using smart technology, regarding if people are willing to use an AR headset for medication self-management?

This paper represents a follow-up to our previous research. Details regarding the development process of the MCIA and technical specifications have been described in previous publications [9]. Focus in this present paper is on the user perspectives.

Methods

Quantitative methods were used for data collection and analysis. The material was explored through descriptive statistics. The research presented in this paper was conducted as a multidisciplinary collaboration between community medicine, computer science and, artificial intelligence researchers.

Setting and Participants

The prototype was tested in a living lab context. The setting was a quiet and home-like environment. Convenience sampling was used, where persons in a medium size town were asked to participate in a study and test a digital tool with the purpose to assist individuals in handling medicine and filling a pillbox. Description of participants is given in Table 1. The evaluation involved 15 participants who were selected based on the following criteria: 1) Different levels of management of medication on a regular basis, 2) Wide range of ages (medication management applies to people in all ages, not just elderly), 3) Different levels of experience from using smart technology in general and 4) A mix of men and women.

Table 1– Characteristics of Participants (n=15).

Parameter	Value (n)	Value %
Age (years)		
mean (range)	49 (17-76)	
median	58	
Gender		
women	9	60
men	6	40
Using medication	8	53
Helping others with medication	1	7
Have experience using smart technology	8	53
Familiar with AR	4	27
Persons older than 65 yrs	7	47

Procedure

Initially, participants were informed about the test procedure, which was divided into 4 sequences: 1) Fitting of the AR headset, including adjusting the size and adequate positioning on the head. 2) Becoming familiar with using the AR headset. Participants were guided by the test leader to explore features in the AR-headset for the purpose of becoming acquainted with using command functions and the feeling of receiving information through holograms. 3) Performing the actual test, handling prescribed medicine, and act on information given in holograms. 4) Responding to the evaluation questionnaire. None of the participants had used or tried on an AR-headset prior to the test.

Functionality of the MCIA

The functionality involved displaying information about the prescribed medicine, thereby helping the user to select the right medicine and dispense pills in a pillbox according to prescription. The participants were able to use voice, vision, and gestures to interact with the system and were presented with both visual and audible output. Visual outputs were in the form of holograms. Output information showed whether the person had selected the right medicine and gave information about how many pills of that particular medicine to put in each slot of the pillbox.

Instrument

Data was collected through a questionnaire which was developed at Nordic Telemedicine Center, NTC: The questionnaire was intended to be used for evaluation of digital innovations developed through the NTC [12]. The instrument comprised totally 20 items, distributed as seven questions, Q1-Q7, regarding personal background information and the following 13 questions, Q8-Q20, were formulated as statements relating to participants' experience of using the MCIA. Responses for Q8-Q20 were on a five-point Likert type scale graded from value 1 (strongly disagree) to value 5 (strongly agree). The lower bound to agree was made at value 4 (4 or 5 = agree). Examples of statements are: "It was easy to understand the presented information," "I felt comfortable using the technology," and "I am willing to use this technology if it was available right now."

Acting on Information Given in Holograms

This section gives a description of the above-mentioned test sequence number 3: Performing the actual test, handling prescribed medicine and act on information given in holograms. During the test, the participant sat at a table. On the table was a sheet of paper with a list of prescribed medicines, an empty pillbox, and five medicine boxes with labels for the prescribed medication (Figure 1).

Figure 1– Illustrations of How the MCIA is Used in a Homelike Environment for Distributing Prescribed Medicine in Pillbox.

All participants used the same mock-up medicine list, while medicine boxes were original cartons from a variety of pharmaceutical companies. When the patient looked at a medicine carton, the MCIA interpreted and acted on the information, supplying the participant with instructions on how many of each pill to put in each compartment of the pillbox. If the participant looked at a medicine which was not prescribed, the MCIA gave information that this was the wrong medicine (Figure 2). The images processed were of the cartons of the prescribed medicine. Typically a carton contains several blisters. Blisters were not scanned as the primary target group for the MCIA are patients with adequate cognitive functions, but who need support and assurance regarding variation in pharmaceutical brand names and generic drug substances.

Figure 2– Visual Information From the MCIA, Presented as Hologram. Examples: (left) instructions on how many pills to put in each compartment of the pillbox and (right) message to not take the medicine.

Results

The results are presented for the sample as a whole and also for subgroups 'Older than 65' and 'Have experience of using smart technology.' This is done in order to be able to answer the research questions regarding if there is a difference in willingness to use an AR-headset for medication management related to age and people's experiences of using smart technology (ST). Nearly half of the 15 participants (47%) were older than 65 years. A majority of participants (53%) had experience of using smart technology, and 27% said they were familiar with AR (Table 1). All participants with values 4 and 5 on Experience of ST were under 65 years old. Four participants older than 65 did have some experience of using ST, but they rated their experience lower than our cut off value (Figure 3).

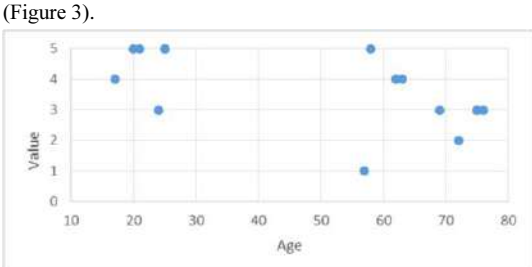

Figure 3 – Distribution of Response Values for Each Participant (n=15) for Variables 'Age' and 'Experience of using smart technology' (Values: 1=no experience and 5=very much experience).

Three of the 15 participants (20%) found it difficult to use the AR-headset, two of them were older than 65. The information was perceived as easy to understand (87%), and more than half of the participants (60%) felt comfortable while using the AR-headset to perform the medicine task. A difference related to age was discovered as all persons but one who said they felt comfortable using the technology, belonged to the younger age group. None of the participants, from either age group, felt that it was stressful to use the AR headset. Regarding the functionalities of the MCIA, 40% prefered talking over using gestures while interacting with the MCIA and a majority, 93%, appreciated receiving audio output along with the holograms. Preference for talking instead of using gestures with hands was more common in the younger age group.

Participants were asked if they, given the technology was available and affordable, would be willing to use the technology a) in the future or b) right now. Also on these questions there were differences between age groups, where all in the younger group said they would use the technology in both scenarios while 50% of those over 65 gave the same response. Variables where differences related to age were discovered are displayed in Table 2.

Table 2– Variables Where Differences in Response were Related to Age, Comparison Between Groups.

Variable	Age < 65 n=8	Age > 65 n=7
Experienced in using smart technology	87%	0%
Feel comfortable using the MCIA.	100%	15%
Prefer talking to interact with MCIA.	42%	28%
Willing to use the technology right now	100%	50%
Willing to use the technology in the future	100%	50%

Discussion

Even though none of the participants had used AR-headsets before they did not feel it was difficult to take instructions from the MCIA to perform the task of handling medicines, and most of them felt comfortable. One aim of the research was to explore if age may be a factor related to whether people are willing to use an AR-headset to support medication-related self-management. Four areas were identified, where differences in opinion could be seen between the different age groups. Participants older than 65 years were more sceptical than those who were younger when it came to feel comfortable while using the AR headset, being willing to use the technology in the future and being willing to use the MCIA now (if it was available and affordable). This result may be connected to the fact that older people in society are among those with least experience of using digital technologies and have more reluctance to change routines [13]. They generally have not used digital services throughout their working life which is an area where people in most professions today need to use digital technology.

One surprising result in the evaluation was that it was the younger group who preferred talking instead of using gestures when interacting with the MCIA. Considering that playing video games using motion sensors, as featured by Nintendo, Playstation and others, have been part of everyday life for families with children throughout the last 15 years, it could be expected that younger persons would find using motion sensors to be an ordinary way to communicate with technology. In previous research with digital interventions for seniors to use social platforms with web camera instead of the telephone, to enable visual contact during conversations with family members, participants stated that they initially felt more comfortable with the telephone because they were used to it [14]. The initiative to develop the MCIA and pursue the evaluation originated from clinical problems and challenges

experienced by nurses and patients in rural home health care environments in northern Sweden. Having difficulties self-managing their medicine and pillboxes is a common reason why patients apply for home health care. With the current shortage of nurses, it is challenging for the health care system to deliver the services and new solutions are needed to support self-management and safe handling of pills [15].

Available on the market today there are several devices and apps featuring smart medicine reminders. Based on input from the initiators to this research, nurses, and patients in rural home health care, the main target group for the MCIA is not patients with cognitive impairment or those who need assistance with reminders when it is time to take the medicine. Instead, the MCIA is aiming to support individuals who unwillingly are forced into dependence on healthcare services because they feel confused and insecure when handling the variety of generic medicines they come across based on their prescriptions. To our knowledge, there are not yet any supportive technologies for this stage of the medication process or targeting this level of self-management.

Limitations

We purposely recruited to include a wide range of ages as medication management applies to people of all ages. With the results at hand, it became apparent that age-distribution among participants was distorted. Most participants were either young adults or retired. Aiming to explore the influence of age related to willingness to use technology it would have been beneficial if the sample also included middle-aged individuals in their 40's and 50's. A majority of patients in the target group for the MCIA device is likely to be found among persons older than 65 years [4, 5]. This was the reason for placing the divider between age groups at 65 years. However, due to the ongoing demographic development, it would be relevant to repeat this evaluation with all participants older than 65 and compare relevance of age between those older/younger than 80 [16].

Another limitation was the cut off where values 4 and 5 were used to indicate "agree." This level was chosen to limit the risk of false positive answers. However, this made it impossible to address the research question concerning if the experience of using smart technology was related to people's willingness to use the MCIA. Several participants in the higher age group had chosen value 3 and with the applied cut-off level they were treated as 'not having experience' which instead gave a somewhat false negative result.

Future work

In our future work, we aim to test the MCIA for a more long term usability evaluation. The evaluation presented in this paper was conducted with test persons in a living lab using mock-up medicine list, a future evaluation is planned in collaboration with a home healthcare organisation, where patients with polypharmacy treatment will test the MCIA AR device in their own homes based on their personal prescriptions. However, based on the results in this paper, the previously mentioned evaluation with participants over 65 needs to be conducted prior to the in-home tests.

Let us point out that the MCIA belongs to a new generation of autonomous intelligent systems that aim to take decisions of their own in order to reach their designing goals. The autonomy of these systems for taking their decisions is also giving place to new research questions about responsibility. For instance, to which extent does an autonomous intelligent system such as the MCIA need to be certified by law enforcement institutions in order to be used by end-users? To answer this kind of questions is out of the scope of this paper. But, we highlight that law enforcement institutions will need to take an active role for certifying intelligent systems such as the MCIA. Let us observe that EU research projects, such as AI4EU, are appearing, and these research projects aim to develop new software methodologies that could guarantee transparency in the design and development of autonomous intelligent systems. In our future work, we will explore the social implications of the MCIA. In particular, to identify which kind of autonomous decisions by the MCIA that can put the end user in a risky situation will be part of our future work.

Conclusions

- We found that using the MCIA implemented in an AR-headset, to assist people with prescribed polypharmacy medicine regimen in filling a pillbox, was feasible and acceptable.
- There were differences related to age regarding people's willingness to use an AR headset for medication self management.
  - People older than 65 felt less comfortable using the technology.
  - People older than 65 were more hesitant to use the technology.

Abstract

There is an important gap in scaling up psychosocial interventions for people with severe mental health problems so that these interventions are not only widely available but also delivered in a timely manner. We examined the feasability of adapting a psychological intervention traditionally delivered face-to-face onto a digital platform. We report both the clinical and technical processes used to adapt and develop the digital platform in a group of people in the early phase of psychosis. The digital platform prompts people to engage with the intervention multiple times a day over a 12-week period. Participants are also able to access a repository of multi-media content to support their mental health. The digital platform has been successfully validated by participants registered with early intervention for psychosis services in the Northwest of England, UK and is currently being tested in a powered efficacy trial.

Keywords:

Mental Health, Mobile Health, Smartphone

Introduction

Schizophrenia is considered a severe mental health problem affecting 24 million people worldwide, with the current cost to society estimated to be £11.8 billion per year in England alone [1]. The early phase of psychosis is a critical period, influencing the long-term course of difficulties. Up to 80% of people will relapse within five-years of initial episode; each relapse increases the risk of developing persistent psychotic symptoms and further disconnection from education, employment, social development and community connections, adversely affecting long-term psychosocial development [2]. Time-sensitive and accessible interventions are urgently needed. Psychological interventions such as cognitive behaviour therapy (CBT) are recommended in the treatment of psychosis. Current approaches to delivering CBT for psychosis involves a scheduled appointment with a qualified psychological therapist or CBT practitioner. Lengthy delays, fears about the stigma involved in accessing services, and a lack of trained staff are just some of the barriers that impact on timely delivery and receipt of psychological input. A high degree of smartphone ownership and use, even among people with severe mental health problems [3], means that it is possible to deliver real-time, ecologically-valid therapy that extends the reach of standard mental healthcare delivery. Smartphone technology offers an unprecedented opportunity to enhance health status by delivering real-time interventions which have the potential to extend the reach of treatment to a patient's own environment, thereby: i) transforming patient experience of, and how they engage with, services; ii) improving the efficiency and co-ordination of care; and iii) supporting people to self-manage their health and wellbeing.

Several self-management apps have either been developed and tested in clinical trials [4,5] or are currently in clinical trial [6], with researchers now turning to passive data collection including behavioural sensing and smartphone use [7] to monitor symptoms and support people with severe mental health problems. We developed a digital health intervention (DHI), Actissist, that delivers a theory-informed, in-the-moment intervention targeting distressing psychotic and psychosis-related experiences. Actissist is unconstrained by the limitations of existing treatment settings and serves as a conduit for interventions available anytime in almost any location. Leveraging technology reduces recall bias and generalisation of problems that often occurs when patients are asked to recall their symptoms, thereby improving validity of symptom reporting. Our intention is early detection of clinical deterioration while at the same time delivering timely, personalised care in one's own environment with a view to empowering people to make informed choices by way of opportunities to modify behaviour directly via a ubiquitous interface (smartphone). This paper describes the development of Actissist: a CBT-informed app for early psychosis. In particular, we describe the iterative technical and clinical process we adopted to developing the clinical content, protocol and technical architecture underlying the software. The Actissist app is currently being evaluated in a large-scale powered efficacy trial in the Northwest of England, UK.

Methods

Clinical Context

The users of the software application are people registered with an early intervention for psychosis service (EIS) in the North west of England and who are within five years of experiencing a first episode of psychosis. EIS exist worldwide and aim to

provide both pharmacological and psychosocial interventions. The Actissist app functions as a standalone app. Patients can choose to share the information in the app with their treating clinician /clinical care team, but they are not obliged to do so. Approval for this work was given by the relevant local NHS research ethics committee.

Developing the Clinical Content of the App

Actissist is grounded in the cognitive model of psychosis. We chose to adapt CBT methods because this is the recommended psychological treatment for psychosis but access to this therapy is significantly limited. The CBT approach proposes that cognitive appraisals contribute to the emergence of unhelpful beliefs and influence the interpretation of anomalous (unusual) experiences. Distress is largely linked to the meaning and interpretation of symptoms and beliefs regarding anticipated consequences. In developing the content, the clinical team distilled key theoretical elements from various academic texts and publications to ensure that the fundamental elements of CBT for psychosis are included in the architecture of the app. The elements identified include coping strategy enhancement, normalising, information, motivational interviewing techniques (e.g. decisional balance, change planning; cannabis misuse domain), psycho-education, activity scheduling, mindfulness, relaxation exercises, recovery videos, resilience building, behavioural experiments, safety behaviour work, cognitive restructuring, interactive fact sheets, to name a few.

Experience Sampling Methodology (ESM)

Psychotic experiences typically emerge in the realm of daily life and are influenced by contextual factors. Experience sampling methodology (ESM) is a method of assessment and intervention that is increasingly being used to understand psychopathology in daily life [8]. ESM uses a structured self-report diary technique to examine variables of interest as they occur in daily life. People are prompted to complete momentary questions multiple times a day over the course of a number of days [8]. As we are interested in delivering a real-time, ecologically-valid intervention in the context of one's own environment, we prompted people to engage with the Actissist app and to deliver in-the-moment CBT-informed tips and strategies to foster self-management of psychotic- and related experiences. Traditionally, ESM methods prompt people to answer a question set between 6-10 times per day over a 1-week period [8]. As the aim of this study was to not to conduct time-series analysis to assess psychopathology in daily life, we invited feedback from our user groups regarding the optimum number of alerts to facilitate engagement with the app. Our main reason for using a prompting schedule of alerts was to facilitate engagement with the app and to remind people to engage in the app, should they wish to do so.

Patient and Public Involvement (PPI) and Qualitative Work

We established an Expert Reference Group (ERG) comprising multidisciplinary group of service users, clinicians, software engineers, and clinical academics (including academic clinical psychologists and a clinical academic psychiatrist) to inform the design and development of the content, clinical and technical protocol in developing the Actissist platform. This was to ensure that the system developed remained meaningful to end-users and language and processes were appropriate for our target beneficiaries. A purposive sample of individual qualitative interviews with EIS patients and focus groups with staff who referred patients to the trial were conducted once the app was developed to understand what features both groups deemed necessary in an app of this nature and to gather ideas for improvement. All interviews were digitally-recorded, transcribed, checked for accuracy and analysed using qualitative methods.

Software Requirements

Software requirements were developed in an iterative cycle of discussing requirements, implementing those requirements deemed feasible by the software team, while incoprating feedback from end-users and stakeholders. The software team analysed the requirements provided by the clinical team in more detail to consider technical feasibility and to provide initial rough estimates of the amount of work required for each feature and the level of risk involved. These estimates were then fed back to the clinical team and resulted in two main related activities that were undertaken in a collaborative manner between software and clinical teams: (i) prioritisation of the requirements; and (ii) refinement of the requirements to align with what was considered feasible technically. The output of this initial phase was a list of the highest priority features for the app along with rough estimates of the amount of work required for each feature. The software team developed features in order of priority. Development followed the Scrum methodology. Scrum is a modern, agile, software development methodology that is widely accepted as an improvement on the more traditional Waterfall model. The iterative development approach within Scrum enables closer collaboration between the software development team and customer (in this case the clinical team and research participants) and allows changes in requirements to be incorporated throughout development. Scrum has the concept of a sprint, which is a timeboxed development effort usually between one and four weeks in duration. The software team used three-week sprints for this project as this presented a suitable balance between the need to be able to respond flexibly to changing requirements and the delivery of a sizeable chunk of developed software within each sprint. At the start of each sprint, a planning session took place attended by all of the software development and test team along with the technical project manager acting as the Product Owner and effectively acting as a proxy for the "customer" (clinical team).

Validation Study

We conducted beta-testing with 10 end-users over a 1-week period once a prototype version of the app was developed to find and eliminate defects and to ensure that the platform was accessible, clear and functional prior to commencing the clinical trial. Emphasis during testing was placed on usability and data security. We then carried out a proof-of-concept, single, blind, randomized controlled trial of Actissist plus treatment as usual (TAU) compared to a symptom-monitoring control condition plus TAU. Thirty-six early psychosis patients registered with EIS across the Northwest of England, UK were randomized on a 2:1 ratio to each arm of the trial. Engagement with the Actissist app was defined as participants completing >33% data entries over the intervention period. There was also a criterion applied to the data entry itself to determine whether it was a valid entry and could contribute to the overall adherence calculation; per participant, there was a maximum of three valid entries per day. Where the participant self-initiated access (or a combination of self- and prompt- initiated) which exceeded three entries per day, only the first three daily entries were contributed to the adherence figure. Satisfaction with the app was measured through qualitative interviews and via a satisfaction questionnaire [9].

Results

Clinical Protocol and Structure of App Content

The Actissist app was informed by CBT principles and, as far as we are aware, is the first CBT-informed app under clinical trial for early psychosis patients. Actissist is divided in two parts but functions as a single app. Actissist emits an alarm followed by a visual prompt at three pseudo-random points per day, six days per week between 10am and 10pm, for 12 weeks. The schedule of alerts used in this study was determined by user-feedback regarding the most acceptable structure of alerts over the intervention period. When a notification is accepted, or the user self-initiates use (when the user feels they would benefit from the support of the app, thereby supporting self-management), they are invited to choose a problem area. The developed app is split into two main areas: "What's bothering me?" and "My Toolkit", each of which are described below.

'What's bothering me?'

This is, what we believe, the core of the intervention. The problem areas targeted by the app are those that have been shown to predict relapse to psychosis [2]. Domains were agreed by the ERG, end-users and clinicians as areas of intervention priority (see Figure 1):

- Voices
- Suspicious thoughts
- Feeling Criticised
- Mixing with people
- Weed / Cannabis

Questions follow a branching system to mirror CBT-style questioning and are structured around a series of question-answer exchanges that focus on cognitive appraisals, rating conviction of beliefs, and identifying emotional and behavioural consequences of cognitive appraisals. Depending on the cognitive appraisal selected, the exchange is followed by rotating cognitive or behavioural tips/strategies for the user to engage in. If no problems are identified, the app simply offers a word of encouragement and is silenced until either the next alert or the user self-initiates use. For instance, for the domain 'mixing with people', questions included "How much have you been out and about?" and "How many people have you chatted to or spent time with?" Answers were selected from a radio button list. Participants were then asked how satisfied they were with this and able to choose from "Not at all", "A little", "Moderately" and "Extremely". If they responded "Extremely", then they were asked what's been good about it and received a positive reinforcement message. If the participant gave any other answer then they were asked some further questions and then received normalising information and helpful tips in managing difficult experiences (e.g. see Figure 2) and CBT-informed content. The messages they received were based on their answer to the previous questions but a number of different messages were available for each answer. This meant that participants received different intervention content each time they used the app even if they gave the same answers as the last time. This was intended to minimise boredom and repetition within the app.

'My Toolkit'

'My Toolkit' comprises a toolkit of multi-media options that operates in a standalone fashion and is split into the following main areas:

- Fact sheets (e.g. low mood, anxiety, self esteem, drug use, etc.)
- Mindfulness and relaxation audio
- Coping strategies
- Recovery videos

Should a user wish to access information in the app without going through the branching questions, they can enter the toolkit repository directly. That is, interacting with the app is not contingent on replying to the question-answer branching exchange.

In addition, a hamburger button directs the user to links including: i) help area, which includes an introductory video that provides a rationale to CBT, local service/support contacts, links to external websites (TED talks, blogs, etc), background information describing the development of the app, terms of use, acknowledgements; ii) daily diary to monitor thoughts and emotions; iii) settings / personalisation features (e.g. wallpaper, colour); and iv) a graphical readout and summary explanation of symptom fluctuations in order to self-monitor fluctuations in mood and psychotic symptoms.

In a 1-hour 'app set up session', a member of the clinical team meets with the participant and downloads the app on either the participant's own phone or on a loaned phone, sets the user a participant ID, username and password. Participants are also given the opportunity to further personalise the app (e.g. choose wallpaper, colour scheme) and orientate themselves to the different areas within the apps. The app is then activated. More specific details of this procedure are described elsewhere [9].

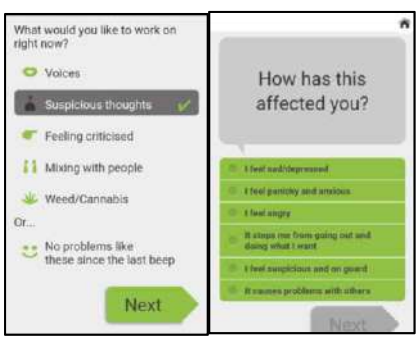

Figure 1 – Screenshot of Actissist Landing Page and Branching Questions

Figure 2 – Example of Normalising Content

Incorporation of User Feedback

User feedback was incorporated in two ways. First, our ERG met at study outset and every three months thereafter over the life of the project. An agenda was set before each meeting, with room for flexibility of topics covered, where system requirements, new app prototypes, and so on were reviewed. Second, qualitative interviews with staff and service users resulted in a number of suggestions for improvement. For example, we developed an initial pool of 79 bespoke sets of tips/strategies (socialisation: 15 tips/strategies; voices: 18 tips/strategies; suspiciousness: 13 tips/strategies; perceived criticism: 18 tips/strategies; cannabis: 15 tips/strategies). In our exit interviews, particiapnts said they wanted more tips and strategies throughout the app to minimise repetition and boredom particularly towards the end of the intervention period when users had selected the same domain repeatedly and starting receiving the same tips and strategies. Participants also said they wanted to personalise when the app sent an alert to engage with the app. Other suggestions included the ability to upload an image of a user's clinical formulation and the ability to set goals within the app to work towards a desired outcome. Where possible, this feedback will be incorporated into the next iteration of the app.

We developed a live document that stores suggestions and ideas for app refinements. This document is colour coded by the clinical team in terms of level of priority and feasiblity. This document is shared and discussed with the technical team when new versions of the app are being prepared.

App Implementation

The most important feature for the app was the branching question-answer exchange; therefore, this was prioritised. In the Scrum methodology, the aim is to provide working software at the end of each sprint. As this was a large segment of the app to build, it required several "sprints" for the development team to implement and it was therefore only possible to start providing working software after a few initial sprints. Thereafter, the implementation of other features were planned so that working software could be delivered at the end of each sprint.

As the app was developed, it was regularly reviewed by the clinical team and any improvements or changes needed were planned and incorporated into a future sprint. This also gave the clinical team an opportunity to re-prioritise requirements as the app took shape and they experienced how it worked in practice. As the development progressed, it became apparent that it would not be possible to implement the full set of features originally desired. The technical and clinical teams therefore re-prioritised the feature set, removing some of the items considered to be of lowest "value". Value was based on the amount of benefit a particular feature would provide compared with the effort and risk involved in implementing it, and whether it was deemed to be a core element of CBT-informed practice. The removed items were recorded for potential implementation in future iterations of the project; these items were compared with other feedback received from service users, clinicians and the Expert Reference Group (ERG).

Security

No identifiable data is captured in the app, instead a numeric id is used to pseudonymise it. Data captured by the app is transferred to a secure server over an encrypted HTTPS (TLS) connection. The data can then be accessed via a web interface by members of the research team. Each research team member has their own username and password to login to the web interface and access to the data is controlled based on a role-based permissions model. This means that some members of the research team can see all participants and some can only see their own participants. To improve security, login attempts are rate-limited to prevent against brute-force security attacks. The software team, who are all data protection trained, are also able to export the data collected during the study to enable the clinical team to carry out analysis. In this case, the data is secured inside an AES encrypted zip file. All of the data is still pseudonymised at this point and only the clinical team have access to patient identifiable information.

Trial Outcome

The Actissist app was successfully delivered and evaluated in a proof-of-concept trial with 24 people using the app (compared with 12 people randomised to a control symptom-monitoring app). In summary and in line with the CONSORT statement, we systematically demonstrated the safety, feasibility and acceptability of delivering a 12-week digital health intervention (DHI) using smartphone technology as follows: i) 24 patients used the app for 12-weeks; ii) the 'accept' milestone for compliance, pre-defined as 50% of the sample completing 33% or more of items was exceeded (actual achieved=75% of participants), as was the 'target' milestone for compliance pre-defined as 50% of the sample completing 50% or more of items (actual achieved=63% of sample); iii) the proportion of compliant participants was comparable to people completing either face-to-face CBT or computerised-CBT; iv) uptake was higher and drop-out lower than face-to-face and computerised-CBT; v) no reported safety issues or treatment withdrawals; vi) recruitment completed ahead of schedule, demonstrating engagement of all stakeholders to participate in, and willingness of participants to be randomised to, a trial of this nature; vii) significant improvements in psychotic and mood symptoms at the end of treatment; viii) high rates of acceptability and subjective benefit of the intervention to patients (90% participants said they would recommend the app to others in a similar position) and overall satisfaction with digital interventions expressed by staff. Full details of trial outcome are reported elsewhere [9].

Discussion

We developed a CBT-informed app for people in the early phase of psychosis. Safety, feasibility and acceptability was demonstrated in a proof-of-concept trial with 24 participants using the Actissist app compared against 12 people who used a symptom-monitoring app. The team has been successful in securing funding for a follow-on efficacy randomised controlled trial, Actissist 2.0, which has enabled a number of improvements to be made to the app functionality as well as to the look-and-feel of the app, which are summarised below. The list of potential requirements were based on feedback from participants during the proof-of-concept trial, feedback from the ERG, the list of items that did not get implemented previously, and some new ideas from the clinical team. These new requirements were prioritised in the same way as in the validation study and the following key changes in version two of the app were made:

1. Improvements to the application UI;
2. Addition of a goal setting feature so that the users can identify up to three goals s/he wishes to work towards during the intervention period;
3. Addition of an "Other" domain so that if a psychosis-specific domain is not relevant the user can be directed

to other potentially relevant mental health-related information to broaden the relevance of the app content to an individual's specific needs and concerns;

4. Option to store and access a clinical formulation image the user developed with their treating clinician.

Regarding point 1), UI design was undertaken by the software development team in the initial development phase of the app. This resulted in an app that had a reasonable look and feel and was sufficient for the proof-of-concept study. However, it became clear that specialist UI design skills were needed to meet user expectations regarding the look-and-feel of the app. A professional UI designer bought in to Actissist 2.0 will produce a series of functioning prototypes that were demonstrated to the clinical team and the ERG and were then subsequently amended to incorporate feedback and suggestions for improvements. We hope that version 2 of the app will further encourage engagement during our current efficacy trial. In response to user feedback in the validation study, version 3 of the app now comproses three parts: 'What's bothering me?', My Toolkit', and 'My goals'. The goal setting and formulations are examples of how user feedback was incorporated in the app: goal progress and uploading a formulation image were not part of the initial system requirements and were included only after users expressed a desire to monitor goals and have the ability to view an image of their clinical formulation.

Our current app has some limitations. At this stage, the Actissist app is only available for Android smartphones. This means that research participants who do not have an Android phone have to be loaned one from stocks held by the clinical team. In future, we intend to implement an iPhone version of the app. The app is limited in addressing only specific domains as opposed to delivering agile, formulation-driven CBT. Furthermore, a limited number of CBT-informed tips and strateiges are rotated within each domain of the app, also limiting the CBT content delivered within the context of the intervention period. The app has to date been trialed in an early psychosis group; we hope to extend trials of the efficacy of the intervention with later psychosis and other mental health problems.

Conclusions

We describe the development and testing of a CBT-informed app, Actissist, which targets priority domains in early psychosis. Actissist is delivered in the context of one's own environment and has been validated in a sample of 24 early psychosis users registered with EIS in the Northwest of England. Actissist was developed to close the gap to patients having access to mental health support and to provide time-sensitive intervention strategies. The app was shown to be safe and acceptable with promising signs regarding efficacy. Full scale efficacy is now being explored in a single, blind, randomised controlled. As a result of further funding, we have refined the app in line with user feedback from our validation study. We are using novel methodology to allow for three version updates of the app throughout the trial to ensure that the technology is not obsolete at the study end-point. Actissist supports self-management and can facilitate shared decision-making in treatment.

Abstract

Epidemiological surveillance systems enable collection, analysis and dissemination of information on the monitored disease to different stakeholders. It may be done manually or using a software. Given the poor performances of manual systems, the software approach is generally adopted. Epidemiological surveillance systems are based on existing softwares, softwares developed from scratch given the specifications or softwares provided by a vendor. These solutions are not always suitable because epidemiological surveillance systems evolve quickly (new drugs, new treatment protocols, etc.), leading to software updates, which can take time (while waiting for a new version) and be expensive. In this article, we present the use of the Model-Driven Architecture (MDA) approach to model and generate epidemiological surveillance systems. The result is a complete MDA based methodology and tool to develop epidemiological surveillance systems. The tool was used to model and generate softwares that are now used for epidemiological surveillance of tuberculosis in Cameroon.

Epidemiological Monitoring, Software Design, Tuberculosis.

Introduction

Epidemiological surveillance systems enable collection, analysis, interpretation, and dissemination of health information to different stakeholders. These information are essential to the planning, implementation and evaluation of public health practices [1]. To strengthen epidemiological surveillance, additional activities are generally integrated. For example, in Cameroon, to efficiently fight against tuberculosis (TB), the Cameroonian National Tuberculosis Control Program (NTCP) in addition to epidemiological surveillance, manages anti-TB drugs, follow-up appointments of patients, sensitize patients, etc. However, these activities are done manually, causing problems like: low rates of promptitude and completeness, the production of basic statistics are generally late, insufficient sensitization of the population, difficulties in the geolocalization of hospitals so as to help patients get to the nearest hospital, and difficulties in managing lost patients (who did not come to take their treatment). The poor performances of manual systems have oriented the adoption of the software approach [2; 3]. For example, Blaya et al. [2] have proven that a web-based system to transmit laboratories reports decrease delivery time of laboratory results, reduce redundancy in resource utilization, and provide faster and more complete notification for public health purposes, decrease the number of reporting errors to Hcs, and improved monitoring of patients because clinicians have greater access to their history and laboratory data.

The rapid advancements and availability of health Information and Communication Technologies offer remarkable enhancement opportunities for epidemiological surveillance systems. The softwares used may be developed from scratch or existing options (e.g., District Health Information Software-DHIS [4], OpenMRS [5]) may be used. These solutions are not always suitable because epidemiological surveillance systems evolve faster (new drugs, new treatment protocols, etc.), leading to software updates, which can take time (while waiting for new version) and be expensive. On the other hand, depending on the data gathered on the field, the epidemiologist may need to collect a new parameter in order to explain a phenomenon (for example, the height of the patients in order to calculate their body mass index). This task may be done by using supplementary materials such as paper form or spreadsheet software (which can lead to a problem of data integration) or new requirements can be introduced and the software updated (which can lead to the problem of software regression). These problems can be mitigated if the system is designed using a well-defined framework or architecture permitting the rapid development and refinement of the surveillance software by non-informatics experts such as health workers. MDA has proven to be one of the best choices [6-10].

MDA provides methods and tools that can be used by domain experts (institutional operators with a deep knowledge in the domain) with limited high-level IT skills to build visual models (composed of graphical notations) and generate source code. Consequently, non-technical users can safely and effectively make changes to their software to reflect their changing needs and understanding of their business [8; 9; 11]. In the context of health informatics, there is a significant number of examples adopting MDA approach [6-13]: tracking patient information, data collection, mobile-health, Crisis and Emergency Management, etc.

In this article, we present the use of an MDA based approach for rapid development/update of epidemiological surveillance systems.

We applied the approach to build and epidemiological surveillance system within the EPICAM (Epidemiology in Cameroon) project. The project aims at improving epidemiological surveillance systems in Cameroon and is conducted by the National Tuberculosis Control Program (NTCP) in Cameroon in collaboration with the Unit for Mathematical and Computer Modeling of Complex Systems (UMMISCO), Centre Pasteur of Cameroon (CPC), and MEDES in France.

The rest of the paper is organized as follows: section 2 presents the MDA based approach; section 3 presents the results of the

implementation of MDA for buiding the EPICAM platform; section 4 discusses the results; and section 5 concludes the paper.

Methods

Tuberculosis is a chronic infectious disease that kills almost two million people per year in the developing world [2]. To ensure high quality care is delivered in an efficient way, efficient information systems are essential. Then, the Cameroonian NTCP have planned a project called EPICAM with the goal to detect and treat TB patients and prevent disease from getting to people at risk (children who have been in contact with a patient or persons living with HIV). During this project, we have followed a set of principles, design activities and phases, based on agile software development and Model-Driven Architecture. In the next paragraphs, we will present the agile software development methodology, the MDA approach, and how we proceeded to develop epidemiological surveillance system in Cameroon.

Agile software development methodology

Agile software method relies on an iterative, incremental and adaptive development cycle which considers that the needs cannot be fixed and proposes to adapt the development to the changes. In a broader sense, agile method can be seen as a process consisting of an initialization step (the base version of the software is developed), an iterative step (new versions based on new specifications and users feedbacks are developed) and an incremental step (a set of new functionalities after an iteration is provided) [14; 15]. It's intended to support early and quick production of working code and allows fast deployment and adoption of health information [6].

MDA approach

MDA is an approach to software design, development and implementation which provides guidelines for structuring software specifications that are expressed as models. It focuses on forward engineering in which the executable source code is (semi)automatically generated from abstract, human-elaborated modeling diagrams such as a class diagram [6-8; 10; 12]. A class diagram describes the structure of a domain by identifying the domain classes (e.g., patient), their attributes (e.g., age, sex), their operations (e.g., calculate a body mass index) and the relationships amongst classes (e.g., the relation between a patient and his/her appointments at the hospital) [9; 13].

The process of building applications using the MDA approach can be summarized as follows: (1) the construction of a Computational Independent Model (CIM) which focuses on the environment in which the system will operate and its required features; (2) the construction of a Platform independent Model (PIM), which focuses on the aspects of the system features that are not likely to change from one platform to another; (3) the construction of a Platform Specific Model (PSM) which is obtained by integrating platform specific details to the PIM; (4) then, the PSM is converted into application code. It is the first and the second steps in the process that involves creativity and manual work; steps three and four are automated by the use of automated tools [10; 12]. The MDA approach is widely adopted to develop health information systems [6; 10].

MDA approach for epidemiological surveillance systems

Based on agile software development method and MDA, the methodology we propose for epidemiological systems development is composed of three main steps: pre-development, development and post-development.

Pre-development step: This step consists of the specification and the analysis of the system to be developed. During the pre-development step, the computer scientist works closely with the domain experts in order to make system specifications and analysis. The result is a first version of the software specification and analysis, containing sufficient information to develop the first version of the software.

Development step: This step is composed of two main phases:

- The first phase consists of the development of the first version of the software given the specifications and the analysis provided by the pre-development step. It proceeds as follows: **(1) Design:** The design consists to define the software architecture, choose the tools to be used to develop and deploy, and define the model (PIM) of the system in the form of a class diagram; **(2) Implementation:** The tools chosen in (1) will be used to transform the model into a platform specific model (PSM) which will be used to automatically generate the software.

  The result of this first phase is the baseline version of the software. The users will be trained on this basic version. Their use will generate feedback which will be very useful to continue the development.

- The second phase is an iterative and incremental phase in which each increment consists of the analysis of user feedback on the current version of software in order to add/remove functionalities. Each iteration proceeds as follows: **(1) Specifications and analysis:** the specifications and analysis are completed; **(2) Design:** the model (PIM) is updated according to new specifications; **(3) Implementation:** the model (PSM) is also updated and a new version of the software is generated. An increment is started after each iteration.

  The result of this second phase is a mature version of the software, tested and validated by the users.

- **Post-development step:** It consists of training the users on the use of the MDA tool to update the model and generate new versions of the epidemiological surveillance system. In fact, our goal is not necessarily to leave the software development to the domain expert, but to facilitate his/her task of the updating of the system to make it more close to his specifications without necessarily needing the help of an IT expert.

Development of the EPICAM platform

In this section, we present step by step how the MDA approach presented was used in order to develop the EPICAM platform for epidemiological surveillance of tuberculosis in Cameroon.

Specifications

To efficiently fight against tuberculosis, the Cameroonian National Tuberculosis Control Program has established a surveillance system through which it collects and shares data with the health professionals in health centers, health districts, health regions, the ministry of health, the general population and partners (Global fund, WHO, Centre Pasteur du Cameroun, etc.). However, this system is manually managed causing problems as previously introduced. Based on these problems, the specifications of an electronic system was developed.

To determine the specifications of the new system, we have collected information at each level (hospital, health district, health region and health ministry) of tuberculosis surveillance. These information were completed with the documents generally used for data collection and analysis. The desired system must permit users to: (1) collect, verify, synthesize data and make reports (weekly, monthly, quarterly) accessible at the district level, the regional level, and the central level; (2) follow

patients and make SMS recall for those who did not come to an appointment; (3) manage anti-tuberculosis drugs so as to prevent stockouts; (4) locate the closest hospitals with respect to the location of patients; (5) sensitize the population by SMS; (6) permit the users to work offline and update their data when they connect to the network; (7) update the system each year by adding/removing some information on data collection supports and reports.

Analysis and design

The software analysis and design helps define an architecture, a tool based on MDA, and a data dictionary. **(1) The definition of the architecture:** The architecture presented by Figure 1 is the architecture of the system which suits an environment like Cameroon where access to Internet is not always available. This architecture is composed of a user component and a server component. The user component may be a web browser connected to the server via Internet. In this case, the client shares data with the server in a synchronized manner. In the case of the offline use of the software, the user component will be a desktop/mobile application with a local database. This application will be used by the users to share data with the server in an asynchronous manner. The synchronization module works as a mediator, which permits the server get new data from the desktop application local database and the desktop application get new update from the server; **(2) Choice of tools:** to develop the software, we have made a survey of MDA based generation tools used in the health domain. This survey helps identify tools such as Open Data Kit [16], Magpi [17] and Imogene [18]. ODK and Magpi are not suitable for us because the softwares generated run on mobile phones. Hence, we have chosen Imogene. Imogene is an open source platform developed by MEDES in France and used for the generation of data collection softwares. It provides graphical tools for creating models and generating tools that help generate applications for different platforms (Android, Linux, Windows, and MacOS). Taking advantage of the MDA approach, Imogene is used to update an already deployed application by updating the model, regenerating the new application and redeploying. The applications generated may be used in a synchronous/asynchronous manner. Imogene was used to generate data collection forms for the prevention and the follow-up of diabetes in France in 2009 and for data collection for tuberculosis surveillance in Georgia. By studying Imogene, we remarked that Imogene cannot completely solve the problem because it just generates data collection applications; **(3) definition of the data dictionary:** A data dictionary, containing the entities, their attributes, their relationships and a clear definition of each entity given by domain experts was established. The definition given by the experts will permit us to present these entities in the user interfaces. From this data dictionary, a class diagram (PIM) was built. This class digram was used to represent the previous entities, their properties and relationships in a graphical manner.

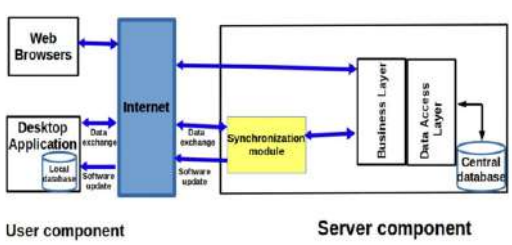

Figure 1– System architecture

Given the analysis and the *design* presented in the previous paragraph, we have developed EPICAM [19]. Based on Imogene, the EPICAM platform is an MDA based epidemiological surveillance system development. In addition to the data collection module provided by Imogene, EPICAM also integrates: **(1) reporting module:** for epidemiological report generation (in pdf format) using BIRT (Business Intelligence and Reporting Tool); **(2) geolocalization module** using OpenLayer, a library for creating interactive map on the Web; **(3) SMS module** for sensitization and patient recall; and **(4) managing drugs module** such as to prevent stockouts. EPICAM was developed to provide full software support for teams desiring to implement epidemiological surveillance system in their environment.

Implementation

Once the specifications, the analysis, and the design were completed, we have started the implementation. The EPICAM platform was therefore used to model (using visual notations) and generate a set of applications (presented in the results section). This first version was deployed in six hospitals in the two largest cities in Cameroon: Douala and Yaoundé. User feedback allowed us to complete the specifications (for example, integrate clinical radiology tests).

Iterations

After the development and the deployment of the software, the user feedback permitted us to complete the model and generate new versions of the applications. For users, everything is transparent, they simply discover new feature (for example, new field in a form).

After the application development, the NTCP selected twenty-five pilot hospitals for the deployment. These hospitals were selected given the quantity and the quality of the data they usually collect, and the ability of the health personnel to use computers. About fifty users were trained to use the softwares and three of them, from the central level were trained to use the EPICAM platform to update, generate and deploy a new version of the software.

Results

During the EPICAM project, we constructed a model, described in Figure 2, integrating the activities generally done by the NTCP. This model describes the entities of the domain, their attributes, relationships between entities and integrates the definition of each entities.

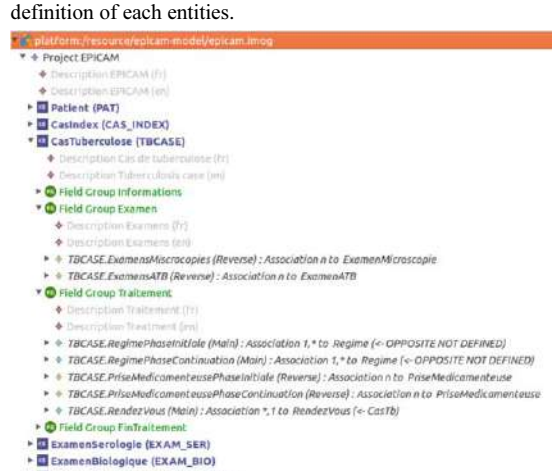

Figure 2– A model for tuberculosis surveillance software generation.

The model of Figure 2 permits us to generate a set of applications: **(1) Administration application:** used to manage health workers information, their roles, and their access rights on data; **(2) Web application:** used for epidemiological surveillance, manage anti-TB drugs, follow-up appointments of patients, sensitize patients, geolocalize the hospitals in order to orient patients. This application works in a synchronized manner. That is, when the health personnel using the application is connected to Internet; **(3) Desktop application** which has the same functionalities as the Web application, but is used in an asynchronous mode. That is, when Internet connection is not available, the system uses the local database as storage system and the local database is synchronized with the server when the Internet becomes availlable; and **(4) Synchronization application:** used to synchronize the client with the server (updating data or updating client applications).

Figure 3 presents an example of user interfaces completely generated using the model of Figure 2. This user interface is composed of the main user interface (entry point of the system) and a form used to register and follow patients (exams, drugs, appointments, etc.) during his/her treatment.

The system was deployed in twenty-five pilots hospitals, where the patients are generally treated for tuberculosis. We supervised the system in the course of the year 2015. Around 3900 (representing 15.6% of the annual number of TB cases in Cameroon) patients were registered and followed using the softwares. Given the success of this pilot phase, the NTCP have adopted the softwares generated as its electronic epidemiological surveillance softwares and extended it in ten regions, twenty new health centers in 2016 and 2017.

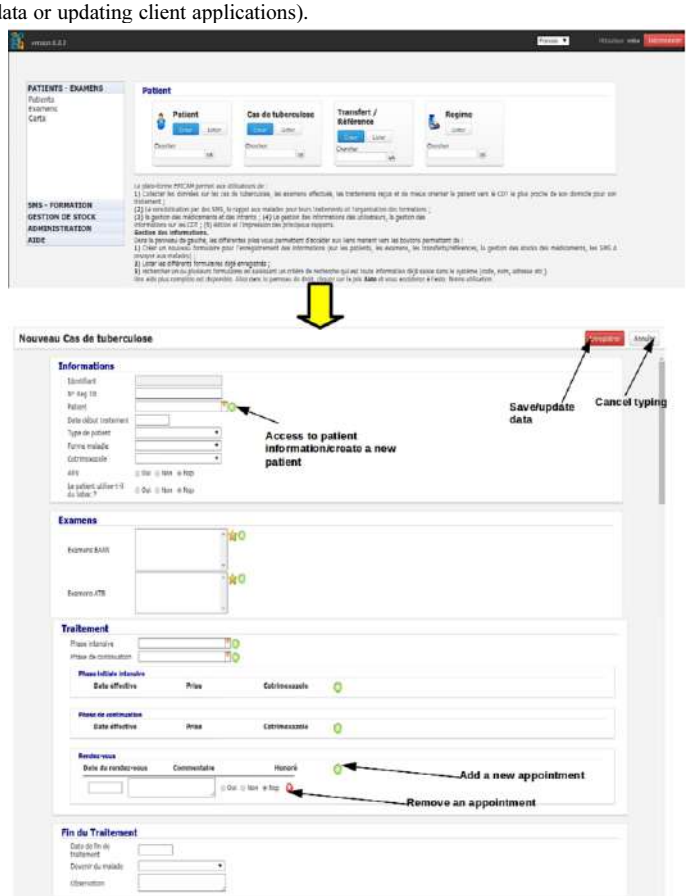

Figure 3– User interfaces completely generated using the model of Figure 2. It is composed of the software entry point and a form to register all the information during the patient treatment.

Discussion

During the EPICAM project, we produced a model for the generation of epidemiological surveillance system of tuberculosis. This model was used to generate a set of applications actually used for epidemiological surveillance of tuberculosis in Cameroon. In 2015, this platform proved its efficiency and has been adopted by the NTCP.

The use of agile software development methodologies to develop health information systems is not new. In fact, due to the complexity of the processes in health care, changes in the requirements may introduce a need for a correction of the implemented system, and can lead to regression [6]. This problem can be avoided by involving end users to the development process; and making an adapted methodology for iterative and gradual development. For example, Atanasovski et al. [6] have used an adapted agile methodology for the design and implementation of a health care information system used in Serbia and Macedonia. However, agile software development may have several drawbacks [15]. In the case of the EPICAM project, the experts were not available every time when needed. Then we were oriented to supplementary materials such as data collection forms, and statistics forms. These tools help us to advance in our job of modelling before user validation. During the validation, some elements not well modelled or defined

were corrected by the users, which took more time and energy. Atanasovski et al. [6] show that agile methodology permitted fast deployment and adoption of health information but they need another approach (e.g., MDA) to assure its extensibility, soundness, interoperability and standardization.

To adopt the MDA approach, several conditions must be considered [9; 12]: (1) the project team must be experienced in modelling. If we take the example of the EPICAM project, during the training of end users in the use of the tool in order to update the model and generate a new version of the system, just one user from the ones trained to model and generate the software has accepted to use the tool; (2) have advanced tooling with appropriate modelling formalisms. The MDA doesn't work if each project is completely different. The time spent to get the model right and the transformation will be higher than working only with code. In the case of the EPICAM project, we have presented that before the adoption of the MDA approach, we have made a survey of tools and one tool was selected and adapted by adding new functionalities in order to fit to the software to be developed. This tool can be used to model and generate epidemiological surveillance systems of other diseases than tuberculosis. Then, this will lead to a positive return on investment.

Conclusions

In this article, we have presented a methodology based on MDA and using an agile methodology to develop epidemiological surveillance systems. This methodology was used to develop EPICAM platform now used for epidemiological surveillance of tuberculosis in Cameroon. During the pilot project in the year 2015, the system showed its efficiency and has been adopted by the NTCP in Cameroon. It should be noted that the methodology presented in this work can be used for the development of any health informatics.

In the future, we plan to integrate the SMS module [20] into the platform in order to permit villages in which Internet access is unavailable or damaged by a disaster to make their data available in time.

Acknowledgements

The EPICAM project was partially supported by grants from PRODESO (Programme Franco-Camerounais pour un Développement Solidaire).

We would like to acknowledge all the health workers for their feedback and constructive comments while using the EPICAM software. Our gratitude goes also to Dr. Nolna Désiré and Dr. Abena Jean Louis from the National Tuberculosis Control Program in Cameroon; Dr. Gaetan Texier from Centre Pasteur du Cameroon; Prof. Maurice Tchuente and Dr. Hippolyte Tapamo from UMMISCO in Cameroon; Mr. Laurent Braak and Mr. Julien Dupouy from MEDES in France and finally, all those who contributed to the EPICAM project.

Abstract

The objective is to study the way physicians use the ECG computerized interpretation (ECG-CI). Anonymous questionnaires were mailed to 282 primary care physicians (PCPs) and 140 cardiologists in France. 225 complete surveys were analyzed. PCPs performed a median of 5 ECGs per month, vs. 200 ECGs for cardiologists. Among PCPs with ECG, 57% felt confident about their skills in interpreting ECGs. Whereas 91.7% of cardiologists first interpreted the ECG by themselves, 27.9% of PCPs first read the computerized interpretation. PCPs found that ECG-CI was more reliable than cardiologists did for atrial or ventricular hypertrophy. PCPs and cardiologists agreed that ECG-CI was reliable for conduction troubles and "normal ECG" statement, but was not for other rhythm or repolarization troubles. PCPs are less experienced with ECG interpretation, but are also more likely to trust the computerized interpretation, whereas those interpreters are not fully reliable.

Electrocardiography, Computer interpretation

Introduction

Cardiovascular disease is the leading cause of death worldwide. According to the World Health Organizatio, 17.5 million people died from cardiovascular diseases in 2012 accounting for 31% of all deaths. In particular, 7.4 million were due to coronary heart disease and 6.7 million were due to stroke [1]. In 2014, cardiovascular disease was the second largest cause of death and the third cause of death before the age of 65 after cancer, accounting for roughly 150,000 deaths every year [2].

In France, cardiovascular risk factors are the second most common reason for consultation with primary care physicians (PCPs), accounting for 13% of primary care consulting grounds [3]. Those risk factors include uncomplicated arterial hypertension (7%), dyslipidemia (3.7%), and diabetes (2.4%) [3]. Cardiovascular diseases also represent 7.7% of emergency visits at the PCP's office. This proportion rises to 22.2% after the age of 70 [4].

Since the introduction of the string galvanometer by Willem Einthoven, the electrocardiogram (ECG) became the most widely used procedure for the diagnosis of cardiovascular disorders, and notably to confirm or exclude myocardial infarction. Since the first attempt of computerized ECG interpretation by Pipberger in the late 1950s [5], many advances in signal acquisition and diagnostic classification have been made. Currently, many electrocardiographs include a program that provides an ECG computerized interpretation (ECG-CI). Many studies have evaluated such computer programs. Those studies present the sensitivity, the specificity, or even the observed agreement rate (an intermediate computation for Cohen's Kappa coefficient, which should never be computed alone) [6–9]. Those metrics are not impacted by the low prevalence rates of diseases and may be too optimistic. Thus encouraging people to feel too confident with the ECG-CI.

The demographic atlas of the French Medical Association accounts 88,886 independent PCPs and 6,163 cardiologists in France, with a mean age of 52 and 51 years, respectively [10]. Among family physicians, 94.4% perform ECGs in the office in the USA [11], and only 62% in France [12].

In France, many studies at a local level have evaluated the use of ECG in general practice. Rural practice and group practice are the key predictors of owning an electrocardiograph. For PCPs, the limiting factors of owning an ECG device appear to be doubt about their own ability to interpret the exam, time consumption, and the fear of legal prosecutions in case of wrongful interpretation [13]. To our knowledge, no study investigated the way physicians consider and use the ECG-CI.

The aim of this study is to determine the attitude of French PCPs and cardiologists towards ECG-CI.

Methods

Participants and procedure

We obtained the 2016 French health professionals registry (RPPS) [14], which registers all physicians in France, and includes their names and specialty. We randomly draw 600 PCPs and 200 cardiologists. Retired physicians, military physicians, PCPs only practicing alternative medicine (e.g. homeopathy or acupuncture), salaried physicians, and physicians who were practicing in the French overseas departments and territories were excluded, as well as physicians whose postal address could not be retrieved. A questionnaire was then sent to 282 PCPs and 140 cardiologists, accounting for 0.32% of

all primary care physicians and 2.27% of all cardiologists in France (Figure 1). The survey was completed anonymously.

Paper questionnaire

A specific questionnaire was developed based on a review of the literature. It was designed to be self-administered, and to assess beliefs towards ECG computerized interpretation, and to evaluate the use of this diagnostic tool. It took approximately 3 minutes to complete. The questionnaire was then improved based on feedback from two academic public health physicians, and on pilot testing on two cardiologists and three PCPs. The final questionnaire consisted of 4 sections. The first section included questions regarding the participants' training in interpreting ECGs, self-perceived skills in ECG interpretation, distance from the nearest emergency department, practice type, and demographic information. The second section was for participants who did not have an electrocardiograph. It asked them to indicate if they formerly used to own an electrocardiograph, the limiting factors of owning an electrocardiograph, and how they handled the need to perform an ECG. The third section focused on participants' practices regarding the type of electrocardiograph they had, how often they used it if they used a support network for the interpretation of ECGs, and the medical causes to use it. The final section asked participants to indicate if they had an ECG-CI, how often they used it, and their confidence towards ECG-CI. The questionnaire included multiple-choice items and 5-point Likert scale items that ranged from "strongly disagree" to "strongly agree" or from "not helpful at all" to "very helpful," with an option either of "no opinion" or "does not apply." Each questionnaire was accompanied by a cover letter describing the study and a postage-paid reply envelope. The subjects were informed that all responses were anonymous and confidential. They had to return at the same time a waiver of informed consent.

Statistical analysis

Random drawing and statistical analyses were then performed using R statistical software, and R Studio [15,16]. Quantitative variables were described using the mean and standard deviation (SD) for symmetric distribution, and median and quartiles (Q1, Q3) for skewed distributions. 95% confidence intervals (CI95) of means were computed using a Student law. Categorical variables were described using number and percentage, and a binomial law was used to compute the CI95. In order to compare PCPs' and cardiologists' answers, we used χ^2 or Fisher's exact test for qualitative variables, Cochran–Armitage test for trend for ordered qualitative variables, and t-test for quantitative variables. All tests were double-sided, and a *p*-value lower than 0.05 was considered statistically significant.

Results

The response rate was 53.8% (Figure 1) and did not significantly differ between PCPs and cardiologists (p=0.46). The demographics and baseline characteristics of respondents are shown in Table 1. Most respondents were men (69.3%), the mean age was 52.6 years (SD=12.5). Respondents and non-respondents were similar in terms of gender and region of the country. Significant differences between PCPs and cardiologists existed for gender, region, practice location and setting, qualifications, distance from an emergency department, ECG-related training, self-perceived skills about ECG interpretation, and ownership of an ECG device (Table 1).

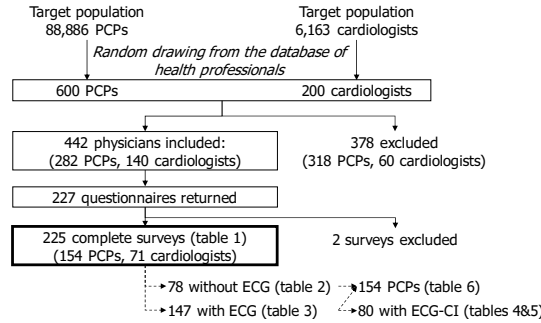

Figure 1. Participant flowchart (sampling fraction: 0.32% for PCPs & 2.27% for cardiologists; response rate: 53.8%)

The attitude of physicians who did not have an ECG device is reported in Table 2. It is worth noting that all cardiologists had an ECG device, therefore only PCPs are described in Table 2. The most important reason not to have an ECG device was to allow easy access to cardiologists or hospitals (71.2% [59.5;81.2]). Patients requiring an ECG in an emergency were first and foremost routed to an emergency room by 91% ([82.4;96.3]) of PCPs, and patients requiring a non-urgent ECG were first and foremost routed to a cardiologist by 93.5% ([85.5;97.9]) of PCPs.

Table 2. Reported attitude about ECG of physicians who do not own any ECG device. Percentages relate to columns.

Item, n (%)	PCPs (n=78)
Formerly had an ECG machine in their office	21 (27.3)
Reasons for not having an ECG machine:	
Easy access to a cardiologist or to a hospital	52 (71.2)
Difficulties in interpreting the ECG	32 (43.8)
Involvement of responsibility	31 (42.5)
Rare indications in current practice	29 (39.7)
Emergency services easily available	23 (31.5)
High purchase and maintenance costs	20 (27.4)
Insufficient reliability of the procedure	14 (19.2)
Time-consuming procedure	11 (15.1)
No diagnostic interest	2 (2.7)
Other	3 (4.1)
For urgent ECGs, patients are referred to:	
The emergency department	71 (91)
A cardiologist	6 (7.7)
A PCP who owns an ECG device	0 (0)
Other	1 (1.3)
For non-urgent ECGs, patients are referred to:	
A cardiologist	72 (93.5)
A PCP who owns an ECG device	2 (2.6)
The emergency department	1 (1.3)
Other	2 (2.6)

No support network	53 (71.6)	67 (98.5)	

Table 3 reports practices relating to ECG interpretation. The median number of ECGs performed per month was 5 for PCPs and 200 for cardiologists (p=0). PCPs and cardiologists had significantly different characteristics of the number of leads, reasons to perform the ECG, and support used for the interpretation (Table 3). In total, 54.8% of devices were equipped with ECG-CI.

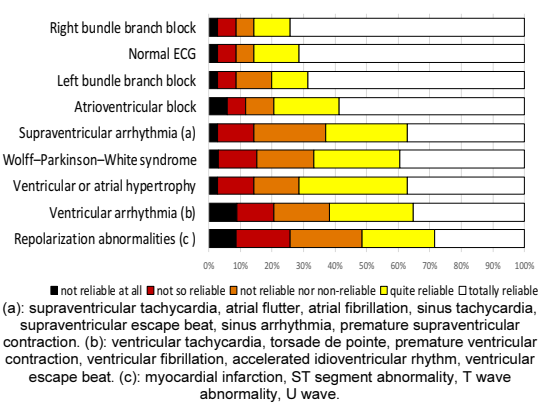
Table 4 shows the most important result of this study: PCPs and cardiologists did not use the ECG devices in the same way: 69.8% [54%; 83%] of PCPs first read the ECG and then the computerized interpretation, although this proportion fell to 52.8% [35%; 70%] for cardiologists, and 38.9% [23%; 57%] of cardiologists even never looked at the computerized interpretation.

Table 4. Usual attitude of physicians having ECG-CI (p <0.001). Percentages relate to columns.

Attitude, n (%)	PCPs (n=43)	Cardiologists (n=36)
Never read the ECG, only read the ECG-CI	0 (0)	0 (0)
First read the ECG-CI, then read the ECG	12 (27.9)	3 (8.3)
First read the ECG, then read the ECG-CI	30 (69.8)	19 (52.8)
Never read the ECG-CI, only read the ECG	1 (2.3)	14 (38.9)

Table 5. Perceived reliability of computerized interpretation (Confidence: 1=Not reliable at all; 2=Unreliable; 3=Neither reliable nor unreliable; 4=Reliable; 5=Very reliable).

Confidence (mean, SD) on the ECG-CI ability to detect some situations	PCPs (n=43)	Cardiologists (n=35)	*p* value
Normal ECG	4 (0.6)	3.9 (0.9)	*0.399*
Ventricular or atrial hypertrophy	3.5 (0.7)	3.1 (1.1)	*0.040*
Right bundle branch block	3.5 (0.8)	3.6 (1)	*0.558*
Left bundle branch block	3.6 (0.8)	3.7 (1)	*0.616*
Atrioventricular block	3.7 (0.8)	3.5 (1)	*0.262*
Wolff–Parkinson–White	3 (0.9)	2.7 (1)	*0.190*
Supraventricular arrhythmia	3.3 (0.9)	3 (1.1)	*0.174*
Ventricular arrhythmia	3.5 (0.8)	3.1 (1.2)	*0.095*
Repolarization abnormalities	3 (1)	2.7 (1.3)	*0.153*



(a): supraventricular tachycardia, atrial flutter, atrial fibrillation, sinus tachycardia, supraventricular escape beat, sinus arrhythmia, premature supraventricular contraction. (b): ventricular tachycardia, torsade de pointe, premature ventricular contraction, ventricular fibrillation, accelerated idioventricular rhythm, ventricular escape beat. (c): myocardial infarction, ST segment abnormality, T wave abnormality, U wave.

Figure 2. Perceived reliability of ECG-CI, by statement

Table 5 and Figure 2 display the perceived reliability of each category of statements of computerized ECG interpretation. The Cochrane-Armitage test reveals a significant difference between PCPs and cardiologists only for atrial or ventricular hypertrophy, where PCPs thought the interpretation was more reliable than cardiologists did (p=0.04). Globally, physicians thought the computerized interpretation was most reliable for conduction troubles and "normal ECG", and was less reliable for other rhythm troubles as well as repolarization troubles.

Among PCPs, Table 6 compares PCPs equipped with an ECG device or not. A physician who had an ECG device was most likely a man, in rural areas, with a private practice, ECG-related diplomas, who worked further away from emergency rooms or cardiologists, and was trained for ECG interpretation (Table 6). However, only 57% of them felt confident about their skills in interpreting ECGs.

Table 6. Descriptive characteristics of PCPs, equipped or not with ECG devices. Percentages relate to columns.

Variable	PCPs with ECG (n=76)	PCPs without ECG (n=78)	*p* value

Discussion

As more and more ECG devices embed software for computerized interpretation, and as the accuracy of such devices remains moderate, it was necessary to know whether physicians owned such devices, and how much they trusted the output of the program. We could analyze 225 questionnaires. An important result was that 49.4% of PCPs were equipped with ECGs. Among them, 58.7% had an embedded interpretation software, and 27.9% reported moderate confidence for its output. PCPs and cardiologists did not use the output the same way: whereas 91.7% of cardiologists first interpreted the ECG by themselves, and eventually read the ECG-CI output, 27.9% of PCPs first read the ECG-CI output, and then tried to interpret the ECG. PCPs and the cardiologists did not have the same qualification level: 68% of cardiologists had a university degree in ECG interpretation, versus 3.95% for PCPs. In addition, 63.3% of PCPs perceived a lack of skills in ECG interpretation. Furthermore, the physicians did not equally trust the computerized interpretation for all the diseases. This study also highlighted factors associated with ECG equipment: PCPs who owned an ECG device were more likely working in rural areas, far away from emergency departments. It is worth noting that, in France, general practitioners can bill ECGs, irrespectively from their post-graduate certificates. The nature of the devices also differed: 61.9% of PCPs were equipped with analog ECG devices whereas 53.9% of cardiologists used digital ECG devices. Only 28.4% of PCPs used support network for ECG interpretation, via fax for 23.0% of them. It also highlighted that having a personal device may have an impact on healthcare consumption: PCPs who did not own a device were more likely to address their patients to emergency rooms. Patients requiring an ECG in an emergency were first and foremost routed to an emergency room by 91% of PCPs, and patients requiring a non-urgent ECG were routed to a cardiologist by 93.5% of PCPs. The main limiting factors for non-equipped doctors was the easy access to cardiologists or hospitals,doubt in their ability to interpret ECGs, and the fear of legal proceedings for wrongful interpretation.

Those results are consistent with the literature. Previous works [13] showed that among PCPs in France, 6% had absolute confidence in computerized ECG interpretation, 65% had confidence when computer declared the ECG as normal, 26% trusted the computer for diagnosis of arrhythmias, and 21% for acute ischemia, whereas several analyses of computerized ECG interpretation accuracy concluded that frequent errors in the interpretation of cardiac rhythm occurred, with many false positives especially for the diagnosis of atrial fibrillation [17–24]. This study also highlighted that the median number of ECGs performed per month was 5 for PCPs and 200 for cardiologists, whereas the American College of Cardiology (ACC) and American Heart Association (AHA) recommended interpretation of 500 ECGs under supervision of an expert to attain initial competency, and the reading of 100 ECGs yearly to maintain competency in ECG interpretation [17].

To our knowledge, no study investigated specifically the way physicians considered and used the computerized ECG interpretation. The answers were of good quality. This work also presents some limitations. The questionnaires were self-administered, and collected declarations of the practitioners about their own practice instead of performing an objective evaluation. The response rate was moderate (53.8%).

Conclusion

The general practitioners are less experienced with ECG interpretation but are more likely to trust the results of ECG-CI. Paradoxically, insufficient knowledge may increase practitioners' trust in technologies that are not 100% reliable.

Abstract

Computerized simulators are important tools that support teaching in many areas. The use of these instruments is often described as significant for students and teachers. In this paper, a software piece was developed to aid decision-making in nursing, allowing the simulation of real situations, addressed in the classroom. The simulator architecture corresponds to a multi-agent system supported by a state machine model. To build the knowledge base, a list of contents was selected, including the Nursing Intervention Classification (NIC). An experiment was carried out with the participation of eleven students of the third year of the course. A questionnaire was applied and, as a result, there were more than 90% of acceptance as a relevant educational tool. The simulation, through this tool, contributed to apply theoretical knowledge to the students, besides helping in the development of the nursing decision-making ability.

Keywords:

Health education, decision making, computer simulation.

Introduction

Decision-making results from a complex cognitive process that associates knowledge with practice [1]. Among management activities performed by the nurse, the management of people is often described as highly complex task [2]. In order to assist the teaching of people management in nursing, this paper proposes the use of a simulator as a tool to support the prediction of the amount of nursing personnel in a common hospital ward. To achieve its purpose, a computer simulator should be as realistic as possible in relation to the simulated scenario [3]. Several factors, including hospitalization unit, patients, relatives, doctors, nurses and other professionals should be considered [4]. The presence of an environment and several actors, interacting with each other, can characterize a multi-agent system where agents, supported by a knowledge base, acts by allowing a simulation of high verisimilitude [5]. In addition to the specialists, who contribute with their knowledge for the elaboration of rules, scripts and decision functions, this work uses the rationale of the Classification of Nursing Interventions (NIC) [6]. The NIC provides a knowledge base about interventions and nursing actions that can guide the simulator's decisions, such as the average times of each nursing activity and the level of knowledge required of the professional who will perform it [6]. Another source of knowledge used in this study is the Brazilian legislation related to the dimensioning of nursing professionals [7] in health services, determined by the level of complexity of care of patients assisted, by the managerial and care model adopted by the health institution, among other factors.

Methods

Technology

The simulator was initially developed as a prototype. After a series of tests, the code was translated to the .NET framework, written in C# language. The presentation layer is based on the WinForms (desktop application) for ease of support and low-level hardware performance (2D and 3D rendering). Since this software is available as free software, no proprietary library was used to build the simulator, resulting in a totally free software available online.

Knowledgebase

The knowledge base is composed of three main sources: 1) The Nursing Interventions Classification (NIC); 2) Experts of notorious knowledge and teachers of the discipline of Nursing Management and; 3) Resolution on the scaling of nursing staff addressed in the classroom. From the NIC taxonomy, the researchers mined a complete set of nursing activities, described through tables, and the average times related to each activity. With this information, it was possible to simulate how long each activity is performed. Other important information gained from the NIC, but with the support of specialists in the nursing area, is the level of knowledge of the professional needed to perform a given activity, whether a graduate or a nursing technician. Professors of the Nursing Management subject developed a set of clinical cases to challenge the student to answer questions during the simulation. These clinical cases were composed of a textual description containing clinical data of the patient allowing the definition of the complexity of the nursing care. The guiding legislation of nursing staffing in Brazil provided a basis for the construction of rules, such as the maximum time that a professional can work continuously and the minimum time of rest, between continuous workdays.

Models and architecture

The multiagent architecture of the simulator is composed of three types of agents: patients, nurses (bachelor degree) and technician nurses (secondary degree), who exhibit autonomous behavior and interact with each other [8]. These agents exhibit two fundamental characteristics: they are able to act autonomously by making decisions that lead to their goals and they are capable of interacting with other agents using human-inspired social interaction protocols and including coordination and co-operation functionalities.

Educational background

Many studies have confirmed the effectiveness of simulation in health teaching as well as in the assessment at the undergraduate and graduate health education levels [9]. Early studies showed the importance of technology in this area [10, 11]. The

computer simulator allows students to experience the work environment of an inpatient unit, including the calculation of the nursing staff, the analysis of the degree of inpatient complexity, clinical reasoning and decision making in nursing interventions. This is the main focus of the whole simulator: to provide a useful virtual environment for students and teachers to experience the day-to-day running of an inpatient unit.

Evaluation

The evaluation was carried out in a classroom with the participation of eleven students enrolled in the subject "Nursing Management" in the third year of the Nursing Bachelor. In this subject, the student learns how to manage a team of nursing professionals, how to deal with Law restrictions and other factors, such as the recommendations of nursing regulatory bodies. In the classroom, after a complete explanation of the use of the simulator, conducted by the research team, each student was connected to the simulator to perform all the tasks required by the virtual environment. After the tests, the students were invited to answer an anonymous, non-compulsory questionnaire. All students answered voluntarily. The questions were based on ten golden rules for the evaluation of health software [12]. The teacher was present during the experiment to inspect the researchers, without influence, control, acknowledgment or coercion on the students' (anonymous) responses.

Methods

A preliminary study was carried out to obtain the necessary data for the construction of the simulated hospitalization unit. A medium-size university-related hospital was used as a model. The adult clinical admission unit has, on average, 20 beds. On a typical day, occupancy is 80%. The work shift is 6 hours, so each day is divided into four shifts (morning, afternoon, early night and late night). Inpatient admission and discharge occur at the end of the shift. The simulator, in its first stage, does not allow the admission or discharge of patients, except in a simulated death, so each simulation process occurs in a period of six hours. Each patient presents a level of care complexity, being able to be classified in: minimum care, intermediate care, high dependence, semi-intensive care and intensive care. According to this classification, Brazilian legislation fixes how long it takes (in mean hours) of nursing care. To classify the complexity of the patient, the nurse performs a clinical evaluation based on predefined criteria presented in a table and the result is obtained from the score of these tables. In the initialization process, the simulator generates a random count of inpatients (up to 20), as well as the level of complexity of each patient. In a preliminary survey, it was concluded that it would be tiring and exhausting for the student interacting with too many simulated patients at the same time, so the strategy adopted was to restrict the student's access to direct care of only three simulated patients. These three patients will require student attention throughout the simulation, requesting medications, questioning and reporting his needs. However, for the management of people, the simulator considers an inpatient unit with a number of patients compatible with reality.

Agents

The "patient" agent is one of the two possible types: autonomous or programmed. The autonomous agent works in response to randomized events from the knowledge base (NIC and regulations) and based on the patient's level of complexity. For example, a patient with a minimal level of care requires random NIC activities of up to the maximum expected by their level of complexity. The scale for the arrangement of the complexity of the Patient used is defined by COFEN 543/2017 [7]. The other type of "patient" agent is the one programmed by the professor of the Nursing Management subject, which defines the actions required by the patient. These actions will cause the simulator to trigger a challenge to the student involving decision making regarding a nursing intervention. For example: the patient feels short of breath, what to do? The "nurse (bachelor)" and "nurse (secondary)" agents respond to patients' calls and perform nursing care. The main objective of these agents is to measure the workload of nursing professionals (nurses and technicians). When a nursing agent is assigned to care, he can't be allocated to another job until his work is done. Therefore, the complexity of care and the number of nursing actions to be performed in each patient indicate the number of nursing personnel and the distribution of these professionals among the patients in an inpatient unit. If the demand for care is too high, the available nursing staff will have to deal with the increased stress as well as with the impairment in quality of service. Figure 1 exemplifies the simulated "nurse" agent state machine. The network nodes are composed of rules that are used to define whether the professional is available or is interacting with another agent (table 1).

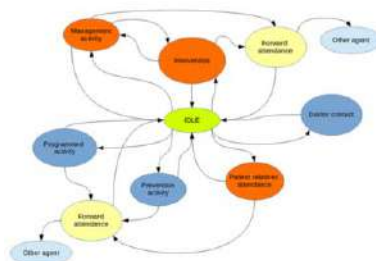

Figure 1 – Nurse state machine

To allow for multiple simulations during a teaching class, the simulated time has been accelerated to one-tenth of the actual time, it means that each simulated minute takes only six seconds to go, so each simulated session will last six minutes.

Table 1 – Agents

Name	Base	Interacts with
Patient	The specialist data; Teacher´s course	Nurses; Physicians; Students;
Nurse	Knowledge base; The specialist data; NIC; Laws and local rules;	Patients; Other nurses; Physicians;
Physician	The specialist data;	Patient; Nurses;

Communication between agents

Since the agents must interact with each other, a communication protocol was created to perform this function, this protocol was based on a data bus that runs on a thread accessible by instances of all agents, once an agent was created, it presents itself to the bus by registering in the main event manager. It is possible, over this bus, to interact with individual agents, one to one, one to many and many to many, allowing to simulate a wide range of communication types found in a hospital (phone call, internal sound system and personal conversation). This protocol allows another type of communication that is not based on messages, but based on events, since a patient can trigger some event like a heart rate monitor alarm and this event is directed to the nearest nurse, as a situation common in a hospital.

Figure 2 illustrates the communication design and the actors involved.

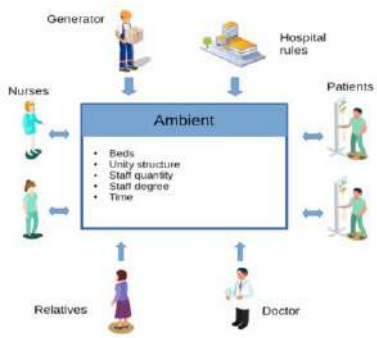

Figure 2 – Communication between agents

Ethics

This research was approved by the Research Ethics Committee under the title "Hospital Environment Simulator for Personnel Management and Dimensioning", CAAE: 57514916.3.0000.5345. Approved on: 08/18/2016. The project includes the classroom test, the use of the questionnaire and the participation of the specialists. All participating students signed a consent term and received full attendance during all phases. The participation was voluntary, and any refusal would not result in the reduction of grades at any level. Throughout the evaluation, students were free to leave participation, without penalties, however, no student left the activity. All images and artwork used in the simulator have been licensed by the corresponding author for use in this software and all software libraries and components are freely distributable.

Results

The results can be described in two different steps: the construction of the simulator and the validation of usability in the classroom.

Simulator

The first step, related to the construction of the simulator, resulted in the development of a discrete software, without complex dependencies, that can be executed with minimum efforts. After login (Figure 3), the student has access to the main screen (figure 4), where the simulation console is located. This screen is composed of inpatient controls, nurses and technicians, time controls, charts and a visual representation of the ward with beds, patients, physicians, nurses, technicians and family members. At this screen, the student has the time and complexity control of the simulation. The main console shows three graphs in real time while the simulation is running. The top chart represents the total of hospitalizations waiting for care. In case the team is dealing well with all internal calls, this graph may be empty otherwise the graph will show an increasing area meaning that the patients are waiting for attendance. The middle graph shows the hourly call amount, a nonlinear plot means a high entropy in the algorithm and shows a random set of calls during the simulation. The graph below represents the average time of care, the area of the chart is the total time of care applied to inpatients.

Figure 3 – Login screen

Although the simulator algorithm calculates the nursing team based on laws and constraints, it is possible to change the variables related to patient, nurses and technicians count through the sliders. By changing these controls, the student can suppress the current rules and try scenarios different from those expected by applying current regulations. At the bottom of the window, there are two more sliders, the top represents the time factor of care and the second is the complexity of care factor, these two sliders allow the student to experience a more flexible simulation.

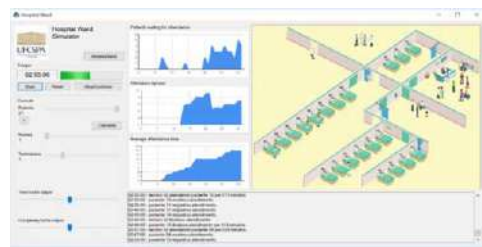

Figure 4 – Main simulation screen

In Figure 5, the student is challenged to evaluate the patient complexity, which results in a score used to classify the inpatient care, based on the recommendations of the COFEN [7]. The correct classification will contribute to the efficiency of care planning, allowing the nurse to distribute the amount of nursing personnel, according to the complexity of the care analyzed. An incorrect classification may cause stress to staff due to lack of people (inpatients labeled as below complexity that really it is), or may increase overall costs, should it require more people than necessary (inpatients labeled as above complexity that really it is).

Eventually, at random times, the student is challenged to solve situations to promote the development of clinical thinking and decision-making skills. In Figure 6, the student interacts with the inpatient due to a call followed by a problem description. Once answered, the simulator will report a feedback to the student. Based on the student's decision, the simulator can change the clinical picture of the hospitalized patient, which may be a better or a worse state

Figure 6 – Inpatient attendance

Evaluation results

As a result of the classroom assessment, a table was compiled to illustrate the student's perception of the tool. The following table (table 2) represents the answers collected from the students, after the class where the simulator was used as a learning tool. The questionnaire was divided into 12 questions based on the ten golden rules for the evaluation of health software [12]. The questions are based on the Lickert style where "1" means "very bad" and "5" means "very good".

Table 2 – Questionnaire results

Question	Mean	SD
1) Was this exercise developed focused on the student improvement?	5	0
2) This type of exercise does stimulate student interactivity with technological tools to solve proposed problems?	5	0,302
3) How about the ability to motivate and focus on solving the problem proposed?	5	0,405
4) At some point during the development of the exercise did you feel pressured and forced to move forward without understanding the problem in its entirety?	0% Yes 90% No 10% Partially	
5) The exercise you have done, regarding your ability to generate autonomy in your learning, so that you can conduct your studies at your own pace?	5	0,302
6) The exercise, regarding the relevance and contextualization of the contents approached for your learning?	5	0,405
7) Do you believe that the exercise performed provides scientific depth on the subject addressed?	100% Yes 0% No 0% Partially	
8) As to the visual aspect of the exercise and how the content was presented, you judge the exercise:	5	0
9) How do you evaluate the ease of use of the exercise interface?	5	0
10) How do you evaluate the attractiveness of the exercise interface?	5	0
11) How do you evaluate the navigability of the exercise, i.e. the ease of finding the information and directions of the next steps?	5	0,522
12) Did you find the exercise too long?	0% Yes 100% No	

Discussion

The adoption of an agent-independent approach has brought important flexibility in the implementation of the simulator, first because it is appropriate to the context of the simulation of environments [4, 8] and second, because it is a simple implementation using parallel computing concepts [3]. In an empirical analysis, it was observed that the behavior of the agents in an inpatient unit would be analogous to the behavior of independent computational agents, and this was confirmed with the bibliographic studies found in [13, 14]. Another important factor for the realization of the project was the decision to implement the communication bus in three models: direct (p2p), group (multicast) and overall (broadcast) [15], making possible the simulation of three forms of communication between agents actors): direct communication (a telephone call), group communication, or overall communication (internal sound system) making compatible, in empirical analysis, with the behavior observed in a hospitalization unit of a medium/large hospital institution. The concept adopted to measure the states of a patient in discrete variables made viable for the use of state machines [3] to simplify the patient's assisted momentum, and the control of the machine states was filled by the professional who has the necessary knowledge, enabling the state transitions according to the information provided. This feature brought a special gain to the simulator because it allows interaction with the observer and the system, seeing not only simple passive analysis but an active approach, placing the user inside the unit, acting and interfering with the actors and the environment. The analysis of the results provided important reflections to the members of the study group that developed this work. All students considered that the exercise was focused on student growth, however, there was no unanimity about the perception that the simulated exercise stimulates the ability to solve the proposed problem (people management). Many hours of work were invested in the construction of the interface of the simulator, and this reflected in the perception of unanimous satisfaction about the ease of use and attractiveness of the simulator, but it is possible to identify a probable bias of confusion because the students do not have many references of simulators of this type for purposes of comparison, so this parameter, in spite of the absolute numbers in the answers, should depart from certainty and accuracy.

In general, it is possible to observe the major satisfaction with the tool, perhaps because the method provides an interactive way of experiencing the hospital ward and viewing staff calculations in a visually appealing manner that was denoted as "much better than numbers in the paper". Another important factor was hospital manipulation through simulation, based on the clinical case provided by the specialist (the subject professor in this case), students not only were able to choose a nursing care action, but also see the results of their decisions in dynamic show. On the other hand, apart from the educational environment, the divergence of the values recommended by the law and the reality found in the professional environments is evident. This divergence is related to a very important gap in the actual workload per nurse in a real hospital and the workload described in the regulations. First, the research group had been concerned about some misunderstanding or any other research bias, but after several analyzes in one unit and reference admission, the concern was resolved and this divergence between real and simulated resulted in a new study on this gap. This part is related to local (Brazilian) laws, but after some research [16] it was possible to determine that this problem affects other places also causing stress, low-quality care and turnover of nurses. Although this finding is very important for the quality and overall satisfaction of the workers, this was not the main objective of this study, but part of another study from the same research group at the same university.

Conclusions

Although the lack of formal validation, it is believed that simulators may play an important role in learning objects. Considering the increasing presence and necessity of virtual learning environments and the lag that traditional methods of evaluation have in such scenarios, more studies are needed to consolidate these tools as alternatives in health education. Simulators may play a role beyond the training environment. By explaining to the student the underlying mechanisms and the motivations that led him to make a decision, it can produce a deeper evolution in this same student, in this sense we believe in the importance of feedback during the execution of the simulation. The simulator may awake in the student the recognition of thought patterns and attitudes, motivating him to question established practices or acquire new skills and strategies for making decisions. We anticipate this, for example, in the still unexplored possibility of comparing log records and their respective motivators to the same student in different scenarios. Over time, the evolutionary analysis of these decision-making patterns could constitute a subsidy for conclusions about the entire process of student formation. We believe that it is necessary to carry out a validation of the method as an alternative to the formal evaluation, which can be obtained by comparing the traditional method (written tests and/or practices formulated by the teacher) and the simulator. It seems to us that an ideal methodology to be applied will consist of homogeneous classes, which receive the content in a usual way and then submitted to the traditional form of evaluation and to the simulator. The group will continue this form of work and intend in the next instance to correct the flaws pointed out in this research and then proceed to a new workshop for didactic-pedagogical validation of the simulator.

When Ants Take Care of Humans: ACO for Home-Care Services Planning Optimization

Yahia Chabane, Christophe Bortolaso and Mustapha Derras

Berger-Levrault, France

Abstract

Current planning approaches for home care services do not generally support the social and human dimension of planning. They focus on optimization criteria that are easily quantifiable, such as the cost. Whereas other criteria such as the quality of the relationship between caregivers and beneficiaries or the satisfaction of the latter are important too as they can highly influence the planning. To address this issue, we investigate in this work the problem of planning optimization for home care service. We propose an extension of the classical ant colony optimization algorithms. Optimization is carried out by several classic criteria such as the cost along with social-based criteria such as the relationship between caregivers and beneficiaries. We also propose a flexible and expressive language to represent the constraints in the form of predicates that can include variables, constants and functions of the problem. This allows each organisation to add its own constraints.

Keywords:

Home Care Services (HCS), Constraint Satisfaction Problem (CSP), Ant Colony Optimization (ACO)

Introduction

In France, according to the National Institute of Statistics and Economic Studies, one in three inhabitants would be 60 years or older in 2050. A lot of these people are in a situation of loss of autonomy and need to receive medical or social care. However, the specialized organisations lack of available places. Consequently, Home Care Services (HCS) are more and more emerging and several types of organisations were created recently. These HCS organisations reduce the overload and indebtedness of hospitals and other institutions and provide a better environment for beneficiaries.

The management of these organisations and more particularly the caregivers interventions planning is complicated and is still largely done manually. A large number of constraints must be considered when producing the plan such as the satisfaction of caregivers, of beneficiaries, skill requirements, working time regulations, variable duration of acts, etc. The production of a plan becomes a big challenge, as we often have to deal with hazards such as the integration of new beneficiaries, lack of staff, and various unanticiped changes.

Automatic plan generation constitutes a great solution to this problem and several approaches are proposed in the literature [10,15,18]. An automatic planning system must be flexible to deal with the hazards of planning, robust to satisfy the various constraints and be executed quickly to deal with emergencies, changes, or event crisis situations.

Current planning generation approaches generally address easily quantifiable criteria such as the cost, the travel distance and the number of caregivers, etc. We advocate that social and human dimensions of the care acts have a strong influence on the planning and must be considered. The satisfaction of the beneficiaries and their relationship with the caregivers are, for instance, important criteria to take into account while planing the caregivers interventions. In addition, constraints addressed traditionnally do not cover all needs of the HCS organisations.

To address this issue, we explore the problem of planning optimization of HCS and we study the potential of Ant Colony Optimization (ACO) algorithms to solve these problems. We chose to represent the problem as a Constraint Satisfaction Problem (CSP). Indeed, it allows us to reuse many tools, approaches and theoretical results about resolution and computational complexity of the problem instances. Moreover, CSP is well adapted to manage the constraints separately from the problem resolution which allows to easily customize or add social and human constraints.

Organisation of the paper. Preliminaries section recalls some basic notions regarding HCS planning problem, CSP and ACO. ACO for HCS optimization section presents our optimization approach, while Experimental Results section exposes the system implementation, experimental results and feedbacks from a qualitative study. Related Work section discusses related works. We conclude and draw future work in Conclusion and Future Work section.

Preliminaries

We introduce and recall some basic notions regarding HCS planning problem, CSP and ACO in this section.

Home Care Services Planning Problem

Home Care Services (HCS) are paid care services, proposed to people in their home. A beneficiary is a person, who is subscribed to a home care service. A caregiver is a competent person that carries out the set of care acts. An intervention is a set of acts performed at a time t by a caregiver c for a beneficiary b. A planning constraint is a condition for carrying out one or more interventions.

The HCS planning problem consists in the definition of a set of interventions to meet the demands of a set of beneficiaries taking into consideration the optimization of the satisfaction number of planning constraint.

Constraint Satisfaction Problem (CSP)

A CSP [19,22] is well adapted to represent several real problems with constraints. A CSP is defined by a triplet (X, D, C) where:

- $X = \{X_1, X_2, \ldots, X_N\}$ is a set of variables of the problem.
- D is a domain function that associates to each X_i its domain $D(X_i)$ (possible values of X_i).
- $C = \{C_1, C_2, \ldots, C_M\}$ is a set of constraints of the problem.

The associated optimization problem consists in the assignment of the variables and in the optimization/satisfaction of a set of constraints or/and an objective function. It is also called constrained optimization problem (COP).

Ant Colony Optimization (ACO)

ACO [7,9] is a meta-heuristic for solving combinatorial optimization problems. It is inspired by the behavior of real ants when foraging. The first ant colony algorithm was proposed by Dorigo [6] to solve the travelling salesman problem which consists of finding the shortest route that visits each city of a given set of cities. The basic principle behind ACO is to produce a collective intelligence from the interaction of individual behaviors to solve a complex problem. Indeed, the behavior of a single ant is not complex, but the result of the collaboration of multiple ants results in the emergence of a complex collective behavior.

Ants foraging consists in finding a source of food and the shortest path between this source and the anthill. Ants converge progressively to the shortest path through an indirect communication mechanism called stigmergy, achieved by the modification of the environment. This mechanism is realized by the deposit of a volatile hormone (i.e. pheromone) on the path taken by the ant. This pheromone has a direct impact on the behavior of the following ant, as they are attracted by the pheromone and more likely to move towards it. This results in ants following the same path as the first ant, but the decision remains stochastic, since other ants take other paths. An important characteristic of the pheromone lies in its ability to evaporate quickly. This makes the less traveled paths disappear (often the longest), and increases the amount of pheromone deposited on the shortest paths, because more and more ants take these paths. This phenomenon allows a short path to emerge (not necessarily the shortest possible path) that almost all ants follow even if some ants take other paths.

It is important for this type of approach to find a good balance between intensification (i.e. exploitation of collected information) and diversification (i.e. exploration of the research space). For ACO, intensification is realized by the deposit of pheromone and diversification through stochastic decision making of ants and the evaporation of pheromone.

Related Work

HCS planning problem is a problem with an exponential number of candidate solutions. Each candidate solution is evaluated, the goal is to find the best rated candidate solution. Intuitively, the resolution consists in listing all the candidate solutions and take the best rated one, but this is not possible in a reasonable time. The complexity [17] of this type of problem is in general *NP-complete* or *NP-hard*.

To design a HCS planning system, we need to answer three key questions: (i) What are the planning constraints ? (ii) How to evaluate a plan ? and (iii) how find the best plan ?

These questions are highly linked to each other, they represents what constitutes a HCS planning system. We investigate a brief overview of the possible answers to the above mentioned questions. The first question concerns the planning constraints of a HCS planning problem, the second question concerns the evaluation criteria of a plan and the used evaluatio function, and the third question concerns the used resolution approaches:

i. HCS planning constraints: they are conditions related to the validity or the quality of the plan. Some conditions must be verified, and others are related to the quality of the plan. The most used constraints in the literature are [5,10,15]: skill requirements, sectors, temporal dependency, time windows, continuity of care, workload balancing, breaks, etc.

ii. Evaluation function: an important factor in HCS planning system is the evaluation function. This function defines the criteria to optimize when generating a plan. Several criteria are used in the literature as [10,15,18]: number of caregivers, travel time, travel time, waiting time, preference, constraint violations, etc.

iii. Resolution approaches: Solving a HCS planning problem consists in finding the best solution optimizing one or more given evaluation criteria from an exponential set of candidate solutions. This set of candidate solutions is called the problem research space. Resolution approaches can be classified according to Completeness and Correctness [18,22]: a correct and complete approaches, a correct and incomplete approaches and an incorrect approaches. The approaches used are generally correct and incomplete, we can cite [5,10,15,18]: tabu search, genetic algorithm, greedy search, local search, adaptive large neighborhood search, etc.

As mentioned before, current planning approaches do not generally support the social and human dimension of planning, while the relationship and the satisfaction of the beneficiaries and the caregivers are very important. In addition, the constraints are very general and do not cover all needs of the HCS organisation.

ACO for HCS optimization

Our choice to represent the problem as a CSP enables us to separate the problem from the application field in order to better manage the representation of constraints and to simplify the adaptation of the solution to other applications. This information structure allow use to easily redefine constraints when required, to adapt the algorithm to different practices in different home-care organisations. About the resolution algorithm, ACO, has been used to solve several optimization problems [8,9,24], and also been successfully used to solve CSPs [13,21,22], which strengthens our choice. This naturally appeared as a relevant solution to our problem.

We present, next, our representation of the problem and BL-ANT-Planning, the proposed resolution mechanism.

Problem Representation

In the following, the representation of our problem in the form of a CSP. We have defined the variables of the problem, the function that associates each variable with its domain and the constraints of the problem.

Variables

We use a matrix $Assign[][]$ and an array $Planify[]$ to represent the variables of the problem, their size are $N \times M$ and N respectively, where N is the number of interventions and M is the maximum number of caregivers needed to perform an intervention.

- $Assign[1 \ldots N][1 \ldots M]$: it is the assignments of the interventions to the caregivers. $Assign[i][j]$ is the caregiver j who will perform the intervention i, such that $0 \leq i < N$ and $0 \leq j < M$.

- $Planify[1 \ldots N]$: it is the plan time of an intervention. $Planify[i]$ is the time slot identifier of the intervention i, such that $0 \leq i < N$. This identifier can be converted to a schedule.

Variables Domains

Let N be the number of interventions and let M be the maximum number of caregivers needed to perform an intervention, the function D that return the possible values of $Assign[][]$ and $Planify[]$ is defined by:

- $D(Assign[i][j]) = \{0, 1, 2, \ldots, K\}$ such that K is the number of caregivers and $0 \leq i < N$ and $0 \leq j < M$.
- $D(Planify[i]) = \{0, 1, 2, \ldots, T\}$ such that T is the number of time slots and $0 \leq i < N$.

Constraints

Let N be the number of interventions and let M be the maximum number of caregivers needed to perform an intervention. We define an expressive language to represent the constraints in the form of predicates that can include variables, constants and functions of the problem. For example:

- $\forall i \in [1; N], \forall j, k \in [1; M], if\ j \neq k$ $then\ Assign[i][j] \neq Assign[i][k]\ or\ Assign[i][j] = 0$ which means that an intervention cannot be assigned more than once to a caregiver.
- $\forall i \in [1; N], \forall j \in [1; M]$ $then\ Qualif\ (i) \subset Qualif\ (Assign\ [i]\ [j])$ where $Qualif\ (i)$ is a function that returns the skills of a caregiver (or necessary skills of acts), which means that a caregiver must have all necessary skills to perform care acts.

Based on that constraint representation, our test involve more than 17 constraints.

BL-ANT-Planning

Algorithm 1 describes the general principle of the approach. A first step (lines 2 and 3) for initializing the algorithm parameters and the pheromone. Then for each cycle (line 6), the ants generate solutions (one solution per ant) and each solution is improved by a local search (line 7). The solutions are then evaluated to update the best solution of the algorithm and the best solutions of the cycle (line 8). At the end of a cycle (line 9), the ants that have generated the best solutions of the cycle depose a pheromone. Finally, the best generated solution is then returned (line 10).

Initialization

In this step, the parameters of the algorithm are initialized and the pheromone is deposited on the possible solutions. Parameters include the number of cycles, the number of ants to use per cycle, the pheromone factor weight and the heuristic factor weight.

Algorithm 1: BL-ANT-Planning

```
   Input: problem ; the input data of the problem
   Output: bestSolution ; the best generated solution
1  begin
2      parameterInitialization(problem);
3      pheromoneInitialization(problem);
4      for i ← 0 to numberOfCycles do
5          for j ← 0 to numberOfAnts do
6              solution ← buildSolution(problem);
7              solution ← localSearch(problem, solution);
8              updateBestsSolution(solution, bestSolution, bestSolutionsOfCycle);
9          pheromoneUpdate(problem, bestSolutionsOfCycle);
10     return bestSolution;
```

Other parameters related to the pheromone are also initialized, the minimum pheromone factor and the maximum pheromone factor that can be found on a solution and the pheromone evaporation rate. Initially, a quantity equal to the maximum pheromone factor is deposited on all solutions.

Solution Generation

To generate a solution, the ant generates an assignment of the variables of the problem satisfying the constraints of the problem. What it generated is ignored if an assignment violates a constraint. The assignment is generated by assigning the variables one by one until there are no variables to assign. The order of the variable assignments is important, an assignment of a variable can restrict the domain of another variable or even make it empty.

1. *Variable selection:* the variable selection technique impacts the performance of the algorithm and the quality of the solution. Several techniques are proposed in the literature [3,19,23]. For performance reasons, we use for now a random selection of variables, where each variable has the same probability of selection. We plan to explore other selection techniques in future works.
2. *Value selection:* the value of the variable is selected from the subdomain that is compatible with the constraints of the problem. The value selection is stochastic and is based on the pheromone factor, deposited between the variable and its possible values, and on the heuristic of assignment evaluation. The probability of selecting the value v_i for the variable V_j is equal to: $p(v_i \rightarrow V_j) = \frac{[\tau(v_i \rightarrow V_j)]^{\alpha} \times [\eta(v_i \rightarrow V_j)]^{\beta}}{\sum_{v_k \in D_{V_j}} [\tau(v_i \rightarrow V_j)]^{\alpha} \times [\eta(v_i \rightarrow V_j)]^{\beta}}$

Where $\tau(v_i \rightarrow V_j)$ is the pheromone factor between v_i and V_j, $\eta(v_i \rightarrow V_j)$ is the heuristic factor of the assignment $v_i \rightarrow V_j$, α is the pheromone factor weight, β is the heuristic factor weight and D_{V_j} is the subdomain of V_j which is compatible with the constraints of the problem.

Improvement Solution

Local search is used to improve the solutions. It is performed before the solution evaluation in order to improve the ant generated solution. Caregivers satisfaction criterion is improved in this step by trying to eliminate unnecessary breaks.

Solution Evaluation

The solutions are evaluated in this step to keep the best solution of the algorithm and the best solutions of the cycle. Several criteria are used to evaluate a solution, including social and human dimension criteria. For example, the cost, the quality of the relationship between the caregivers and beneficiaries, the respect of the geographical area, the satisfaction of caregivers and beneficiaries, etc. Each criterion is evaluated on a scale of seven levels [1,16]. Then, an average of all criteria is calculated according to the weight of each criterion, this average will represent the evaluation of the solution.

Table 1. *List of identified planning constraints and optimization criteria.*

Related to	Planning constraint	Optimization criteria
Beneficiary	Time constraints and absences, state of the beneficiary and his entourage	Time preferences, regularity of the caregivers and plans
Caregiver	Qualification/skills, respect of employment contracts, lunch break, absences	Optimization of employment contracts, time preferences
Intervention	Synchronization with external services, caregiver/beneficiary incompatibility, replacement degree, equipment, travel time, mutual plans, implementation interval, intervention difficulty	Intervention priority, hardness
Organisation	Travel time, legislation, work rate, schedules of external structures	Compactness, costs, caregiver contract, sectors, substitute preferences

Pheromone update

At the end of a cycle, the pheromone factor is updated. A quantity evaporates and another quantity is deposited on the best solutions of the cycle. After each update, all the pheromone factors must be between the predefined minimum pheromone factor and maximum pheromone factor.

The evaporation of the pheromone is simulated at the end of each cycle by the multiplication of the pheromone factor by the pheromone evaporation rate. The pheromone deposit is not carried out as in nature, it is delayed until the end of the cycle and only performed on the best solutions of the cycle. The quantity of pheromone deposited depends on the quality of the solution. Pheromone deposition is only performed for the best solutions of the cycle unlike natural ants that deposit pheromone in all cases. We think this will help a faster emergence of solutions, we also plan to test other strategies.

Implementation

Our solution is implemented as a black-box service which takes as input a file formatted as JSON, specifying the list of caregivers, beneficiaries and the constraints to consider. The solution outputs a set of calendar files in iCal format. Each iCal file represents the plan of one caregiver.

The architecture of the application is modular, the definitions of the problem, of the constraints and of the resolution algorithm are decoupled. The software architecture make it also easy to integrate another resolution algorithm (i.e. other than ACO, such as genetic algorithm for instance), we can also change the representation language of constraints to cover a more expressive or less expressive language for better performance. This allows us to easily adapt our implementation to other applications and other problems.

Results

We test our approach in a twofold perspective. First, we did a quantitative study, focusing solely on algorithm performances. We then organised workshops with some HCS organisations to qualitatively test the algorithm on real cases. This enabled us to customise the solution evaluation function in order to improve the selection of solutions. This also allowed us to verify the accuracy and the usability of the proposed approach with practitioners.

Quantitative study

We started by studying for real case of planning, the influence of the algorithm parameters on the quality of the generated plans and the research quality. The quality of the generated plans is evaluated on the optimization criteria that we present in the following section and the research quality is measured by [4,11,20]: (i) a similarity ratio, in order to know if the collected information is well exploited and (ii) a resampling ratio, used to know if the research space is well explored by the algorithm. The best algorithm parameters found is (4, 2, 0.05, 0.1, 10) represents respectively the values of: 1) pheromone factor weight, 2) heuristic factor weight, 3) pheromone evaporation rate, 4) minimum pheromone factor and 5) maximum pheromone factor.

Regarding performance, we ran the algorithm on a machine with a 2.7Ghz i7-7500U processor and 16 GB of RAM. For an organisation with 268 beneficiaries, 37 caregivers, and 142 interventions to plan, the execution lasted 2 minutes for 10000 cycles with 15 ants by cycle.

We have a promising first results. They, nevertheless need to be consolidated and compared with other approaches. We have identified some benchmarks [2,12,14] for this comparison.

Qualitative study

We worked with five HCS organisations, initially to determine the planning constraints and optimization criteria they use. These HCS organisations are in different cities and are different size. The number of beneficiaries managed varies from 200 to 700 with 30 to 100 caregivers.

Table 1 lists the planning constraints and optimization criteria used by the five HCS organisations. Note that, a slight difference between the supported constraints list and the importance of each optimization criteria of the HCS organisations, this difference is related to the localization and the size of the HCS organisations.

We then tested the algorithm on the data of these organisations and we compared the generated plans with the plans they generate manually.

Table 2 presents a result of a comparison for an organisation with 268 beneficiaries, 37 caregivers, and 142 interventions to plan. This comparison is based on the number of caregivers needed for planning, the duration of all breaks and the regularity of interventions, such that an intervention is regular if the caregiver provided a car for the beneficiary at least twice.

Table 2. *Comparison of generated plans with organisations plans*

	Organisations plans	Result at 2min	Result at 30min	Result at 60min
Number of caregivers	21	19	16	15
Duration of all breaks	3120	3560	2660	2240
Number of regular intervention	140	142	142	142

The first results are promising, we improve the three criteria after 100000 cycles (30 min) and two criteria after 10000 cycles (2 min). Note that the number of regular interventions converges

quickly, we cover 100% of interventions directly after 10000 cycles. These results remain to be confirmed on benchmarks.

Our results indicates that our solution generates plannings which are alsmost as good as the one done manually after only 2 min of computation with a standard computer. Furthermore, it also shows that after 60 mins of computation it provides solutions involving potentially 28% less caregivers. This could results in better service allowing caregivers to spend more time with beneficiaries and/or cheaper home-care service.

Conclusion and Future Work

In this paper, we proposed and implemented a resolution algorithm for the planning problem in the context of Home Care Services, based on Ant Colony Optimization. We used a Constraint Satisfaction Problem to represent the problem. The implemented application is structured into modules to facilitate its extension and adaptation to other problems. Since the algorithm is non-deterministic with a stochastic solution construction, the correct parameterization that is at the core of the mechanism needs to be further validated.

The next objective of our project is to compare the performance of our approach with other approaches on benchmarks. We plan also to study the impact of different parameters and try other pheromone deposition techniques or variable selection strategy. We will also look at what is done on CSPs in terms of filtering variables domains, representation and constraints management.

Abstract

Coding accuracy in case-mix databases enables efficient funding of health facilities and accurate epidemiological statistics based on patients' stays information. We assume that the data collected in the electronic health record, especially drug prescriptions and medical reports are relevant for checking the consistency of the coding of diagnoses. We evaluated a new coding control tool, "TOLBIAC control", embedded in the Web100T coding assistant. This tool interacts with the Vidal Application Programming Interface and the electronic health record of the University Hospital of Saint-Etienne. The micro-average F-measure was 0.76 for drug prescriptions and 0.55 for free text medical reports. This initial evaluation has revealed that drug prescriptions in EHRs can successfully be used to develop an automated ICD-10 code-control tool. Nevertheless the "TOLBIAC control" tool is not yet fully effective for widespread use because of its limited performance in text analysis, a feature that is currently undergoing improvements.

Keywords:

Drug Prescriptions, International Classification of Diseases, Diagnosis Related Groups, Clinical Coding, Electronic Health Records

Introduction

In many countries, funding of public and private hospitals is based on a prospective payment system. Hospitals are reimbursed according to Diagnosis Related Groups preset tariffs [1]. In France, this system relies on the French Hospital Activity Database which requires every inpatient and outpatient stay to be coded using a Standardized Discharge Summary (SDS) [2]. The SDS aggregates all diagnoses and medical procedures associated to patients' stays. Diagnoses are coded following the International Classification of Diseases, Injuries, and Causes of death (ICD-10) [3]. The process of coding has to follow mandatory national guidelines, published by the French Health Ministry, in order to ensure consistent practices among hospitals.

In addition to hospital reimbursement, the accuracy of SDSs is essential for nationwide hospital management, statistics, economy, research, and epidemiology [4]. Furthermore, physicians from the French National Insurance regularly ensure that clinical coding matches patients' medical records, if not, heavy fines may be applied [5].

Coding is mainly performed by physicians and specialized clinical coders. To support experts in the coding process, automated code prediction tools could be used. Such tools can suggest codes that are not manually detected, and thus can be acted on for completeness. Code prediction can be made based on the data from the EHRs using machine learning algorithms, rule-based systems, or their hybrid. An example of a rule is: "if serum potassium is more than 6.5 mmol/l, suggest E87.50 hyperkalemia" [6].

While many studies have shown interest in coding predictions [7–9] based on the comparison with elements available in the EHR, to our knowledge, no study has described an automated standardized code controlling tool that benefits from such data in addition to information collected in SDSs. To fill this gap, and to overcome the difficulties associated with handcrafted code harvesting [4,10], the TOLBIAC project (Terminologies and Ontologies for Linking Billing Information and Accurate Clinical data) aimed to define, model, implement, and evaluate the consistency between the information in the EHRs and the processed SDSs. As part of this project, the "Tolbiac-Control" tool was developed and integrated in the graphical user interface of Web100T® coding system to enable the use of ICD-10 codes for the hospital stays..The company managing the registered drug database VIDAL developed the tool.

To control the validity of existing codes, "Tolbiac-Control" is based on three hypotheses. First, hospital drug prescriptions are a good indicator of the presence of various pathologies [11]. Some studies successfully predicted codes using information on drugs prescribed in EHRs [9], and other studies showed that prescriptions may be a valid proxy of prevalence of diseases [12,13]. Therefore, even if there are some known limitations [14], data concerning drugs prescribed in hospitals could be used to assess whether an ICD-10 code rightfully belongs to the patient's SDS or not.

The second hypothesis is that the use of unstructured data from EHRs, such as text from clinical reports may be used for code control. Unstructured data has been widely used for code prediction and suggestion [8], and may likewise be useful for code control.

Abhyankar et al. [15] and Halfon et al. [14] showed that the utilization of multiple data sources improves the prediction of codes. Moreover, some pathologies are complex and not represented in a single data source [15]. Consequently, our third hypothesis is that combining the usage of prescribed drugs and clinical text altogether may improve code control.

In this pilot study, we present and evaluate the "Tolbiac-Control" tool in its prototype phase. The evaluation is achieved for each of the control features proposed by the tool: the control based on drugs prescribed in EHR and the control based on unstructured text from medical reports associated to patients' stays. We also performed an exploratory evaluation using the combination of both the features.

Methods

Implementation

The "Tolbiac-Control" tool takes as input the drug codes, free text from medical reports, and ICD-10 codes selected by physicians or clinical coders. With this input, the tool proposes two checking features, one based on the drug prescription structured data, and the other on free text reports (Figure 1). A colored button is automatically generated for every single code for both the controls under verification feature to indicate if the code is justified (green), unjustified (red) or should be verified (orange). The lack of a button for the drug verification means that there is no drug indication for a specific diagnosis. The tool uses the VIDAL database and the ICD dictionaries for this verification (Figure 2).

For drug verification, the UCD identifiers (*Drug Common Unit of Dispensing*) of the drugs prescribed during the stay are used to extract drug indication codes from the VIDAL database. Free-text verification is achieved using a REST web service proposed by the text mining engine "VIDAL" [16]. The service takes the free text of stays' report encoded in UTF8 as input. The text-mining engine uses the multi-terminology approach F-MTI to propose ICD-10 codes based on the input text.

Figure 1- Tolbiac-Control Interface in a Patient's SDS Integrated in Web100T® Encoding Software

The codes extracted from drug and free-text verification methods are compared separately to the codes assigned by health professionals to associate a "Justified" marker for matching codes, "Unjustified" for mismatch, and "To verify" if the tool is not able to decide based on the available data. In addition to these three markers, a fourth marker "No UCD available" is assigned when a coded diagnosis has no corresponding specific drug indication (e.g. physical traumas, congenital conditions).

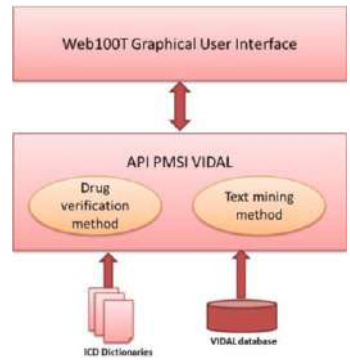

Figure 2- Structure of Tolbiac-Control Tool

Evaluation

We randomly selected a corpus of 32 inpatient stays in 17 medical specialties at the Public and University Hospital of Saint-Etienne during June 2017. The stays had previously been coded as usual by clinical coders or physicians, and utilized 282 ICD-10 codes. The average length of stay was 8 days and an average of 10 drugs were administered per stay.

To evaluate the "Tolbiac-Control" tool, we compared its automated code-control verifications with those of two assessors who had access to the same documents. The first was a trained clinical coder (IT) who looked for elements of EHRs justifying ICD-10 codes in evaluated SDSs. The second was a medical resident (RC) who ensured that the markers "no UCD available" were appropriately reported and assisted the clinical coder in case of uncertain situations. Verifications achieved by the assessors were considered as the "ground truth".

Quantitative approach

The results were tabulated in a confusion matrix, with the output from the "Tolbiac-Control" in rows and the cross-checking by the assessors in columns. As the verified codes were not uniformly distributed over the markers, we had to look at the effectiveness of the classifier one class at a time before averaging the entries. We estimated the one-versus-all confusion matrix for each marker, as seen in figure 3 (3 entries for text control with 3 markers, and four entries for UCD control with 4 markers).

		Clinical coder verification, ground truth	
		Justified	**Other markers**
TOLBIAC code control markers	**Justified**	True Positives	False Positives
	Other markers	False Negatives	True Negatives

Figure 3- Example of a One-versus-all Confusion Matrix for the "Justified" Marker

For example, for the text-control element, we used 3 binary classification tasks where one class (e.g. "Justified") was considered as the positive class while the combination of all the other classes ("Unjustified" and "To verify") constituted the negative class.

The main statistical measure used to evaluate the "Tolbiac-Control" tool was the micro-averaged F-measure, which is the harmonic mean of precision and recall. It is a synthetic indicator that allows to perceive the overall preciseness and robustness of the classifier [9]. Its formula is described in equation (1):

$$f - measure_{micro} = 2\frac{precision*recall}{precision+recall} \quad (1)$$

Micro-averages were preferred over macro-averages. As some marker modalities such as "To verify" or "No UCD" were vastly underrepresented, we decided to take into account the respective weight of each modality for a better representation of the results.

Precision, also called positive predictive value, can be defined as the fraction of relevant marker modalities among the retrieved markers. For an information retrieval system, high precision means that it retrieves more relevant markers than irrelevant ones. The formula is described in equation (2) with "k" being the modality marker, TP for true positives and FP for false positives:

$$Precision_{micro} = \frac{\sum_k TP_k}{\sum_k TP_k + \sum_k FP_k} \quad (2)$$

Recall, also called true positive rate or sensitivity, is the fraction of relevant marker modalities that have been retrieved over the total amount of relevant markers. An information retrieval system with high recall means that it retrieves most of the relevant results. The formula is provided in equation (3) with FN for false negatives:

$$Recall_{micro} = \frac{\sum_k TP_k}{\sum_k TP_k + \sum_k FN_k} \quad (3)$$

Accuracy is the proportion of true results, both positives and negatives, among the total number of examined cases. It measures how well a classification system correctly identifies or excludes a situation. With TN for true negatives, the formula for quantifying accuracy in a one-versus-all confusion matrix is described in equation (4):

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (4)$$

Classification error is the percentage of incorrect markers to the total number of markers analyzed, and was calculated along with its 95% confidence interval.

To analyze the combined effect of the two code-control features (drug-based and text-based), we built the decision tree described in figure 4 on the basis of the following rules:

1. The code is labeled "Justified": if the information that justifies the code is compliant with a drug identifier and/or present in free text.
2. The code is labeled "Unjustified": if both sources (drug-based and text-based) state that the information is "Unjustified" or "To verify".

We dichotomized the decisional outcome with only "Justified" and "Unjustified" markers, assuming that the clinical coder has to check back the validity of the code if it is "Unjustified" or "To verify".

The decision result was assessed against the clinical coder's ground truth using the previously described metrix. Statistical analyses were performed with the R language and environment for statistical computing and graphics version 3.4.0 (with the packages "ggplot2" version 2.2.1, "lattice" version 0.20-35 and "caret" version 6.0-8.0).

Qualitative approach

A clinical coder (IT) from the Medical Information Unit of the University Hospital Center of Saint-Etienne who is familiar with several coding tools evaluated the graphical interface. The evaluation included reviewing usability of the module according to different criteria: ease of use, clarity and precision of the display. Text analysis was assessed by evaluating elements of free text from EHRs that led to the chosen marker of a code. The consistency of the detected terms and their use by the TOLBIAC text control tool were also verified.

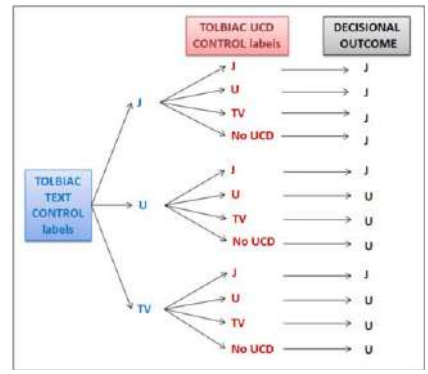

Figure 4- Decision Tree for Combined UCD and Free-text control. J= "Justified" Marker, U= "Unjustified" Marker, TV= "To verify" Marker, "No UCD"= No UCD

Results

Quantitative approach

Among 282 codes, the UCD code control feature of the "Tolbiac-Control" tool found 112 (39.7%) codes "Justified", 97 (34.4%) "Unjustified", 15 (5.3%) "To verify", and 58 (20.6%) codes with no UCD indication. Table 1 shows the results of the evaluation of the UCD code control.

Table 1 - VIDAL UCD Control Feature (n= 282)

Accuracy, n (%)	212 (0.752)
Classification Error, % [95% CI]	0.248 [0.198-0.298]
Recall	0.752
Precision	0.762
F-measure	0.757

Among the same 282 codes, the text code control feature of the VIDAL module found 66 (23.4%) codes "Justified", 172 (61.0%) "Unjustified", and 44 (15.6%) codes "To verify". Table 2 presents the results of the evaluation of the text code control.

Table 2 - VIDAL Text Control Feature (n= 282)

Accuracy, n (%)	146 (0.517)
Classification Error, % [95% CI]	0.483 [0.425-0.541]
Recall	0.519
Precision	0.673
F-measure	0.555

Among 282 codes, the text and UCD combined code control found 146 (51.8%) codes "Justified" and 136 (48.2%) "Unjustified". Table 3 shows the results of the texts and UCD code control combined.

Table 3 - VIDAL UCD and Text Control Features Combined (n= 282)

Accuracy, n (%)	187 (0.663)
Classification Error, % [95% CI]	0.337 [0.282-0.392]
Recall	0.626
Precision	0.869
F-measure	0.728

Qualitative approach

The clinical coder was able to easily use the interface of "Tolbiac-Control" within the encoding software without any prior training. She found that the information was displayed clearly with immediate visual access to the code-control markers for each ICD-10 code. In addition, the interface regrouped all drug prescriptions as well as medical text retrieved from EHRs, which can be conveniently accessed directly from the coding tool. No issues were reported with the graphical interface, and the usability of the tool was described as convenient.

Some issues related to text analysis were observed. The "Tolbiac-Control" tool did not identify negation. For example, "there is no appendicitis" written in a medical report is acknowledged as the ICD-10 code K35 "acute appendicitis". In addition, the tool did not always detect pathology localization. For example, for "fractured radius" in an operative report, the tool identified "fractured" but not "radius".

Furthermore, the tool might wrongly identify word fragments as individual terms. For example, in "transverse", the word fragment "ver" (which means "worm" in English) was recognized within the word, and a coded Helminthiase (an intestinal parasitic worm) was wrongly acknowledged as "Justified" in a patient's discharge summary.

In some cases, the same code could be assigned several times for the same stay, which often happens with handcrafted coding. In our sample, this was the case with seven codes. We noticed that for some the codes, the tool generated a different marker for each occurrence from the same EHR.

Discussion

We recognize that code control using drug prescriptions is promising for this pilot study of the "Tolbiac-Control" tool. The drug control feature retrieved 75% of the relevant information and classified them with the right marker 76% of the time. This result is consistent with other studies showing the reliability of this approach for code prediction or as proxy of disease prevalence [13]. We showed in this study that using drug prescriptions is also useful for code control. In addition, this data source is reliable as drug prescriptions are systematically encoded in EHRs with no missing values.

The text control feature has less conclusive results. It retrieved about half of the relevant markers, and classified them correctly in 67% of the cases. As with numerous other studies [17,18], using free-text unstructured data to improve coding is challenging. In particular, hospitalization reports and clinician notes, called "notational text", often contain abbreviations, lack of punctuation, poor grammatical structures [17] as well as spelling mistakes and missing values [7]. These inherent obstacles added to the limitation of the text analysis feature of the "Tolbiac-Control" tool and might explain its lower performance. However, the F-measures are within the boundaries of the results found in the literature for natural language processing and machine learning methods currently applied to ICD-9 or ICD-10 coding in different languages (about 0.50-0.90) [17,18,20].

With drugs and text features combined, we observed a 10% improvement in precision as compared to the use of each data source separately. However, the recall and F-measure decreased when using the combined features compared to the use of the drug-based feature alone. Thus, contrary to other studies, classification was not improved by combining two data sources, mostly due to the deficiencies of the text-control feature.

As clinical coding is growing in complexity and importance in hospitals, there is an ever increasing need for automated computerized assistance to increase quality, productivity, and efficiency [8]. The "Tolbiac-Control" tool gathers drug identifiers, medical reports files, and code control markers in a simple window in already existing encoding software. Coupled with its easy-to-use visual interface, the tool might be a suitable choice for the current needs of code control professionals.

Although "Tolbiac-Control" was tested in one hospital, we were able to achieve a broad range evaluation with different medical specialties and large sets of codes unlike previous studies that focused on limited types of specific diagnosis [5]. Knowing that some pathologies are easier to code using an automated tool than others [14], our study showed the overall effectiveness of the proposed control tool and the potential of its use in a wide variety of clinical situations. While our study focused on a specific national institution, accurate coding in Diagnosis Related Groups-based information systems is an international concern. Our work, especially related to the use of drug identifiers for code-control, could be used in other institutions and countries.

The main limitation of the current tool certainly is the low performance of the text-based control feature. This feature needs to better identify the link between medical entities in clinical free text. Another practical enhancement is to automate free-text extraction from available reports instead of the required manual upload of unstructured data in the current version. The VIDAL is currently working on improving its API to overcome these limitations. The generalization of the tool with other encoding software is also in progress.

Another limitation of the study is the limited sample size. As the "Tolbiac-Control" tool is still a prototype, the analysis was made on 282 ICD-10 codes, imported from 32 patient stays. Further experiments on a larger sample size are required to confirm the research hypothesis with higher statistical power. Also, we relied on a single medical coder to evaluate the interface and usability of the tool. Considering the subjective nature of qualitative approaches, it is an important limitation to bear in mind at this stage of the project.

Once an improved version of the "Tolbiac-Control" is available, we aim to perform further analysis with larger samples to verify if code control is more efficient with some specialties than with others, as revealed by previous studies regarding code prediction [14]. Furthermore, it would be interesting to assess the utility of using the results of biological tests and implantable medical devices as features for code control along with drug-based and text-based features. The integration of biological tests analysis is already scheduled for the next version of "Tolbiac-Control", and it is expected to improve the quality of the tool.

Conclusions

This work shows that information contained in drug prescriptions in EHRs can successfully be used to develop an automated and systematized ICD-10 code-control tool. The "Tolbiac-Control" tool could become an asset for clinical coders, and might improve code precision, which would enhance the quality of SDSs data.

The proposed tool evaluation was done in a prototype phase. Although this tool is not yet entirely functional for a general use, it is currently undergoing improvements based on the observed issues, mainly about the usage of unstructured data.

Abstract

As pressures on healthcare systems increase, due to an ageing population, hospital admission avoidance interventions have been emphasised. These interventions can be difficult to objectively evaluate due to non-randomised roll-out, requiring observational methods with carefully selected control groups. This study aims to identify the defining characteristics of elderly patients receiving admission avoidance home visits. We conducted a record linkage study using routinely collected data to compare characteristics and outcomes of the general elderly population and a subset of high-risk patients. Intervention patients were found to have significantly different demographics and admission rates compared to the general population, having four times higher admission rates at baseline. However, they share similarities with high-risk patients, particularly in that after a period of increased admissions, both groups experienced a reduction in the following year. Identifying defining characteristics of the target intervention population can guide the careful selection of a control group for evaluation.

Home Care Services; Evaluation Research; Informatics

Introduction

Within the last decade, there has been an increased emphasis on reducing unscheduled admissions to the hospital, reflecting the need to better manage the increased pressures faced by health systems due to the changing demographic profile of European populations [1]. This has led to the development of alternative care models, focusing on proactive rather than reactive care. Alternative care models include proactive chronic condition management, intermediate care, community-based care interventions and using telemedicine, telehealth and digital health solutions. Young states that intermediate care "is conceived as a range of service models aimed at 'care closer to home' by expansion and development of community health and social services," including hospital-at-home services [2]. There are currently two main hospital-at-home models: *early discharge models* where hospital-level care is provided at home following early discharge from hospital, and *admission avoidance models*, in which multidisciplinary rapid response teams provide treatment, assessment and support for a short period of time [1,2].

The latter models are concerned with unscheduled care, differentiating them from models such as health promotion visits or preventive home visits, which involve assessments primarily aimed at preventing new problems for patients living independently in the community [3].

Hospital-at-home models are complex interventions with several interconnecting parts. Their evaluation can prove challenging, often because the interventions have not been fully defined or developed at roll-out [4]. Furthermore, they are also prone to evolve over time, particularly within a community setting [5]. Randomisation may be unfeasible or inappropriate, with the decision to evaluate often being made in hindsight [5].

Observational studies can provide an alternative evaluation approach where randomisation is unfeasible; however, these evaluation studies require a robust design and methodology. Often evaluations may use the general non-intervention population as a control group and use standardisation of likely confounders, such as age and sex. However, the inclusion criteria of hospital avoidance interventions will usually be linked to the outcomes being measured for evaluation [5].

Hence, trends in hospital activity for the intervention population and the characteristics that define them will differ greatly from that of a general elderly population. This is particularly the case in people over 65 years of age with a history of emergency admissions (also known as high-risk patients), whose levels of hospital use have been shown to naturally reduce over time compared to the general elderly population, due to both mortality and regression to the mean [6]. In their study, Roland et al warranted further research for defining high-risk patient groups for interventions to reduce admissions [6]. To evaluate the effect of a healthcare intervention on hospital admissions, a carefully selected control group is essential and, in the case of interventions for high-risk patients over 65 years of age, must match the intervention group according to their defining characteristics [6].

The aim of this paper is to identify the defining characteristics of patients receiving admission avoidance home visits, for which the decision to evaluate was made in retrospect and referral criteria has been loosely defined (as is common in complex community interventions).

This was done by comparing patients receiving the intervention to two groups: the general population over 65 years of age and a subset of high-risk patients in the area of interest. We first compared patient characteristics in these three groups, obtained through healthcare record linkage of several datasets, some of which have never previously been used in research.

We then made a temporal comparison of hospital admission rates for the three groups. Identifying characteristics that define the intervention patients will enable the appropriate selection of a comparison group for evaluation, which is essential for a robust evaluation in this setting, and may prove useful to others evaluating similar services and interventions.

Background

'Closer to Home' programme

In 2011, the Scottish Government rolled out the Reshaping Care for Older People (RCOP) strategy with the vision that older people should live full and positive lives at home or in a homely setting [7]. The allocated RCOP strategy Change Fund resulted in a number of local initiatives across Scotland aiming towards promoting home and community care. The Forth Valley (FV) health-board includes a central area of Scotland with an estimated population of 57,317 residents aged 65 and over in 2017 [8]. 'Closer to Home' is a coordinated programme, set up in December 2015, to achieve the RCOP aims within the NHS Forth Valley health board. We have developed an evaluation framework for the 'Closer to Home' programme which has been previously described elsewhere [9].

'Enhanced Community Teams'

The 'Closer to Home' programme includes Enhanced Community Teams (ECTs) which are multidisciplinary rapid response teams of nurses, physiotherapists, occupational therapists, social care staff and, more recently, specialty-trained general practitioners (GPs) (from January 2017). In this paper, ECT is the intervention of interest.

The ECTs provide both early discharge and admission avoidance home visits, with a focus on the latter. Care is provided 24 hours a day, 7 days a week. Referrals are made mainly through the patient's GP, however, referrals can also be made by discharge coordinators, emergency department clinicians, the ambulance service, and other community services. The criteria for referral are loosely defined but state that the patient must require immediate hospital-level support that can be provided at home and must be registered with a FV GP. Treated patients are predominantly elderly, frail patients over 65 with long-term conditions. Acutely ill elderly patients who did not receive the intervention received usual care which includes hospital admission along with community services such as district nursing which may support a patient's recovery but are not aimed at admission avoidance.

Implementation of the ECTs was staggered in the first year in a non-randomised fashion, area by area through contact with GP practices and other potential referral sources to promote the teams. ECTs use NHS FV's Multidisciplinary Information System (MiDIS) for the recording of community activity data, including assessments and contacts with patients such as home visits.

Methods

Constructing a study cohort

A cohort of patients was defined to include any patient within FV who was aged 65 years or older at any point between a year before the time the ECTs were started (December 2014) and the time at which the cohort was constructed (April 2018). To construct this cohort, two main datasets were combined: one consisting of a list of the patients registered with a GP in FV, and one consisting of records of deaths registered in FV by the National Records of Scotland. These datasets are used nationally and go through several quality checks. These were combined to create a cohort of 65,189 patients.

Record linkage methods and ethics

Linkage of patient datasets was conducted using deterministic record linkage in SQL Server (Management Studio 2008), which allows full control of the linkage process. Pre-merge data cleansing to resolve typographical differences was required to enable linking keys to be matched [10]. In Scotland, the Community Health Index (CHI) is used to uniquely identify patients, often used in linking patient datasets [11]. Using the CHI and postcode as linking keys, demographic, hospital activity and prescribing records were linked to the compiled cohort described previously.

Research ethics approval was not required for this study as it is for the purpose of a service evaluation based on retrospective analysis of routinely collected data. Caldicott approval within FV and the Information Services Division (ISD) for Scotland was obtained for the request for prescribing data. All analysis was conducted on pseudonymised data.

Identification of intervention patients

Intervention patients were identified from datasets collected from MiDIS. These datasets are not used for national reporting and prior to this study, have never been used in research, hence they required multiple linkages and data cleansing in consultation with the ECTs to understand each variable held. The main linked MiDIS datasets were a master patient dataset and datasets of episodes of care, individual contacts, and episode registrations. This linkage combined with consultation with ECT members enabled the compilation of a validated dataset containing episode details, including number of contacts, type of patient and discharge reason, from which intervention patients were identifed (1,294 records).

Main linked datasets

The linked datasets which are locally held include emergency department attendance data, community health visit data and a master patient dataset for any patient having received inpatient, day case or outpatient care in FV. The linked datasets which are nationally held include outpatient attendance data (Scottish Morbidity Record for outpatients (SMR00)) and hospital inpatient stay data (Scottish Morbidity Record for general acute inpatients and day cases (SMR01)) [11]. Data for prescribed items dispensed in the community were obtained for each patient in the cohort through a request for data through ISD.

Demographic data linkage

The linked demographic variables include age, gender, GP practice, locality, deprivation, ethnicity, marital status, smoking status, living alone, and a care home stay indicator. These primary variables were compiled in an analytical dataset and additional secondary variables were created from these. Due to missing values for the primary variable living alone, marital status was incorporated to create a secondary variable indicating if the patient has been recorded as living alone or not at any point, with not married being classified as living alone and married/cohabiting as not living alone. This reduced the missing values by 34.0%. An additional variable was created combining nursing home residency and having had a stay in a nursing home, to characterise patients who have had a nursing home stay (used as a proxy for functional status with high dependency needs).

Hospital inpatient stay records were linked to obtain a Charlson comorbidity score for each patient, which identifies and gives weights to each of 17 comorbidities according to the relative risk of one-year mortality [12].

The comorbidities were identified from International Classification of Diseases codes (10^{th} revision) (ICD-10) recorded as hospital diagnoses [12] (923,465 records). An algorithm within R package "icd" was then used to generate the Charlson scores for each patient using ICD-10 codes recorded in the past 5 years [13].

Hospital activity and prescribing data linkage

Hospital activity data linked for each patient included the number of emergency and elective inpatient hospitalisations (from SMR01), two years before and after the implementation of ECT (2014-17) (100,071 records). Prescribing data linked for each patient included prescription items dispensed and reimbursed by the NHS in the community (94.6% were prescribed by a GP). This data included the number of items prescribed and the number of British National Formulary (BNF) classes (paragraphs) covered by the prescribed items (1,510,018 records). The average monthly number of BNF classes was selected for use as it reduces variation and reduces the effect of exaggerated polypharmacy for patients who have multiple medications in the same BNF paragraph (class), hence it was deemed a better proxy measure of multimorbidity [14].

Population selected for analysis

The activity data collection period was set as data registered between the 1st January 2016 to the 1st May 2018. From the 65,189 patients in the compiled cohort, exclusion criteria were applied before analysis. Patients receiving the intervention outside of the collection period were excluded (including only episodes occuring between 1st January 2016 to the 1st May 2017, to allow for outcomes to be collected for one year post-intervention). Patients were included if they were over 65 years of age at the start of the collection period, registered with a GP in FV, had not transferred to another health board and had not died at the start of the collection period. Intervention patients who were receiving palliative care or whose episodes of care were recorded as failed (due to inappropriate referrals or inability to contact the patient) were excluded. This left a total of 566 intervention patients and 60,901 patients from the general population.

Data analysis

A subset of high-risk patients, defined as those who had two or more emergency admissions in the same year that the intervention patients experienced a deterioration in health (2016), were grouped separately from the general population in order to compare their characteristics and identify their hospital activity patterns, following Roland et al's comparison [6]. To test for differences between demographic variables in the intervention group, the high-risk group and the remaining population, Welch two sample *t*-tests were used for continuous variables, chi-squared tests were used for categorical variables and Fisher's exact test was used for categorical variables with small observed values in contingency tables.

A temporal comparison was made in admission rates per person between the intervention patients, high-risk patients and the general population (all patients) using the denominator equal to the number alive in each year of the comparison, which Roland et al were unable to do because of a lack of data on deaths. They have previously shown, however, that including mortality has little impact on overall conclusions [6]. Data analysis was conducted in R Studio (R v3.4.1).

Results

Demographic differences

The ECT intervention group and the general population were shown to be very different in the analysis of demographic data. The differences between the general population and both the intervention and high-risk groups were all found to be significant at the 0.1% level for each of the variables shown in *Table 1*. Differences in ethnicity and the average number of prescriptions were not found to be significant between the intervention and high-risk group, while other variables showed significant differences (at the 5% level for care home stay and deprivation, and at the 0.1% level for all other variables).

The proportion of patients aged 75 and older was found to be higher in the intervention group than the other groups (83.5% of intervention patients, 62.4% of high-risk patients, and 38.9% of general population) (*Figure 1*). A greater proportion of intervention patients were female and had a care home stay compared to the other groups. Another major difference between the groups was that 38.5% of the general population were found to have no hospital inpatient stay records in the past 5 years compared to 4.6% in the intervention group, hence had no Charlson score. Greater proportions of high-risk' patients had moderate to severe Charlson comorbidity scores than intervention patients, and only 3.2% of the general population had severe scores. The intervention group had an average of 6.6 monthly prescriptions (BNF classes) with 21.7% of the group having more than ten prescriptions, while the general population had 4.2 on average with only 3.0% having more than ten prescriptions.

Other differences were observed in ethnicity, deprivation, smoking status, and having lived alone, however one of the greatest differences is in the missing values for these variables. There are much lower numbers of missing values for the intervention and high-risk groups, indicating that they have greater interaction with the healthcare systems where these data are recorded. Excluding patients with missing values, 41.5% of intervention patients were recorded as having lived alone, compared to 19.6% of high-risk patients and 12.5% of the general population. Among ethnicity, smoking status and deprivation, when excluding patients with missing values, such great differences were not observed between all three groups.

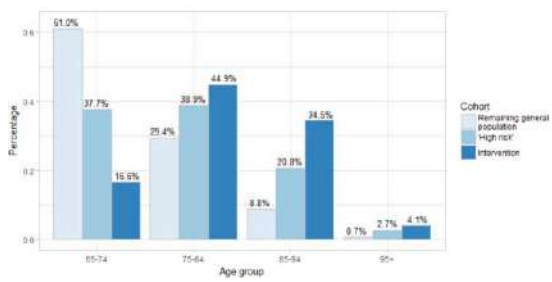

Figure 1– Age distribution of population aged 65 and over

Hospital activity differences between groups

All reported admission rates account for deaths as previously described. In the year prior to ECT implementation, the general population (all patients) had an admission rate of 0.17 emergency admissions, while the other groups had much higher admissions (0.68 in the intervention group and 0.81 in the high-risk group).

This means that prior to implementation of ECT the admission rate in the intervention group was 4.0 times higher than that of the general population but 0.8 times lower than that of the high-risk sub-group.

In the year following the implementation of the intervention, the rate of admission in the full general population increased by 27.5%, while both the high-risk and intervention groups had multiple times higher rates (see *Table 2* and *Figure 2*), reflecting a deterioration in health for intervention patients at the time of being admitted to the ECTs.

Two years on from the implementation of ECT (2017), the admission rate for intervention and high-risk patients decreased drastically from the previous year (by 32.0% and 60.8%

respectively), while in the general population a small increase was observed (5.0%).

Table 1 – Characteristics of the intervention group, high-risk and remaining population over 65 years in Forth Valley

Variable	ECT group (n=566) n (%)	High-risk group (n=2,467) n (%)	Remaining population (n=58,434) n (%)

Discussion

The results of the study confirm that the characteristics of intervention patients differ significantly from those of the general elderly population in NHS Forth Valley. In comparison, the intervention group are older, a greater proportion were female, have higher comorbidity scores, higher prescriptions, four times higher hospital admission rates in the year prior to the intervention and a much higher proportion of intervention patients have lived alone or had a care home stay (proxy for high functional dependency). These characteristics, among others, have previously been identified as being associated with the need for home care [15]. A previous systematic review has also identified older age and Charlson score as risk factors for hospitalisations in community-dwelling elderly patients [16].

Compared to the high-risk patients, intervention patients were older, a greater proportion were female, a higher proportion had lived alone or had a care home stay but had a lower proportion of moderate to severe comorbidity scores. The difference that was most evident in variables with missing values was that the intervention and high-risk groups have much lower frequencies of missing values, indicating greater interaction with the healthcare system.

Overall, ntervention patients had lower admission rates than the high-risk group, however, their patterns of hospital activity were similar. In the year after ECT implementation (2016), both intervention and high-risk patients experienced multiple times higher emergency admission rates, followed by a dramatic reduction (rates including mortality) in the subsequent year; in the general population, a small decrease was observed. These results have been observed in a similar comparison of high-risk patients as previously noted [6]. Similarly, Roland et al. found a drastic reduction in emergency admissions per person in the high-risk patient group (a 75.0% decrease compared to 69.5% decrease in our study when including mortality) [6].

Hence, as Roland et al also found, admissions after the intervention should be compared with a control group satisfying the same criteria that define the intervention group (which can be approximated by their characteristics) [6].

Limitations

Due to the retrospective nature of this study, it is subject to a number of limitations. Retrospective analysis is always limited by the fact that the data may not have been collected for research purposes. For example, input options in MiDIS for discharge reasons can differ according to the user profile, hence this required standardisation through the consultation process with ECT. This study is also limited by data availability. The intervention patients are often described as frail and elderly. Frailty has been difficult to define but has been characterised by physical function, gait speed and cognition [17], which are not routinely collected for the full FV population. Hence, these variables may define the intervention patients, but we have been unable to investigate them. The Charlson comorbidity measure used in this study also has its limitations due to its reliance on ICD-10 codes which in FV are held in hospital records. Hence comorbidity information was not available for patients with no hospital records. In addition, the deterministic data linkage by personal identifiers used in this study is limited in that identifiers are subject to recording errors, hence links can be missed [11]. For prescribing data, ISD was able to confirm that in NHS FV personal identifiers were captured correctly for 96.3% of prescribed items between 2015-17.

Conclusions

In conclusion, this analysis has enabled the identification of defining characteristics of the intervention patients compared to both high-risk patients and the general elderly population, and has highlighted the differences in hospital activity between them. The intervention group are significantly different to the general elderly population, but share some similarities with high-risk patients. The identified characteristics will aid the selection of an appropriate control group, in the evaluatation of the effectiveness of the intervention, which currently ongoing.

The results also highlighted that high-risk patients experience reduced hospital admissions after a period of increased admissions, which has also been shown in other studies. Overall, the analysis indicates that a carefully selected control group is required for the evaluation of the intervention.

Abstract

This paper presents a pioneering and practical experience in the development and implementation of a clinical decision support system (CDSS) based on natural language processing (NLP) and artificial intelligence (AI) techniques. Our CDSS notifies primary care physicians in real time about recommendations regarding the healthcare process. This is, to the best of our knowledge, the first real-time CDSS implemented in the Spanish National Health System. We achieved adherence rate improvements in eight out of 18 practices. Moreover, the provider's feedback was very positive, describing the solution as fast, useful, and unintrusive. Our CDSS reduced clinical variability and revealed the usefulness of NLP and AI techniques for the evaluation and improvement of health care.

Keywords:

Critical pathways; decision support systems, clinical; natural language processing

Introduction

A clinical pathway is a structured multidisciplinary care plan tool built on evidence-based medicine, which states essential goals and key elements in the management of a well-defined group of patients [1]. Although there is no single and widely accepted definition of a clinical pathway, the aim of these tools is to improve quality of care, reduce risks, improve patient satisfaction, and promote efficient use of healthcare resources [2].

The benefits of implementing clinical pathways in routine clinical practice are well documented and include increased hospital efficiency [3; 4], decreased length of hospital stay [5], and lowered costs [6]. In order to obtain these benefits, implementations of clinical pathways should comply with a minimum set of basic principles [7]; the lack of implementation of these principles by healthcare professionals negatively impacts patient care [8-10].

Computerized approaches are considered promising tools for increasing adherence to clinical pathways [11]. For example, adherence to clinical guidelines for acute decompensated heart failure [12] and glucose regulation in an intensive care unit [13] were successfully improved using computerized pathways in user-friendly formats. Other studies implemented a CDSS that sends computerized clinical reminders to professionals [14; 15]. Yet another evaluated adherence to acute bacterial rhinosinusitis guidelines in three phases: 1) inform each participant about personal adherence rate, 2) perform an educational intervention about clinical pathways, and 3) introduce a CDSS [16]. However, a study that investigated whether the redesign of a CDSS leads to a more appropriate prescription of antimicrobials was not able to detect the expected improvement [17]. Obviously, many factors, such as poor usability or lack of follow-up, can have a negative impact on the desired outcome. A successful CDSS implementation needs to detect and eliminate these factors.

Clinical pathway adherence can be measured from the patients' perspective (adherence to treatments) [18-20] or the professionals' perspective (adherence to clinical pathways) [21-24]. However, what these studies have in common is that the adherence was evaluated using questionnaires, a process which requires significant amounts of time and resources. A thoughtful implementation of healthcare information technology (HIT) can greatly improve the efficiency of clinical pathways [25].

Inspired by the discussion about the use of clinical practice guidelines in primary care in Spain [26], we present a real-time CDSS to improve adherence rates to clinical pathways. The real-time CDSS proposed was developed by Accenture[1] and integrates Savana's[2] EHRead Technology which automatically extracts valuable medical information from unstructured free text information contained in electronic health records (EHRs). Our results demonstrate improvements in clinical adherence due to the use of the real-time CDSS. The real-time CDSS reduces the variability of healthcare and establishes a method for measuring adherence. It also helps to understand the difficulties in implementing clinical pathways and how to overcome them.

Methods

Savana System

Savana [27] was founded in 2014 with the goal of using AI to improve the quality of health services. Savana has developed EHRead, a powerful technology that applies the latest NLP, machine learning and deep learning techniques to analyze the unstructured free text information written in millions of EHRs and automatically extract highly valuable medical information. The pipeline consists of different modules performing tasks such as sentence segmentation, tokenization, text normalization, acronym disambiguation, negation detection, and a multi-dimensional ranking scheme. To execute these tasks, the pipeline combines linguistic knowledge, statistical evidence and state-of-the-art continuous vector representations of words and documents in the clinical domain learned via shallow neural networks. The Savana Manager software is the first medical linguistic engine that applies this concept to the Spanish language, converting the

[1] https://www.accenture.com/
[2] https://www.savanamed.com/

valuable information contained in EHR free text into an interpretable and user-friendly format. A general overview of the CDSS interface is shown in Figure 1.

Figure 1 – Savana Manager Interface

Implementation and Evaluation Process

The real-time CDSS was implemented and evaluated in the primary care area of Castilla-La Mancha's Health Service (SESCAM)[3], serving a region in Spain with more than two million inhabitants. 24 healthcare centers with a total of 86 physicians (general practitioners and pediatricians) participated in this pioneering experience.

The CDSS proposed consists of a real-time tool developed by Accenture which continuously processes the notes taken by professionals during their medical consultation. This technology integrates Savana's EHRead Technology whose objective is to extract and identify the most important clinical information from EHRs. The CDSS warns professionals when the case meets a criteria for a recommendation.

In order to assess the ability of this CDSS to improve clinical pathway adherence, a well-defined methodology was carried out. This methodology consists of the following steps:

1. Translation of clinical pathways into rules by the Savana medical team. These rules define which clinical terms are relevant for each pathway and how they relate to each other.
2. With these rules and the information automatically extracted by Savana Manager, the professionals' adherence to the different clinical pathways is evaluated. To achieve this goal, a dataset of more than 2.5 million documents from emergency and primary care services, archived during a time period ranging from 01/01/2016 to 31/05/2017, was analyzed. We refer to this as the first measurement period.

   From this evaluation, those clinical pathways that had less than 90% compliance were translated into recommendations by our medical team. These recommendations were implemented in a real-time alert system in an attempt to improve adherence rates. Table 1 shows the 18 recommendations defined and their degree of compliance in clinical practice in the first measurement period.
3. Once the proposed CDSS was implemented, an additional adherence evaluation was performed. In this second measurement period, a dataset of more than 345,000 clinical documents, archived during a time period ranging from 27/11/2017 to 31/12/2017, was analyzed in order to assess the benefits of our CDSS.

To quantify the changes in adherence rates to clinical pathways between the first and second measurement periods, we compared the number of documents in which the patients' cases followed the correct clinical pathway before implementation with the number correct after the implementation.

We tested whether the difference between the two proportions (adherence rates before and after implementation) was significant using a two-proportion z-test, which is calculated as:

$$Z = \frac{P_2 - P_1}{\sqrt{\bar{P} \cdot (1 - \bar{P}) \cdot \left(\frac{1}{n_1} + \frac{1}{n_2}\right)}}$$

where $\bar{P}$ is the proportion of successes over all of our samples combined:

$$\bar{P} = \frac{n_1 \cdot P_1 + n_2 \cdot P_2}{n_1 + n_2}$$

P_1 and P_2 are the adherence rates of samples 1 (before implementation) and 2 (after implementation); n_1 and n_2 are the respective sample sizes.

The null hypothesis H_0 is that there is no improvement in the adherence after implementation:

$$H_0: P_2 <= P_1$$
$$H_1: P_2 > P_1$$

The p-value is equal to 1−Z, assuming the standard normal cumulative distribution. H_0 is rejected if the p-value is lower than 0.05.

Results

Adherence rates to clinical pathways improved in eight out of 18 recommendations when our real-time CDSS was employed, achieving 100% compliance in some cases (Table 2, Figure 2). The improvement was statistically significant in three cases ($p < 0.05$). Considering that this was a preliminary study, these results are promising. The greatest increase in degree of improvement (76%) occurred in recommendation #10 ("SSRIs should not be prescribed to patients with chronic lower back pain unless they are also suffering from depression"). This means that before implementation of our CDSS, professionals often prescribed the use of SSRIs in cases for which it was not clinically recommended; afterwards, the number of these cases decreased dramatically.

The remaining ten recommendations could not be evaluated due to one of two main reasons: 1) these were recommendations for referrals to another service or requests for evidence which require a long period of time to check whether the referral or follow-up in question was requested, or 2) the volume of data was insufficient to make an analysis and draw conclusions. Although one month is a short period of time to evaluate the impact of a CDSS, subsequent evaluations will enrich these results. Importantly, this preliminary assessment made it possible to come up with an initial measure of the CDSS's effectiveness.

[3] See http://sescam.castillalamancha.es/

Table 1– Set of recommendations implemented and their degree of compliance before CDSS implementation

	Recommendation	Degree of compliance (%)
Osteoarthritis of the Hip and Knee	1. Glucosamine and chondroitin sulphate should not be routinely given to patients with hip or knee OA, as there are no relevant clinical benefits	84
	2. The routine use of NSAIDs is not recommended in patients with OA of the hip or knee who have coexisting cardiovascular pathologies such as heart failure or ACS	88
Anxiety	3. Patients with post-traumatic stress disorder should be referred to the mental health team	83
	4. Patients with anxiety should be prescribed pregabalin rather than benzodiazepines due to improved tolerance, fewer side effects, and the possibility of long-term use	9
Headache	5. Fluoxetine doses should not be divided due to a half-life of up to 72h	86
	6. All patients over 50 with headache and temporal arthritis should be referred to a specialist	83
	7. Patients suffering from cluster headaches should be advised to avoid alcohol	2
Dyspepsia	8. Patients over 55 years old with dyspepsia should be referred for a gastroscopy	61
Lower Back Pain	9. Physiotherapy is the treatment of choice for acute lower back pain	42
	10. SSRIs should not be prescribed to patients with chronic lower back pain unless they are also suffering from depression	24
Heart Failure (HF)	11. The use of antialdosterones is recommended for all patients with NYHA stage II-IV HF and a LVEF of < 35%	75
	12. The follow-up for HF patients should include a chest X-ray at least once a year in order to evaluate the cardiothoracic ratio	71
Urinary Tract Infection (UTI)	13. Patients with prostatitis should have a urine sample sent for microscopy and culture	44
	14. Fosfomycin and co-amoxiclav should be avoided when treating UTIs in young men (14-45 years old)	82
	15. Pregnant women diagnosed with a UTI should have a urine sample sent for microscopy and culture	50
Heart Murmur	16. Patients with a heart murmur and a personal or family history of cardiac illness should be referred to a specialist	72
Osteoporosis	17. Calcium should not be routinely given to patients under 70 years old who are diagnosed with osteoporosis	68
	18. Pharmacological treatment (biphosphonates) should not be routinely given to patients over 80 years diagnosed with osteoporosis	84

OA=Osteoarthrosis; NSAID=Non-Steroid Anti-Inflammatory Drug; ACS=Acute Coronary Syndrome; SSRI=Selective Serotonin Reuptake Inhibiting Drug; NYHA=New York Heart Association; LVEF=Left Ventricular Ejection Fraction.

In order to evaluate how our CDSS affected physicians, we monitored the number of alerts/recommendations on a daily basis. In the second measurement period, a total of 534 recommendations were provided, which translated into 15.7 alerts per day. This means that, on average, each of the 86 physicians that participated in this experiment received 1.8 alerts per day. This shows that our real-time CDSS is non-intrusive and is therefore highly unlikely to produce alert fatigue.

Table 2 – Comparison of the degree of compliance with recommendations before and after the implementation of the CDSS

Rec #	Compliance % (Before)	Compliance % (After)	Improvement %
4	9	16	7 (p=0.145)
10	24	100	76* (p=0.01)
12	71	87	16* (p=0.01)
13	44	71	27 (p=0.053)
14	82	100	18 (p=0.108)
15	50	100	50* (p=0.013)
17	68	73	5 (p=0.314)
18	84	100	16 (p=0.096)

Statistically significant improvements (*t*-test, $p < 0.05$) are starred (*).
The term "before" refers to the first measurement period (01/01/2016 - 31/05/2017).
The term "after" refers to the second measurement period (27/11/2017 - 31/12/2017).
The period between 01/06/2017 and 26/11/2017 was used to extract the data provided by the healthcare centers and to train and configure the CDSS.

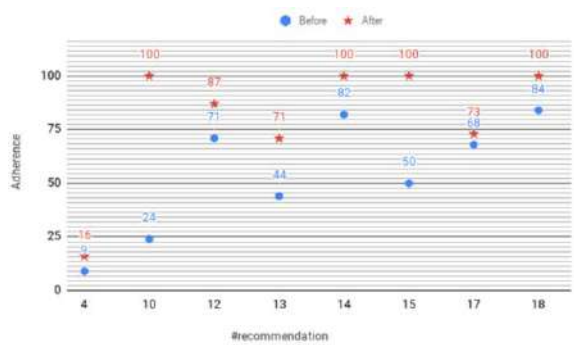

Figure 2 – Graphical representation of the improvement in adherence rates between the two measurement periods

Finally, a presidential session with our team and the participating physicians was carried out to directly obtain feedback from the users. The general response was very positive; the solution was described as fast, very useful and unintrusive, since it did not affect the dynamics of their work.

Discussion

The adoption of AI and big data in healthcare is increasing since numerous studies have shown that these techniques help to solve a variety of problems for patients, healthcare centers, and the healthcare industry in general. These new applications

are more than just technological and analytical tools; they transform healthcare ecosystems by interactively connecting medical data, personalized medicine, and AI with clinical staff to improve patient care.

A new example of this ongoing transformation is the real-time CDSS presented in this paper. In fact, the results are very promising, although their preliminary nature means they must be interpreted with caution. An improvement in adherence rates was achieved in eight of the 18 established recommendations, this improvement being statistically significant in three of them. An important feature of our CDSS is its ability to adapt recommendations over time, thereby achieving proactive management of best practices.

One limitation of our project – indeed, any project working with EHRs – is EHR incompleteness. This can sometimes result in an insufficient amount of information for meaningful processing and measurement.

Our CDSS is currently in operation, and a more complete analysis will be provided in the near future. We will extend the project to the rest of the Healthcare Centers of Castilla-La Mancha and add recommendations for nurses. We will also add the capability to deactivate recommendations that achieve a degree of compliance of greater than 90%. Finally, we will enable professionals to add their own recommendations and follow their evolution in their adherence to clinical pathways.

Conclusions

This paper presents the first real-time CDSS based on NLP and AI techniques implemented in the Spanish National Health System. It allows measurement and improvement of the adherence of primary care physicians to the clinical pathways established by the Health Service. This CDSS helps professionals in their decision-making process and reduces the variability of clinical practice in the healthcare centers, having a very positive effect on overall quality of care.

Abstract

This paper explores the impact of an electronic medication management system (EMMS) on users in an intensive care unit using the Unified Theory and Use of Technology constructs. It also explores the impact of having a consistent EMMS hospital wide, as it is the first Australian hospital to implement the same EMMS hospital wide. The research model was evaluated using survey data from 100 nurses, doctors and pharmacists both within the ICU and externally, to assess the usability and acceptability of the system. Results showed that performance expectancy, effort expectancy, social influence and facilitating condition all correlate with overall user satisfaction. Overall, teams external to the ICU are in strong favor of its implementation whist user acceptance from within the ICU itself is poor.

Keywords:

Electronic Health Records, Intensive Care Units, Medication Systems

Introduction

The Intensive Care unit (ICU) is a complex environment that requires healthcare providers to balance competing tasks and responsibilities in their care for patients. Caring for complex patients requires communication and coordination of multiple healthcare team members and changes in work routines could affect their ability to provide safe, high-quality care. The ICU team consists of a range of staff including nurses, doctors and pharmacists. It involves coordinated patient management by internal intensivists and doctors, as well as external teams to the ICU such as surgeons, infectious diseases specialists, anesthetists, geriatricians and several others. All members require ease of communication, visibility of the medication charts and changes to medication regimens.

The patient record remains the principal instrument for ensuring continuity of care. The ICU is a data-rich environment and there is discordance between the mass of data and the capacity of paper-based documentation, which can lead to major defects in information processing [1]. There are many barriers to efficiency using a paper-based documentation system. Traditionally, on admission to, and discharge from, the ICU, a patient's paper-chart would be ceased, and a new chart would be written up by the ICU doctor. Transcription errors on admission to and from the ICU, as well as illegible handwriting [2,3], time spent on manual data entry [4], low quality of, and frequency of, medication errors [5] are just a few of the challenges that can result in inefficient workflow, medication errors and poor productivity [6]. Electronic medication management systems (EMMS) aim to improve work processes for all end users by presenting medication information that can be easily accessed during a patient's hospital stay.

However, EMMS that are unable to support clinical work-flow efficacy [7] can generate unintentional consequences that can harm patients [8]. Unintended consequences resulting in errors have been variously labeled 'system-related', 'technology-induced,' and 'computer-related' [9,10]. A frequent subgroup is system-related errors arising from the use and functionality of an EMMS which would be unlikely or unable to occur in paper-based medication ordering systems [10]. These are typically caused by the inability of the EMMS to match healthcare work patterns and settings, creating user acceptance barriers. It is therefore necessary to evaluate the claim that an EMMS will enhance the quality of patient care and increase documentation efficiency.

A Case Study

In Australia, the NSW state government eHealth Strategy for 2016–2026 is to develop a digitally-enabled and integrated health system delivering patient-centered health experiences and quality health outcomes [11]. A key component of this strategy is the roll-out of a commercial electronic medication management system referred to locally as- 'eMeds' (Millennium®, current code level 2015.01.25, Cerner Corporation, Kansas City, MO) to replace paper medication charts in general wards in 178 NSW state hospitals. eMeds is a physician order entry system. Prescribing using eMeds involves selecting items from a drop-down menu of predefined order sentences triggered on drug selection. When selecting a medication, it includes order sentences which contain details of the drug, strength, dose, and form, with the option to edit details in the order sentence. All orders are subjected to series of checks including drug allergies and interactions. EMeds is incorporated into the patient electronic medical record which contains all other aspects of patient care such as pathology, imagining etc.

In NSW hospitals, eMeds is being rolled out to general wards, whilst the ICUs are generally implementing an alternate commercial EMMS, known as the electronic record of intensive care or 'eRIC' (MetaVision ICU, iMDsoft®, Tel Aviv, Israel) or are remaining paper-based. This is creating hybrid or dual prescribing system environments. Studies have shown stakeholders believe this practice to have negative impacts on communication, with some users reporting missing patient information [12]. To ensure crucial patient information was not missed, it was proposed that eMeds EMMS be implemented in a 13-bed general ICU of a tertiary hospital in NSW, Australia, to align with the general wards which include surgical, acute and aged care wards. Prior to its implementation the remainder of the 750-bed general hospital had already been using this system for 3 years while the ICU during that time was out of scope, using the paper National Inpatient Medication Chart (NIMC) [13]. Across NSW there are 81 public hospital ICUs [14], 15[11] of these have implemented the alternative eRIC system [15] in the ICU and eMeds throughout the remainder of

their hospital. This is one of the first hospitals in Australia to implement the eMeds EMMS system in the ICU, creating a consistent prescribing system across its facility. However, unlike the remainder of the hospital that is using computerized physician order entry (CPOE) and electronic clinical documentation across all aspects of care, the ICU are only using CPOE for medications and diagnostics tests. Additionally, some orders, such as continuous infusions and blood products, remained on a large-format daily ICU flowsheet at the request of the ICU medical staff.

This provided a unique opportunity to evaluate the impact of this EMMS in the ICU setting, as well as the effect of having the same system facility wide. Despite the coordinated care required amongst teams within and external to the ICU, most studies have focused primarily on a single group rather than the impact across all teams involved in the medication management process. Our research goal is to apply an existing technology acceptance model to evaluate the usability and acceptability of nurses, doctors and pharmacists within the hospital.

Methods

We chose a formative evaluation for this study. This paper focused on the results of a survey that was part of a larger case-based mixed-methods approach, as recent review of evaluation of health care IT recommends methodological pluralism, including both qualitative and quantitative methods [16].

Participants

The evaluators focused on the three main clinical groups (nurses, doctors and pharmacists) in both the ICU and the remainder of the general hospital. Usability evaluation studies need to provide a comprehensive image of usability by focusing on more than one single end-user perspective[17]. The survey link was sent to 70 ICU nurses, 15 ICU doctors and 2 ICU pharmacists. The possible maximum of non-ICU staff was difficult to obtain due to the nature of rotating shifts between nurses and doctors for a single patient's hospital admission. Staff were anonymous and of mixed age, gender, experience and seniority. These groups were chosen as they are central to the operation of the EMMS. Staff external to the ICU were included to determine the hospital wide effect of transitioning from a hybrid prescribing hospital environment of paper-based and an EMMS to a homogenous one. It also allowed for the comparison of the impact on teams involved in the direct use of the system with those on the receiving end of patients transitioning in and out of the ICU. Staff completing the survey were expected to have worked in the ICU and other relevant wards three months prior and during the implementation of eMeds in the ICU.

Survey Design

The survey was developed by the project team and based on the Unified Theory on Acceptance and Use of Technology (UTAUT) to evaluate the acceptance and use of eMeds. The UTAUT [18], was chosen as the framework for the development of the survey as it has been widely applied and empirically tested to investigate factors that could influence individuals to adopt and use technology in various environments [19].

UTAUT integrates eight theories on technology adoption and provides a comprehensive view of the factors related to users' adoption behavior [20]. The main UTAUT constructs are [18]:

- Performance expectancy (PE): ''The degree to which an individual believes that using the system will help him or her attain gains in job performance.''
- Effort expectancy (EE): "The degree of ease associated with the use of the system."
- Facilitating conditions (FC): ''the degree to which an individual believes that an organizational and technical infrastructure exists to support use of the system."
- Social influence (SI): "the degree to which an individual perceives that important others believe he or she should use the new system."

According to the UTAUT, PE, EE and SI are theorized to influence behavioral intention to use a technology, while behavioral intention and FC determine technology use [20]. The UTAUT does not specify the methods or parameters to be used, as it is a case by case basis. In this paper we report on the survey outcomes designed against the UTUAT framework.

The survey used a 7-point Likert scale (1 – strongly disagree; 7 – strongly agree). It consisted of 69 questions capturing a range of user feedback questions, however this paper focuses only on data from 33 questions relevant to the UTAUT framework. The survey also had two open ended questions that asked, '*why do you think eMeds in the ICU is or isn't sustainable?*' and *'general comments regarding eMeds'*. Surveys sent to the ICU and non-ICU staff were identical, except for the questions under the effort expectancy construct. Effort expectancy between ICU and non-ICU were not compared directly as the questions under this construct were not in both surveys. Due to the nature of the questions, i.e. *'I find it easy to get the eMEDs system to do what I want it to do,'* which is not specific to the impact of eMeds in the ICU on non-ICU wards, they were removed from the non-ICU staff survey. The surveys were pilot tested on four participants. The phrasing and selection of question involved a methodological trade-off between following established standards and adapting these to adequately fit the case at hand.

Survey Distribution

Three months after the implementation of eMeds in the ICU, the survey was distributed to ICU nurses, doctors and pharmacists. One hundred ICU staff were emailed an online survey link or given physical copies. The second survey was sent to the nurses, doctors and pharmacists on the wards that ICU patients are commonly transferred to. Two reminder emails were sent out within 1-month after the initial email. Non-ICU staff completing this survey were expected to have been involved in the care of a patient transferred from the ICU. Participants were provided a coffee voucher upon survey completion.

Analysis

Data from the survey was collected and stored using a Research Electronic Data Capture Tool (REDCap), 8.3.1 (Vanderbilt University, Nashville). It was subsequently analyzed for descriptive, correlation and Cronbach's alpha statistics using the Statistical Package for the Social Sciences 22 (SPSS) (IBM Corp. Released 2016, Version 24.0. Armonk, NY: IBM Corp).

Results

A total of 100 surveys were received. Table 1 gives the response rates for the individual wards and professions.

Overall User Satisfaction

In technology-acceptance research, factors that may influence people's acceptance of systems are typically correlated with (self-reported) usage of systems. Because use of this system was mandatory, the items included in this study were correlated with user's overall assessment of the system. We first examined

the user's general satisfaction with the EMMS by examining responses to the survey item, 'overall, I am satisfied with the way of working with eMeds.' Overall, ICU doctors were dissatisfied, (mean = 1.78, SD =1.72) particularly in comparison to non-ICU doctors (mean = 5.71, SD =1.14). Similarly, ICU pharmacists were less satisfied than non-ICU pharmacists (mean = 3.00, SD=1.41 and mean = 5.22, SD= 1.20 respectively) and ICU nurses less than non-ICU nurses (mean = 4.83, SD= 1.37 and 5.72, SD = 1.49 respectively. Of the 6 groups, non-ICU nurses were found to be the most satisfied. When examining the correlation between overall satisfaction and the UTAUT constructs, overall satisfaction was significantly correlated with all four constructs ($p < 0.01$). Overall satisfaction was positively moderately correlated with performance expectancy (r= 0.499), facilitating condition (r= 0.455) and effort expectancy (ICU, r= 0.361, non-ICU, r=0.463). It was most strongly correlated with social influence (r= 0.510). Suggesting that all 4 constructs play a role in the overall assessment of the system.

Table 1 – Survey Response Rates

	ICU staff	Non-ICU Staff
Profession	Respondents N, (response rate %)	Respondents * (N)
Doctors		
Senior doctors	5, (45%)	3
Junior doctors	4, (80%)	5
Unspecified	0, (0%)	7
Nurses	29, (41%)	36
Pharmacists	2, (100%)	9
Total:	40, (45%)	60

**Unable to obtain response rate % as the possible maximum of non-ICU staff was difficult to obtain due to the nature of rotating shifts between nurses and doctors for a single patient's hospital admission.*

The UTAUT Constructs Reliability

Cronbach's alpha was calculated for each of the constructs and found to be, for performance expectancy, $\alpha = 0.94$ consisting of 3 items, for facilitating condition, $\alpha = 0.93$ consisting of 3 items and for social influence, $\alpha = 0.89$ which consisted of 2 items. For the ICU staff survey, the effort expectancy construct consisted of 3 items with $\alpha = 0.91$. All the alpha values are above the recommended threshold of 0.7 [21] . The reliability of all 4 constructs are deemed satisfactory.

Performance Expectancy (PE)

The non-ICUs overall assessment of performance was satisfaction with the system compared to ICU staff, with a mean difference of -1.70 ($p<0.001$) (Table 2). Statistically significant mean differences between groups within the ICU were unable to be calculated due to the small sample size of individual professions. Of the three groups examined within the ICU, doctors perceived the system as supporting them the least in attaining gains in their job performance (Table 3). However, perception of performance expectancy varied across the three ICU groups. ICU nurses and pharmacists were slightly in favor of the EMMS increasing their job performance, with an average mean response rate of more than 4. Interestingly, all professional groups external to the ICU staff, rated performance expectancy higher than ICU groups and all groups perceived the EMMS useful to some degree in achieving a greater job performance. The highest mean response was from the nurses (mean = 5.81, SD= 1.58), followed closely by the doctors (mean = 5.60, SD= 1.60) and pharmacists (mean = 5.44, SD= 1.13).

Effort Expectancy (EE)

Overall, the ICU staff were neutral in their view on the degree of ease associated with the system (mean = 4.28, SD= 1.71). However, when broken down to the individual groups, table 3 shows that ICU doctors did not believe there was a degree of ease associated with use of the system (mean= 2.0, SD= 1.58). Similarly, to the trend in PE, ICU nurses and pharmacists (table 3) believed there to be a degree of ease associated with the system, with an average mean response rate of more than 4. Externally to the ICU, mean response to the question, 'the features of the eMEDs system meet the needs of my work tasks,' was favourable and had a mean value of 5.33 (1.69) and were positively supported by all three groups (Table 3).

Facilitating Condition (FC)

Unlike the other two constructs, there was consistency in the perception of FC across all groups both within and external to the ICU. Table 2 shows that both the ICU and non-ICU wards believed the hospital provided them with the required implementation and ongoing support for the system. All sub-groups both internal and external to the ICU had a mean average of more than 4. When comparing which group felt they had the most support, of all the groups Table 3 shows that both the ICU and non-ICU pharmacists agreed that the support was greatest. Nursing groups internal and external to the ICU rankings were the next followed closely by externals doctors and internal ICU doctors. The impact of hospital support is consistent across all three groups internal and external to the ICU.

Table 2 – Comparison of the Overall Mean for Each Construct of ICU and Non-ICU staff

	ICU Mean (sd), N	Non-ICU Mean (sd) N= 60 (All items)	Mean difference
PE	4.00 (1.66) N= 40	5.70 (1.51)	-1.70 (t_{78}= 5.08 , P <0.01)
EE	4.28 (1.71) N= 40	5.0 (1.65)	*
FC	5.16 (1.39) N= 37	5.73 (1.54)	-0.56 (t_{81} =1.69, P <0.10)
SI	4.35 (1.73) N= 37	5.73 (1.59)	-1.374 (t_{73} = 3.93, P < 0.01)

** Unable to compare means of EE as questions under the constructs differed between ICU and non-ICU ward. The N varies between each construct for ICU staff due to removal of non-response data. Missing data occurred throughout the survey, but did not exceed 10%.*

Social Influence (SI)

Both the ICU and non-ICU collectively perceived their seniors and colleagues as being in favor of the implementation of the EMMS in the ICU. The mean average of both the ICU and non-ICU group was more than 4 (Table 2). This suggests that department heads have provided managerial support throughout the implementation of the system. However, when broken down to individual group levels, Table 3 shows that the greatest managerial support was held by nurses within and externally to the ICU. Alternatively, whilst overall the ICU believed their seniors to be in support of the system, Table 3 shows that the ICU doctors alone had a contrasting view (mean = 2.44, SD= 1.67)

Across all 4 constructs, Table 2 shows that for the ICU staff, there were overall lower means and higher variations across all 4 constructs. However, non-ICU staff have higher means and lower variability across constructs, indicating there is greater consistency in the support for EMMS from external groups to the ICU, whilst there is less support and greater variability in opinion amongst groups within the ICU.

Table 3 – Comparison of mean responses of individual groups for ICU and non-ICU staff under the four UTAUT constructs.

	ICU STAFF mean (sd)			NON-ICU STAFF mean (sd)		
	Nurses	Doctors N=9	Pharmacists N= 2	Nurses N= 36	Doctors N= 15	Pharmacists N= 9
PE	4.59 (1.30) N=29	2.0 (1.32)	4.50 (0.7)	5.81 (1.58)	5.60 (1.60)	5.44 (1.13)
EE**	4.89 (1.08) N= 29	2.0 (1.58)	5.5 (0.71)	5.69 (1.53)	4.80 (1.90)	4.78 (1.79)
FC	5.31 (1.32) N= 26	4.44 (1.42)	6.50 (0.71)	5.75 (1.80)	5.50 (0.97)	5.89 (1.51)
SI	5.00 (1.30) N=26	2.44 (1.67)	4.50 (0.71)	5.94 (1.56)	5.90 (1.85)	4.78 (1.09)

** *Effort expectancy between ICU groups and NON-ICU groups not directly comparable due to the difference in which asked between each group due to the nature of the questions and their relevance to the ward. The N varies between each construct for ICU nurses due to the removal of non-response data. Missing data occurred throughout the survey, however this did not exceed 10%*

Comments Section

The survey responses to the open-end questions for ICU staff were more commonly negatively swayed. The most common responses given by ICU-doctors focused on the increased time it takes to prescribe medication and the negative impact it has on workflow. Similarly, all three ICU groups commented that whilst eMeds is appropriate for a general ward, this benefit did not extend to the fast-paced ICU environment. Across the three groups within the ICU, nurses had the most positive comments, outlining that it improved workflow and transition of care. Groups external to the ICU also commented that having eMeds within the ICU positively impacted on their own workflow and the transition of care of patients.

Discussion

The first major objective of the introduction of eMeds in the ICU was to optimize workflow and workload. Usability is an intrinsic characteristic of a technology that impacts end-users' interaction with the technology; it leads to higher work efficiency in case of good usability, but in case of poor usability it may also slow down user performance, decrease users' satisfaction, and expose users to use errors [17].

This study reveals a clear difference in overall satisfaction between ICU and non-ICU staff. The ICU believed the eMeds EMMS not to be an appropriate fit for their setting. Task Technology Fit (TTF) focuses on the degree to which systems characteristics match user task needs [12]. Studies have suggested that in the absence of customized interfaces and tailored workflow support, the fit between the information entry and review needs of doctors, and the features offered by EMMS is likely to differ [22]. Previous studies show that the system and its users should be studied together and considered, as both are vital for implementation in order for the process of system adoption to be met with less resistance [23]. As revealed in the comments, the ICU staff believe the EMMS is appropriate for general wards but does not align with the ICU workflow. Suggesting that an EMMS fit for the general hospital, does not necessarily transcend to the ICU setting.

An EMMS should facilitate the aggregation and synthesis of multiple data elements for physicians [22]. Traditional paper-charts involves the extraction of data from various sources, over several pages in the file, and then collate the information. An EMR system, in contrast, makes such data easy to retrieve and, review [22]. As the ICU has continued to adopt the hybrid method of CPOE and paper documentation as well as selected medications, this scattered display of information and various sources continues. Thereby potentially impacting the perception of the benefits of an EMMS by the ICU staff.

General wards external to the ICU are at the stage of optimization of the system to align with workflow, thereby have overcome initial user resistance issues that may arise during the shakedown phase and may have facilitated use. Whereas, currently within the ICU there are continued efforts being employed to make improvements. It is currently unknown if these issues would remain after 6-12 months of using the system in ICU. Evidence suggests that it may take up to 2 years post-implementation until the unit returns to complete stability [24]. The greater satisfaction of ICU pharmacists in comparison to doctors could also explain this as ICU pharmacists were using this same system in the rest of the hospital prior to its implementation in the ICU, whilst the other two groups (doctors and nurses) were not.

Similar to previous studies, these results confirm that groups of professionals react differently when EMMS are implemented, making it difficult to implement a one-EMMS-fits-all across professions and departments. The finding that within the ICU, doctors were least satisfied compared to the nurses and pharmacists in areas related to PE and EE could be attributed to doctors being responsible for the entering of information into the EMMS. Physicians are at the frontline and perform not only knowledge work, such as making decisions and crafting treatment regimen based on patient information, but also data entry. Accordingly, the influence of EMRs on different groups may differ if the technology provides disparate impacts with respect to information review versus information entry [22]. Previous studies found that a low level of usability plays an important role in unsatisfactory implementation of an EMMS which led to disruptions of workflows and accordingly negative impacts on job performance [25,26]. A literature review that looked at the impact of a critical care information system on time spent documenting by nurses and physicians revealed 25% of studies found an increase in time spent charting, 42% found no difference, and 33% of studies reported a decrease [25]. The benefits in effort are more likely reaped by those downstream who are not required to manually enter data.

The study also showed that users put a stronger emphasis on PE and EE, rather than facilitating condition or social influence . This could be attributed to its use being mandatory and had hospital management support. Resulting in the necessary resources and support for its successful implementation. This study also aimed to determine the effect of having the same EMMS hospital-wide rather than the popular dual prescribing environments. It was assumed that introduction of eMeds would favor workflow, workload and be beneficial hospital-wide. The results showed that whilst the general wards perceived having eMeds in the ICU as supporting them in their productivity, and effort, the ICU itself did not believe the system supported their work environment. This is the first Australian study that investigates the user perception from all three key groups within the ICU involved in the use of eMeds. It is also the first to explore the benefits of having the same EMMS facility wide. A key outcome is that external ICU users believe it to create a safer workflow and eases the patient transition throughout the hospital. The significant difference in impact on performance expectancy and effort expectancy between groups within and externally to the ICU could be attributed to the benefits associated with the electronic

environment such as remote access and transparency of the patient medical journey.

Limitations

This paper focuses on the quantitative results of a survey which was part of a larger case-based mixed-methods approach. Concepts and results found from the survey will be triangulated with qualitative and medication safety data. Furthermore, the 45% response rate from ICU staff, the difference in sample size between ICU and non-ICU staff and within sub-groups calls for caution when interpreting the results.

Conclusions

This study aimed to determine the acceptance and usability of an EMMS system in the ICU setting, and the impact of having a homogenous EMMS hospital wide. It found that performance expectancy, effort expectancy, facilitating condition and social influence were all moderately correlated with user's overall satisfaction with the EMMS. It demonstrated that implementation entailed changes in work processes which were challenging for all ICU groups. Whilst user acceptance from within the ICU itself is poor, teams external to the ICU were in strong favor of its implementation. As this is part of a mixed-method case study design which includes triangulation of data, further investigations are being made into the core user-resistance concepts through qualitative evaluation methods.

Abstract

Developmental delay is a deviation from the regular development of normative milestones during childhood. Early stimulation is a standardized and straightforward technique to support children with developmental delays (aged 0-3 years) in reaching basic motor skills, which are essential for the execution of everyday activities, such as playing, feeding and locomotion. In doing so, early stimulation reduces the chances of permanent motor impairment, thus allowing the child to live a more functional life. However, outcomes of this treatment depend heavily on the involvement of the family, who are required to continue the early stimulation activities at home on a daily basis. To empower and educate families to administer standardized early stimulation programs at home, we developed an electronic early stimulation program, which provides personalized guidance to parents to administer early stimulation; together with evidence-based clinical decision support to therapists in tailoring ESP to observed needs.

Keywords:

Child development, Mobile health, Patient education

Introduction

Child developmental delay is defined as a deviation from the regular development of normative milestones in the areas of cognitive, language, social, emotional and motor functioning [1]. Globally, developmental delays are the most common chronic condition during early childhood. With the recent outbreak of the Zika virus, which causes microcephaly in newborns limiting their development, delays in child development have become a major public health concern in Brazil [2]. Treatment for developmental delays in children between 0-3 years comprises a standardized exercise program—known as the Early Stimulation Program (ESP) [3] that targets cognitive and motor function development. ESP therapy is administered by a therapist, who determines the extent of the developmental delay, with respect to age-specific normative milestones. From an intervention standpoint, the therapist formulates a child-specific ESP to help the child attain normative, age-specific developmental milestones.

Given the large number of Brazilian children with developmental delays, there exists an *imminent and urgent need* to provide them with comprehensive ESP support. However, ESP therapy is only available at a limited number of specialized therapeutic centers, meaning that many of the affected children do not get appropriate treatment in a timely manner. To address the threat to the child development, in 2016 the Brazilian government launched the Brazilian Early Stimulation Guidelines [3] which aim to guide health professionals about how to provide standardized treatments for developmental delays. Additionally, the government, international organizations, health care centers and communities to uphold children's right to treatment for developmental delays through parent education programs about how to perform ESP to their child. However, these initiatives were not enough to reach the high volume of children who experience developmental delays. Therefore, there is an imminent need to implement a feasible, scalable and accessible solution to addresses the lack of healthcare resources for children with developmental delays, especially in large country like Brazil.

To overcome the issue of timely access to ESP resources, we are pursuing a *home-based ESP delivery* approach that remotely engages and trains the parents of affected children on how to administer early stimulation exercises at home. To train parents on how to perform specific early stimulation exercises, we will deliver short videos (max. 2 minutes) illustrating how to perform the early stimulation exercises through mobile phones. Video-based patient education programs have been shown to be an effective method to improve the patient's knowledge, decision-making ability and self-management efficacy [4]. Based on the video-based educational material, parents will be able to perform the early stimulation exercise at home and also record the child's treatment progress through a mobile app for follow-up consultation.

In this paper, we present our digital health based ESP therapy intervention called the BraziLian Early Stimulation System (BLESS) that is designed to provide early stimulation therapy to children in the age group 0-3 years so that they achieve the five most important age-specific motor development milestones—i.e. head control, rolling, sitting, standing and walking. To engage and educate parents to consistently and effectively pursue their child's ESP, we use the "prepared-informed-motivated" approach, proposed by the WHO Innovative Care for Chronic Conditions (ICCC) framework [5] which aims to empower the child's family to self-manage their child's chronic problems in partnership with professional healthcare providers. We use the developmental motor milestones scale proposed by World Health Organization (WHO) [6] and the International Classification of Functioning and Disabilities (ICF) [7] to assess a child's developmental delay and in turn to provide a ESP for the child. We develop a personalized ESP for the child that takes into account the parents' educational and efficacy levels to administer ESP with different levels of self-management of the child's treatment (i.e. acquisition, fluency, maintenance and

generalization) [8]. To personalize the ESP to the child's needs and parents' efficacy level, we have developed an intelligent ESP personalization model to assist therapists in designing ESP that is tailored to *the child's developmental needs* as well as the *parents' observed relevant skills*.

BLESS incorporates **(a)** a mobile health app that serves as an *accessible and personalized ESP self-management tool* for the child's family. It allows parents to receive the prescribed early stimulation videos and associated educational material and it supports them in administering the prescribed ESP in a home-based setting, as well as tracking parent's adherence to ESP; and (**b**) an *ESP therapy planning and decision support tool* to support therapists to design an evidence-based ESP. The desktop-based therapy planning tool is suitable for fast-paced clinical routines as it assists the therapist to assess the child developmental status using standardized assessment tools as per clinical guidelines; design a personalized ESP for a child based on this assessment; conduct follow-up examinations to monitor the child's developmental progress; overview compliance and progress of their patients with their ESP; and, if adjustment is needed communicate with the child's parents.

BLESS is being deployed at a reference center for Maternal and Child healthcare in the Northeast of Brazil, where there is a high incidence of developmental delays in children, due to the Zika virus—but only limited ESP therapy is available.

In this paper, we discuss BLESS in terms of its ESP personalization decision model, the formulation of the parent training content, and technical architecture and functionalities. A pilot evaluation of BLESS is currently underway and will be reported in a follow-up publication.

BLESS ESP Personalization Decision Model

To generate an ESP that will maximize the child's motor and cognitive development, our approach involves tailoring the relevant ESP based on the child's developmental needs. For that purpose, we have developed an ESP personalization model that based on an assessment of a child's impairment for normative milestones selects the appropriate early stimulation exercises. To computerize the ESP personalization decision model, we applied knowledge translation strategies [9,10] to collect knowledge from (a) ESP clinical guidelines, local protocols and standardized child development assessment tools; and (b) local experts, therapists and families whose children have followed ESP therapy. BLESS decision model is shown in Fig. 1 and is based on the criteria listed in Table 1.

For effective child development therapy, it is important to prioritize one developmental milestone at a time as it engages parents to focus on the child's most relevant need at the time, improving their skills in a step-wise way, and prevents them from being overwhelmed if the child has multiple development needs. This treatment delivery method has been shown to be effective in improving parents' skills to administer home-based therapies to their child [8,11].

In operation, considering the milestones expected for the child's age group, the therapist assesses each successive milestone and inputs the diagnosed impairment value (ICF value) into the decision model shown in Fig. 1. In line with the criteria from Table 1, the decision model proceeds as follows:

- In case of major impairment (ICF value = 3/4), select the current milestone for ESP. Else, continue processing the successive milestones until attaining a severe/complete diagnosis, or until all milestones are processed. Health experts consider tackling major impairments more important than dealing with prior milestones in the achievement pattern, even if these have mild/moderate impairment (ICF value = 1/2).
- Once all milestones are processed and no major issues were found, select the first milestone in the achievement pattern with any issues (ICF value > 0) for ESP (if any exist). Since no severe/complete impairment (ICF value >= 3) was found for any age-relevant milestone, the achievement pattern can be safely followed to improve the child's development.

Table 1 – Criteria for BLESS personalization decision model

Criteria	Especification
Age	Five age-groups, related to the average age of motor milestones achievement (0-4 months; 5-6 months; 7-9 months; 10-12 months; + 13 months).
Expected milestones for age	Five motor milestones expected for each age-group (head control, rolling, sitting, standing, walking) [6].
Impairment classification	Impairment level classification for each milestone (no impairment; mild/moderate impairment; and severe/complete impairment) [7].
Impairment severity	Achieving the milestone classified as a severe / complete impairment level is prioritized for obvious reasons—also, families tend to better engage in the child's most visible needs.
Order of milestone achievement	The milestone achievement pattern, respecting milestones which are prerequisite for subsequent milestones (e.g., head control before sitting, etc.).

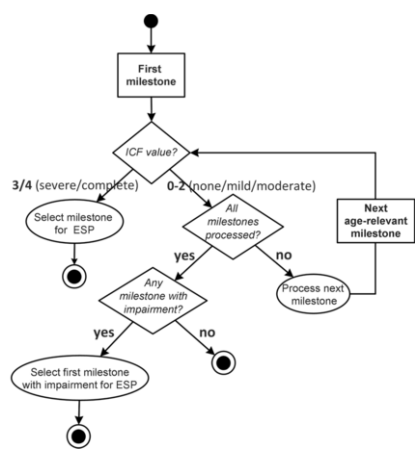

Figure 1 – BLESS personalization decision model

Once a suitable developmental milestone is selected, the personalization decision model proceeds by selecting ESA pertaining to the milestone and the child's specific impairment level. At the end, this process generates an ESP that is personalized to the child's current needs.

BLESS Patient Education Material

BLESS provides patient education content to improve the parent's knowledge and skills to effectively perform early stimulation exercises to their child at home. Our education approach is guided by chronic care frameworks [5,11] and other that stipulates strategies and content to engage and

empower individuals so that they can achieve effective self-management. We gathered and incorporated ESP-related educational content from a variety of local resources, including the Brazilian Early Stimulation Guidelines [3], official documents of the Brazilian Ministry of Health [12], as well as tacit knowledge and practical expertise of therapists.

For our approach, videos are a key medium to educate parents to perform early stimulation exercises with their child [4]. The primary educational medium are videos that illustrate how to perform a specific early stimulation exercise. We have prepared 60 early stimulation exercise videos, where each video is 90-120 seconds long and demonstrates in a step-by-step manner how to perform an exercise with the child, with a commentary of instructions narrated by a trained therapist. Additional educational content was organized in terms of 12 orientation packages, which comprise written educational material about handling their child's everyday activities, such as promoting extra stimulation during feeding, waking up, bathing, playing, posturing, communicating, etc. These orientation packages are selectively provided to parents based on their informational needs and skill levels as observed by the therapist. The videos and educational content are in Portuguese in plain language [13] at a readability level compatible with 6-8 years of educational level. All educational material was reviewed and validated by therapists and experts in ESP.

Digital Health Components of BLESS

BLESS comprises of two main components: (1) an *ESP therapy planning and decision support tool*, which allows therapists to generate evidence-based, personalized ESP; and (2) a *mobile BLESS family app*, which provides early stimulation videos to guide children's parents to perform early stimulation with their child; together with orientation packages, to better support their child during everyday activities at home.

The ESP therapy planning and decision support tool was developed using a 3-tier architecture, where the user-interface tier was programmed using ReactJS and Javascript d3 libraries; the application tier was developed using Java SpringBoot; and the database tier deploys MySQL. The mobile BLESS app was developed for Android, using Android Room for persistence and retrofit library for network communication.

ESP Therapy Planning and Decision Support Tool

The BLESS *ESP therapy planning and decision support tool* is a web-based tool to assist therapists in adminstering ESP therapy, based on clinical guidelines and local clinical protocols. The tool is designed as a shared decision making and planning environment, engaging both the therapist and the child's parents to determine the course of ESP therapy for the child. The tool provides the following functionality: (**a**) assess the child developmental status, using standard assessment tools, (**b**) design a personalized ESP for the child, in reponse to the assessed developmental deficiencies; (**c**) perform follow-up examinations, to monitor developmental progress and prescribe corresponding ESP; and (**d**) provide an overview of the therapist's patients in terms of compliance and progression with their assigned ESP.

The therapy planning workflow involves three 3 main tasks: (**i**) patient registration, (**ii**) family registration, and (**iii**) ESP consultation. Steps (**i**) and (**ii**) record demographic data about the child and the family needed for patient / family follow up and outcome analysis. Following the registration steps, the tool assists the therapist to perform the consultation in 3 steps:

Assessment Step

We computerized standard patient and family assessment tools, to (**a**) assess the child's impairment of normative development milestones; and (**b**) assess the family's performance in daily living activities, including observations on postures and positions, playing, and communication; as well as questions about feeding, playing and other activities; and (**c**) registering other impairments, needs and therapies, accomapnied by optional comments. Fig. 2 shows the screenshot of part (**a**) of the assessment step.

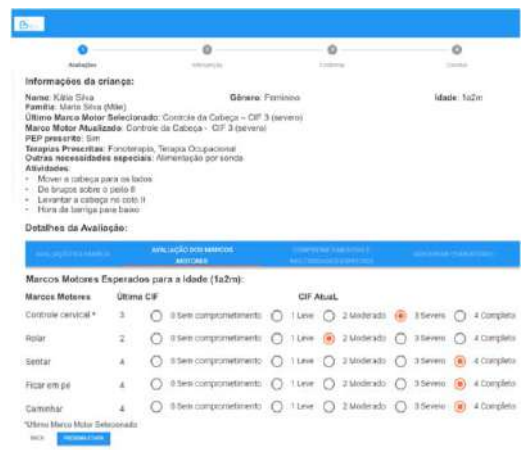

Figure 2 – Assessment step of BLESS therapist platform

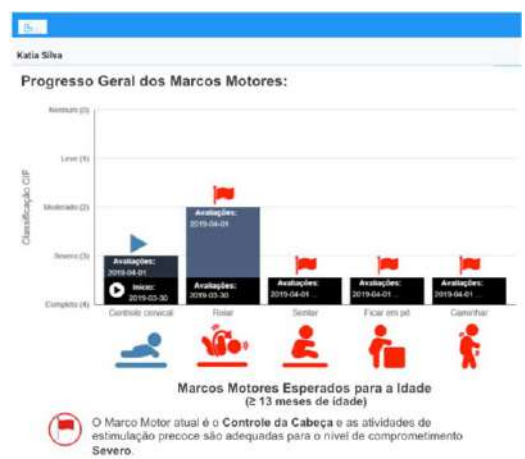

Figure 3 – Overall patient progress of BLESS therapist platform

ESP Planning Step

Our strategy for therapy planning involves designing ESP that focus only on the most critical developmental milestone to avoid putting a cognitive overload on parents and hence compromise their ability to comply with the ESP therapy schedule [14]. An ESP spans 8 weeks, and comprises 4 different early stimulation exercises that should be performed at least 3 times a week for 2 weeks.

The ESP therapy planning tool operationalizes the ESP personalization decision model (Fig. 1), and based on the assessment results supports the therapist and child's parents to jointly design an ESP that is tailored to the child's development needs. To educate the child's parents on how to perform activities of daily living the therapist further selects appropriate ESP orientation packages.

Confirmation Step

At the end of the consultation, the tool generates a report summarizing the child's and family information, current developmental stage of the child and the prescribed ESP withorientation packages. This confirmation step concludes the in-clinic consultation process. After the prescribed ESP is activated and the constituent early stimulation exercise videos with the educational material are delivered to the BLESS mobile app on the parents' mobile phone. The patient's profile page summarizes their progress in the form of an overall progress chart detailing the achieved milestones, and indicates the extent of family engagement by tracking the ESA execution via the BLESS mobile app (Fig. 3).

BLESS Family Mobile App

The BLESS mobile app is designed to guide parents to administering the prescribed early stimulation activities to their child. It offers the following features:

Guidance for ESP Exercises

In line with the prescribed ESP, the BLESS app's home screen indicates the stimulation activity that should currently be performed (Fig. 4a). After selecting an exercise, parents are shown the educational video together with associated info (Fig. 4b). Realizing that consistent internet connection may be an issue in some areas, therefore the mobile app downloads the ESP-relevant videos once after which they can be viewed as many times as needed regardless of the Internet connection. As new ESP are assigned, the stored videos are automatically deleted from the mobile phone (to save storage space). Synchronization with the server occurs in an opportunistic way, i.e., whenever Internet connectivity is available.

Monitoring of ESP Completion

The BLESS mobile app allows parents to monitor their progress in completing the ESP, as shown in Fig. 4c. This progress is informed by the completion of exercises as indicated by the parents (Fig. 4b). Further, the recorded progress is communicated to the ESP therapy planning and support tool, and used to update patients' status.

ESP Orientation Packages

The BLESS mobile app provides orientation packages on daily living activities for parents to effectively perform the ESP. The orientation packages are structured into separate pages that are suitable for the form factor of a smartphone. The mobile app supports navigation between pages and bookmarking them for repeated use (Fig. 4d).

BLESS in Action

During operation BLESS runs in concert with the therapist, whereby in a shared decision making environment the family and health professional tailor an ESP towards the child's development needs. To support the parents perform the ESP relevant educational material is also delivered to the parents.

We demonstrate the working of BLESS using a case-study of a 13-months-old child who has multiple levels of impairment for 3 milestones—i.e., severe impairment for head control, moderate impairment for rolling and complete impairment for sitting, standing and walking. Moreover, the family demonstrates not knowing how to stimulate the child at feeding, bathing and playing time. Based on the therapist's assessment, the decision logic model (Fig. 1) will create a personalized ESP by (a) selecting a suitable milestone to be targeted, based on the decision criteria (Table 1), and (b) selecting a group of ESA based on the impairment level. In this case, BLESS will select an ESP focused on head control due to its higher impairment level (severe) and its precedence in the milestone achievement pattern—note that it will not be possible for the child to achieve *rolling* or *sitting* without proper head control. Further, based on the therapist's observations of their DLA needs, orientation packages on feeding, bathing and playing issues can be selected and deleivered to the child's parent.

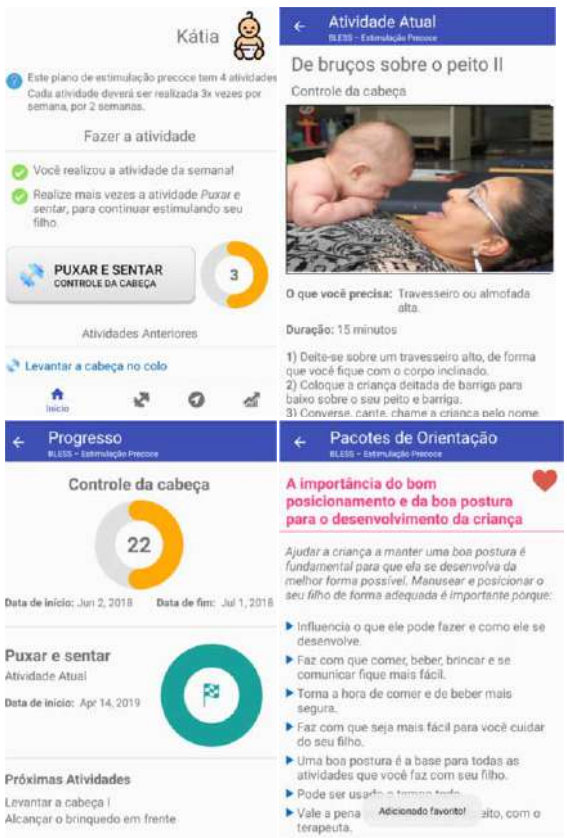

Figure 4 –BLESS mobile app screenshots: Guidance for ESP exercises (4a); ESA video screen (4b); Overview of ESP progress (4c); and orientation packages (4d)

As a follow-up, once the head control milestone has improved and the family demands addressed, a subsequent milestone is selected and new orientation packages can be chosen.

BLESS Implementation and Evaluation

BLESS is to be deployed at a reference centre for Maternal and Child healthcare in the Northeast of Brazil where we are gearing for a 6 month pilot study, involving 30-35 patients with their families and 4 therapists, to assess the (a) usability

of the BLESS system components; (b) impact on child development, parent knowledge and therapist practice routine; and (c) impact on service delivery costs. The pilot involves three stages as follows [15]: (i) Engaging and training the therapists to uptake BLESS. The thereapists will have one month to familiarize themselves with BLESS, where they will run case studies to build familiarity and confidence in the decision model operationalized by BLESS; (ii) Enrolling patients and their families into the pilot study, which includes installing BLESS on their mobile phones and training them to use it; (iii) Collecting study data over a 4-month period to evaluate BLESS. Both the therapist and family components of BLESS will track information about usage and compliance.

Discussion

We presented a Digital Healthapproach to translate knowledge on the achievement of normative motor milestones and early stimulation guidelines into a point-of-care ESP platform for therapists and patients' families. The key contribution of our solution is the integration of two recognized assessment instruments (i.e., gross motor milestones and ICF classification) to generate evidence-based ESP the educational content. An additional innovative aspect of BLESS is the personalization of the ESP based on standard child development assessment tools—the child development systems suggest relevant developmental activities but they are not tailored towards the child's developmental needs [3,12,16].

From a clinical standpoint, the computerization of knowledge on child development assessment and early stimulation enables the therapists to make better decisions regarding therapeutic planning and in turn offer quality health education for parents. The use of the mobile app allows us to reach a larger population of children with developmental delays which currently do not receive timely ESP. From the parents' perspective, the contribution of our work is a self-management program which engages and empowers parents to manage the child's condition in home-based setting, whilst reducing the frequency of in-person consultations which lessen the family burden and financial costs for families living in remote areas.

Conclusions

BLESS presents a unique solution to provide standardzied, tailored and timely treatment to children affected by developmental delays. Our solution takes into account the child's current therapy needs to achieve the necessary normative milestones. Our approach engages and educates the child's parents to administer ESP at home, whereas the therapist is remotely monitoring the child's progress and coordinating the selection and delivery of specific ESA to the parents. Families now have the opportunity of receiving cultural compliant and comprehensive educational content, with the goal of increasing the adherance to the child's treatment and ultimately leading to better health outcomes. Our solution is innovative and relevant to current Brazilian public health needs, and provides a low-cost treatment easily accessible to Brazilians, even in remote areas; and may be scalable to other aspects of child development.

A Generic Rapid Evaluation Support Tool (GREST) for Clinical and Commissioning Decisions

Jack Dowie[ab], Vije Rajput[c], Mette Kjer Kaltoft[b]

[a] *London School of Hygiene and Tropical Medicine, London, UK*
[b] *University of Southern Denmark, Odense, Denmark*
[c] *Stonydelph Health Centre, Tamworth, UK*

Abstract

A fast and frugal generic tool can provide decision support to those making decisions about individual cases, particularly clinicians and clinical commissioners operating within the budget and time constraints of their practices. The multi-national Generic Rapid Evaluation Support Tool (GREST) is a standard preference-sensitive Multi-Criteria Decision Analysis-based tool, but innovatory insofar as an equity criterion is introduced as one of six. Equity impact reflects the number of population QALYs lost or gained in moving from Old (current intervention) to New (contemplated intervention). In the exemplar UK implementation Claxton's NHS Willingness to Pay per QALY is the numeraire. Any weight from 0 to 100% may be assigned to the equity criterion but its presence affirms that it is persons-as-citizens who experience any opportunity harms or benefits arising from actions within the health service commons. A fully-operational but demonstration-only version is available on open access, as proof of concept and method.

Keywords:
Clinical, Decision Support Systems, Health Equity

Introduction

Clinicians and clinical commissioning groups are routinely making decisions about the use of new and/or expensive interventions for individual cases, including patients with multiple morbidities. They may be facing an increasing number of such decisions in the UK, if the recent High Court decision regarding off-label/licence drugs is upheld

(https://www.bbc.co.uk/news/health-45588983).

We perceive a major gap in the support available for such decisions. NICE-type evaluations can cover only a tiny minority of interventions and their remit is currently restricted to on-label use. Decision aids developed according to normative standards such as IPDASi [1] are very limited in coverage, constitute information aids rather than decision support tools that produce an opinion, and rarely introduce budget considerations. Guideline recommendations, such as those produced by GRADE, cannot, by definition, reflect individual preferences, only group or sub-group averages, and leave the decision maker analytically unsupported in the task of processing the extensive summary of evidence at the point of decision.

Whenever a proposed NEW intervention is to be comparatively evaluated against a current OLD one within time and resource constraints, a flexible, rapid, generic and inexpensive decision support tool is needed.

The required tool must be practical and useful. It must meet the SMART criteria - Specific, Measurable, Achievable, Relevant, and Timely - to the extent each of these are reasonable in the given decision context. More simply, the decision support must be 'fast and frugal'. It must be pitched at the most appropriate point (trade-off) on the 'rigour-relevance' continuum. It will therefore be a long way from a highly analytical NICE-type evaluation in one direction, but also far removed from an expert deliberation-based guideline in the other. While endorsing long term efforts to develop normatively superior methods of linking evidence and clinical practice [2-6] or dealing with the complexities of value-based care [7-8] we have the simple but limited ambition of providing a rapid and practical method of improving on the present decision making process, whatever it is. The tool will not seek to replace or deter the development of superior tools, but reflect the belief that the *normatively* best, or even normatively *better*, may be the enemy of the *empirically* better – a point well-accepted in relation to drugs and devices, not yet for decisions. Evaluations should reflect this and use the actual process they would replace as comparator.

Method

Multi-Criteria Decision Analysis (MCDA) can provide the basis for such fast and frugal decision support tools. Given their basis in this technique they can provide an opinion on the worth of each Option (one of the actions that can be taken) by combining its Ratings (how well it performs on relevant Criteria) with the criteria Weightings (how important each criterion is relevant to the others), making the opinion a preference-sensitive one. Introductory materials and numerous examples of the implementations of MCDA in the decision support context are available at http://cafeannalisa.org.uk including the short video 'Powtoons'. In the space available and to avoid duplication we leave further details of Method to the following Results section and the online tool introduced there.

In Multi-Criteria Decision Analysis-based tools, it is entirely feasible to include an equity outcome criterion and our proposed tool, implemented in the Annalisa template [9], does this. However, we emphasize that this innovation occurs in the context of a more extended, multicriterial analysis, otherwise

the tool will not be appropriate in person/citizen-centred healthcare decision making.

Result

The Generic Rapid Evaluation Support Tool (GREST) is presented here as proof of concept and method, based on internal testing, and as the basis for feedback in relation to future development and implementation.

The two options in GREST are OLD (the current intervention, such as usual/standard/current care) and NEW (the contemplated replacement). The six criteria in the default prototype are:

- A condition/decision-specific Biomarker (e.g. Bone Mineral Density)
- A condition/decision-specific Function(al) Index (e.g. Six Minute Walk Test)
- Option (test/treatment) Side effects
- Option (test/treatment) Burden (e.g. arising from frequency and mode of delivery of medication)
- Health-Related Quality of Life (HRQOL)
- Equity (reflecting the Harm/Foregone Benefits to Others in 'North-East' cases and Benefit/Foregone Harm to Others in 'South-West' ones – see below)

It will be noted that Life Expectancy is not a criterion in the current GREST, so if there is any effect on this from the new intervention, it would need to be discussed separately in the light of the GREST opinion. It will also be noted that monetary cost is not a separate criterion, being introduced only through the sixth, equity, criterion.

To engage with the tool and understand the method underlying it, go to https://ale.rsyd.dk (enter 1513 as survey ID). This version is in English and uses the EQ-5D-5L tariff for 11 countries to establish Health-Related Quality of Life (HRQOL) values used in deriving the ratings for both the HRQOL and Equity criteria. Nine tariffs are from https://euroqol.org/eq-5d-instruments/eq-5d-about/valuation-standard-value-sets/crosswalk-index-value-calculator[10]; others tariffs included are for Poland [11] and China [12],

This is a demo version provided as a proof of concept and method on open access. Only anonymous, non-confidential data should be entered. No responsibility is taken for data security.

The performance ratings of OLD and NEW on the first five criteria in GREST are elicited in whatever way is compatible with the clinician's or clinical commissioning group's practice timescale and resources. The Ratings for both OLD and NEW should be the BEANs (Best *Estimates* Available Now) and hence as evidence-based as is possible, and as expertise-based as is necessary, within the *actual* resource and time constraints of the decision makers. The person/patient is to be regarded as the expert on Treatment Burden. The derivation of the ratings for the equity criterion is explained in a separate sub-section below.

The relative importance Weighting of each criterion, including equity, is elicited on a 0-100% scale, where 0 indicates of no importance and 100% of extreme importance. The six responses are summed and percentaged to give and display the set of provisional criterion weights that add to 100%. In this interactive tool they may be changed by cursor on inspection of their graphical display. More sophisticated weight elicitation procedures, such as swing weights or discrete choice experiments, may have greater normative appeal than Visual Analog Scales, but lack either individual applicability or practicality in the typical time and resource scale contemplated.

Figure 1: North-East Case with 5.9% Equity Weight

Figure 2: North-East Case with 50% Equity Weight

The GREST output is in the form of a 'deciographic' - a single screen showing all Ratings, Weightings, and the evaluation Scores for OLD and NEW. As in all standard MCDA applications, the Score combines the relative importance criterion Weightings with the evidence- and expertise-informed option performance Ratings, by the Expected Value algorithm.

Giving 50% weight to equity in Figure 2 (bottom) rather than the 5.9% in Figure 1 (top) flips the opinion to OLD.

The ratings in the above example are purely illustrative. We imagine NEW to be superior on Biomarker, Function, and HRQOL, but inferior on Side Effects and Treatment Burden – and, by the definition of a 'North-East' GREST, it produces net 'Harm to Others'. The 50% Equity rating for OLD reflects complete uncertainty about its value. In the Ratings panel a longer bar always means better and in the Weightings panel a longer bar always means more important.

The Equity Criterion

Person-centred care – and value-based healthcare - is not all about the rights of the person. Persons are also citizens who have responsibilities and duties within a resource-constrained public health service. Only by applying a *generic outcome measure* as a criterion within a personalised *multi-criterial* decision analysis can we move to the coherent involvement of equity in decision making about clinical cases. In GREST, the equity outcome criterion is defined and measured as the Harms or Benefits to Others created in moving from OLD to NEW in a resource-constrained service. In measuring these,

any *condition-specific* outcome such as *cancer* mortality/morbidity, as contrasted with *all-cause* mortality/morbidity, is ruled out as equity-irrelevant.

We have chosen Health-Related Quality of Life (HRQOL) as our generic equity outcome measure, the current GREST explicitly eschewing evaluations where NEW alters life expectancy. We use EQ-5D-5L as the HRQOL metric, though the method is not tied to any specific instrument.

Where the NEW intervention is *more expensive* than the OLD, but also *more effective*, we are in the North-East quadrant of the Cost-Effectiveness plane. There will be 'opportunity harms' (*foregone benefits*) to others, usually anonymous and unidentifiable, as a result of substituting NEW for OLD.

Where a NEW intervention is *less expensive* than the OLD, but also *less effective*, we are in the South-West quadrant of the Cost-Effectiveness plane, the only one recognized in NICE, where lower effectiveness is disallowed as a source of improved cost-effectiveness. This restriction of cost-effectiveness to *incremental* cost-effectiveness constitutes political interference with the implementation of a neutral technique [13]. In this quadrant there will be 'opportunity benefits' (*foregone harms*) to others, usually anonymous and unidentifiable, as a result of substituting NEW for OLD.

In measuring the foregone benefits and harms in the UK context, we use Karl Claxton's estimate of the NHS's revealed willingness to pay (WTP) for a Quality-Adjusted Life Year (QALY) of £12,000. 'The central or mean estimate of £12,936 is likely, if anything, to be an overestimate', hence our use of £12,000. [14] (p4).

Equity impact is calculated as the number of QALYs that would be moved from Others to the recipient of the NEW intervention. So, if the NEW intervention (assuming no life expectancy effect) costs £24,000 per year compared with £1,600 for the current OLD treatment (Extra cost = £22,400), and it improves HRQOL from 0.23 to 0.59 (QALY gain = 0.36), the Equity impact (Harm to Others) created by adopting NEW is calculated as:

£22,400 / 0.36 = £62,222 per QALY
£62,222 / £12,000 = 5.2.

The generation of the 1 QALY involved in substituting NEW for OLD for a single (identifiable) person creates a QALY loss of 5.2 to anonymous others elsewhere in the service. At the population level there is a net loss of 4.2 QALYs from the shift. This loss may all be borne by one anonymous person, or be distributed as lost quality-adjusted weeks or days across small or large numbers of people. The fact is that this distribution is unknown. (The issue of 'statistical compassion' is raised in the final section.)

If we reverse the OLD and NEW data and move into the South-West quadrant of *decremental* cost-effectiveness, the arithmetic is the same but the effect the opposite. Substituting NEW for OLD now creates a QALY gain of 5.2 to anonymous others elsewhere in the service. At the population level there is a net gain of 4.2 QALYs.

To map the QALY movement on to the required 0-1 ratio scale for the MCDA-based tool, we take its reciprocal, subtracting this from 1 in the South-West case. Moving 5.2 QALYs becomes 0.193 in the NE case (Figures 1 and 2) and 0.807 in the SW (Figures 3 and 4).

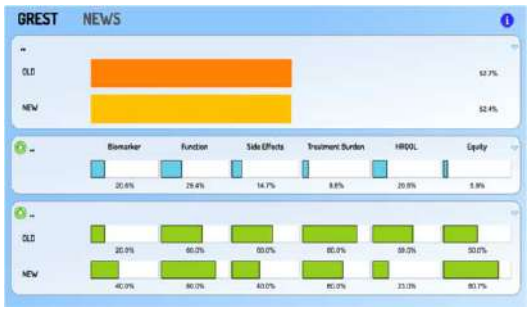

Figure 3: South-West case with 5.9% equity weight

Figure 4: South-West case with 50% equity weight

The above screens result from reversing the data in the earlier example, making NEW a South-West intervention, where it produces lower HRQOL but at greatly reduced cost, in contrast to the North-East situation where it produces the same amount of higher HRQOL but at greatly increased cost.

Giving about 6% weight to equity in Figure 3 (top) is insufficient to shift the verdict in favour of NEW, but assigning 50% weight in Figure 4 (bottom) clearly does so.

What can we conclude about the change in equity in these two situations? The most reasonable assumption is that the anonymous others who are either gainers or losers from NEW will be randomly distributed. Under this assumption and assuming an equity rating for OLD of 50% (reflecting complete uncertainty), the net effect of NEW will be to *increase inequity* if it is a North-East intervention (replacing the less costly and less effective OLD) and *reduce inequity* if it is a South-West one (where it is less costly and less effective than OLD).

The magnitude of the effects will be a function of the numbers in the particular clinical case. But we can note that at a service level, the potentially very large numbers of opportunity harms from NE interventions may add up to a massive increase in inequity while the failure to consider SW interventions can add up to a huge potential failure to reduce inequity. The same applies in the individual screening context.

Discussion

Claxton makes our basic point in relation to NICE decisions about new drugs, where the threshold being used is far above the average observed WTP for a QALY of £12.000, but it is equally pertinent at the clinical/clinical commissioning level.

"The evidence suggests that more harm than good is being done, but it is the unidentified and unrepresented NHS patients who bear the true (health) opportunity costs. Although finding reasons to approve new drugs is undoubtedly politically expedient, this cannot be ethically literate, because the interests of NHS patients, whether they are identifiable or not, are just as real and equally deserving of the type of care and compassion that can be offered by a collectively funded health care system. It is to be hoped that NICE will begin to place the unidentified NHS patients who bear the real opportunity costs at the heart of its deliberative process." [15] (p6).

The GREST tool does not mandate any amount of concern with the impact on others, but it does mandate a statement of the weight to be assigned to it, in the 0 to 100% range, in generating the opinion of the decision support tool. As persons-as-citizens, we incur both a right and responsibility to be informed of the impact on others of our use of the health service commons in self-producing and co-creating health [16].

Objections to introducing a societal element into clinical decisions can be expected from clinicians as well as patients, but rejected on the ground that equity is a social matter for all citizens, and it is not for a profession to decide as they should to be able to 'protect their patients' from concern with it. In any case, a healthcare budget-holder cannot escape this wider responsibility for all those within their aegis.

Treating any individual person as a means to achieve some population policy end– to reduce the incidence of this, increase the uptake of that – has to be rejected even if it is in their *perceived* individual best interests. (Infectious diseases are an exception where the law rightly takes away the right of an individual to directly jeopardise the health of others.) But neither is it ethical for the person as citizen to be left in – or allowed to opt into - complete ignorance as to the impact on others, in whatever direction. An empirical resolution of the clash between individual and community [17] is brought no nearer by simple repeated noting of its existence, or by attempts to solve it solely at the collective level, leaving the individual uninvolved in any direct way.

The person is not only a citizen, but usually a member of a family or other group of significant others. Nothing said here is meant to imply that the person will not wish to take the feelings and consequences for these near others into their decision making. Nor to imply that the benefits of a 'family focus' in provider care should be ignored or underestimated. We merely note that if relatives are driving demands to 'do everything possible' against the perceived implicit, or explicitly expressed, wishes of the patient, this transparent support will be helpful in empowering the patient.

Both the ethical requirements of 'patient-centred' care and the legal requirements of 'reasonable patient' care suggest that the introduction of 'equity' into clinical practice guidelines, recently advocated [18-21], is not an appropriate way to go. The GRADE subgroup propose that guidelines panels recommend that clinical practitioners 'consider' the ways in which an individual patient may be affected through being a member of a 'disadvantaged' group. However, this seems to be ethically suspect, insofar as it could potentially distort the personalized option ratings for, and personal criterion weightings of, the specific individual. The case for a personalized decision analytic approach using individualised ratings and weightings is well made by Wasfy and colleagues [22] and not satisfactorily refuted by Lightner [23]. GREST is on offer whether or not guidelines panels were to abdicate from making a recommendation in the face of uncertainty [24].

Everyone seeking to participate in the equity debate is confronted by the sociopsychological phenomenon, emphasised by Williams and Cookson, among others, of the difficulty individuals have in relating to the thousands of anonymous others who have equal rights in the health service commons.

"For many people [the] notion of 'statistical compassion' seems to create both intellectual and psychological difficulties. It is as if personal empathy with one or two individuals is possible, but, paradoxically, if many individuals are involved, this capacity to empathise diminishes. This difference between focusing on groups and focusing on individuals also distinguishes economists (and managers) from clinicians and others dealing with people at an individual level. The latter often claim that they are under an ethical duty to do everything possible for the person in front of them no matter what the consequences might be for everybody else. If this assertion is taken at its face value, it would imply that clinicians should ignore their responsibilities for the welfare of their other patients except when that patient is in front of them. It seems most unlikely that any clinician would actually behave in that way, so perhaps the statement should not be taken at its face value, but regarded instead as part of the rhetoric of medical practice, designed to bolster the doctor-patient relationship. But whatever may be the role of such statements, it is clear that in a public policy context, where distributive justice is an explicit objective, it is clearly not ethical for a clinician to ignore the consequences of his or her actions concerning the treatment of one patient for the health of other patients for whom the system is also responsible." [25] (p1866).

Conclusion

The individual can only self-produce their health, and co-create it with healthcare professionals and significant others, within the wider environment and socioeconomic constraints in which they live and work. Most of the recent advances in key health indicators (e.g. life expectancy) are attributable to sectors other than healthcare, so that the creation of health and health equity needs to be approached within a much wider and comprehensive framework [26]. Equitably, cost-effective, cross-sectoral public health policies are an essential complement to any changes in clinical decision making [27].

However, the transparent introduction of equity considerations into decision making in relation to individuals can play an important role in affirming the social nature of a public health service. A public health service is not a private health service. It is ultimately the person-as-citizen who is experiencing any opportunity harm or benefit that arises from an action within the health service commons [28]. All health service decision makers should therefore be showing the 'statistical compassion' appropriate to their level of responsibility. GREST provides a simple way to allow the opportunity implications of a decision to be highlighted, but then set at whatever level is desired - including zero.

Author Contributions: JD developed the generic GREST tool in response to a challenging clinical decision, incorporating the insights and suggestions of VR and MKK. He wrote the paper, incorporating their observations, revisions and additions.

Funding: This research received no external funding. The software used for GREST was installed at https:// ale.rsyd.dk as part of a nationally funded project to develop decision support tools. (Danish National Board of Health/SATS J.nr. 1-1010/116/27.)

Conflicts of Interest: Jack Dowie has a financial interest in the Annalisa software implementation of MCDA, but does not benefit from its non-commercial use.

Design and Implementation of a Tool for Pharmacists to Register Potential Errors in Prescribed Medication

Abstract

Adverse drug events are frequent and may be mitigated with the implementation of functionalities within Health Information Systems. We developed a tool that allows Pharmacists to register and communicate to providers potential errors in prescribed drugs in terms of medication omission, unjustified stop of medication or other reasons.

We included all interventions performed by Pharmacists for admitted patients between July, 31st 2018 and October, 23rd 2018.

During the study period, 193 interventions were carried out by Pharmacists. 117 (60%) were intended for registering medication omission, 7 (4%) for unjustified stop of medication and 69 (36%) for other reasons. 112 interventions lead to the provider performing the suggested action (58%), 77 (40%) were rejected and 4 (2%) required no action.

Although there were errors in the use of the tool, a great amount of interventions were accepted, thus representing a better quality of care for patients.

Keywords:
Electronic prescribing, patient safety, medication errors

Introduction

Medications are widely used therapies associated with multiple benefits for patients, but they can also cause adverse events, leading to thousands of hospital admissions every year [1]. Adverse Drug Events (ADE) are defined as harm caused by medical interventions related to drug administration [2]. Most of the preventable ADEs are due to errors in the prescription of medication [3].

The Institute of Medicine (IOM) strongly recommends the development of automated information systems with clinical provider order entries (CPOE), either with or without clinical decision support systems (CDSS) [4], in order to enhance reliability, quality and safety in the use of medication [5]. There is evidence that the implementation of CPOE decreases many of the problems associated with handwriting issues (illegible writing, incomplete orders, incorrect doses) [6,7]. Furthermore, when CPOE are complemented with CDSS it can offer predetermined values of dose, route of administration and frequency for commonly prescribed drugs [8], verify medication allergies, interactions, dose adjustment and therapeutic duplication [9], leading to a further reduction in ADEs [10].

However, either because alerts are ignored due to "alert fatigue" [11] or because the patient's clinical condition can vary (e.g., alterations in the renal function), changing the appropriateness of a prescription, asynchronous safety nets are needed besides CDS systems [12]. This is why it is important to combine technology with clinical judgement.

Clinical pharmacists provide high value for patients, physicians and additional members of the healthcare team in the management of medication [13], and the IOM considers them an essential asset for the safe use of drugs [14]. One of their missions is to formulate recommendations to providers with the intention to improve the management of patient medication (called pharmaceutical interventions or PIs). PIs can be related to the adequacy of a prescribed medication (wrong or ineffective medication) or a dose (overdose, low dose), the lack of a needed medication (omission of a usual medication or need of a new one) or the need to obtain a new laboratory test for monitoring [15,16].

An indirect way to evaluate the contribution of clinical pharmacists to the optimization of pharmacological therapy is to determine the amount of medication-related problems that are addressed or prevented with their interventions [17]. Rates of acceptance of such interventions by providers of up to 90% have been reported [18,19]

Hospital Italiano de Buenos Aires (HIBA) has an Electronic Health Record (EHR) with CPOE and CDSS, and pharmacists perform and register on average 2,500 interventions monthly, out of the 165,600 prescriptions they check (1.51 interventions/100 prescriptions). Given the need of the staff of the Pharmacy Department to perform and register interventions related to the omission of a medication, and in order to comply with the standards of the Joint Commission International (JCI) to optimize medication reconciliation, we decided to develop and implement a tool for that purpose.

Our general objective is to describe the development and implementation of a tool that allows pharmacists to perform and register interventions on medication that is not currently prescribed (omission, unjustified stop or other reasons).

Our specific objective is to analyze preliminary results of the use of this tool by physicians and pharmacists during the first 12 weeks of implementation, considering the actions taken within the tool and the actual prescription of drugs.

Methods

Setting

HIBA is a non-profit organization founded over 165 years ago in Buenos Aires, Argentina. Its network includes a highly

specialized university hospital which provides healthcare for ambulatory care, emergencies, admissions, clinical and surgical specialties, critical care, home care and chronic patient care. It has its own health maintenance organization (HMO), called Plan de Salud, with over 165,000 affiliates, and it provides healthcare services to 1,500,000 patients insured by other companies. Every year, over 45,000 patients are admitted, 45,000 surgical procedures are performed and 3,000,000 ambulatory consultations take place in our network. In 2015 HIBA achieved accreditation from the JCI, and became reaccredited in 2018.

Since 1998 we gradually implemented a Health Information System developed in-house to manage clinical and administrative information. Our Electronic Health Record (EHR), named ITALICA, is web-based, modular and problem-oriented. This EHR covers all the spectrum of healthcare: outpatient, inpatient, emergencies and home care. ITALICA includes functionalities such as CPOE for drug prescription and laboratory and imaging studies and visualization of study results.

The pharmacy service (PS) consists of a head of service, two sub-managers, 23 pharmacists and 11 pharmacy residents, who add up to a total of 34 pharmacists who perform medication validation. There are also 40 people dedicated to the preparation of medication.

Prior to drug dispensation, pharmaceutical validation is carried out. In the 1990s, the American Society of Health-System Pharmacists (ASHP) set the minimum standards for Hospital pharmacy services. The JCI defined that a pharmacist must validate all prescribed drugs before dispensation [20,21].

Through medication validation, pharmacists verify the prescription, evaluating if the prescribed medication is in accordance with the patient's clinical condition, if there are any contraindications or interactions and if dose-adjustment is required according to age, weight and laboratory results. This confers a greater value to the pharmaceutical process, allowing crossed control and providing greater security to the cycle.

However, pharmacists could only validate existing prescriptions, and they were unable to register in the EHR an intervention on a medication that was not currently prescribed. Therefore, communication between pharmacists and providers was carried out informally (through e-mails and telephone calls), thus elevating the chances of occurrence of potential errors and not registering important information in the EHR. Additionally, there was no chance of finding patterns that could help improve the prescription process.

Study design

This is an observational, descriptive and analytical study of a retrospective cohort in the HIBA. We included all interventions performed by pharmacists with the new tool on admitted patients of all ages from July, 31st 2018 through October, 23rd 2018.

Categorical variables are presented as absolute frequency and relative frequency (percentage). The rate is presented as prevalence, with its respective 95% confidence interval.

Features of the tool

We developed a tool that allows pharmacists to register interventions related to one or more of the following:

- Medication omission: lack of prescription of a necessary medication
- Unjustified stop of medication: prescription of a medication stopped without providing a reason for doing so
- Other: specification of type of intervention and reason.

When using it, the pharmacist must also explicate whether it is a miss (defined as an event that caused harm to the patient) or a near miss (defined as a potential error that was prevented before it caused harm to the patient), and describe the intervention in a free-text field. Lastly, the user must choose which providers to communicate the intervention to (the treating team is set by default) (Figure 1).

Figure 1– Capture of the developed tool

Afterwards, these physicians receive an e-mail with all the aforementioned information and a telephone number of the PS in case doubts arise regarding the intervention.

These interventions are visualized by providers in the EHR in the Medical prescriptions menu. They can choose to accept the intervention (which redirects to the drug prescription module) or reject it (providing a reason for rejection).

All medical and pharmaceutical users were informed about this tool through institutional e-mails and tutorials posted in the EHR prior to implementation.

Results

Types of intervention

Throughout the 85 days of the study period, from July, 31st 2018 to October, 23rd 2018, 193 pharmaceutical interventions were carried out, of which 184 were near misses and 9 were misses. 60% (n=117) of such interventions were related to medication omission, 36% (n=69) to other reasons and 4% (n=7) to unjustified stop of medication (Figure 2).

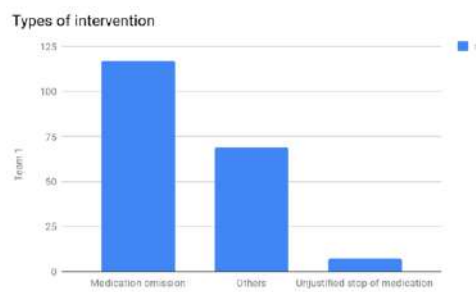

Figure 2– Types of intervention

The rate of interventions was 2.27/day (193 interventions/85 days). The mean number of weekly admissions at HIBA during 2018 was 697 (99.59 admissions/day), so the estimate ratio of interventions to admissions is 0.02. If we consider the number of prescriptions (165,600/month, approximately 5,520/day), the estimate ratio of interventions to prescriptions is 0.0004.

Use of the tool by providers

As to the response of physicians, 29.02% (n=56) of interventions were accepted, 9.84% (n=19) were rejected and in 41.45% of the cases (n=80) no action was taken. Pharmacists cancelled 17.62% (n=34) of the interventions they performed themselves, and 2.07% (n=4) did not require acceptance nor rejection, since they were merely for informative purposes (Figure 3).

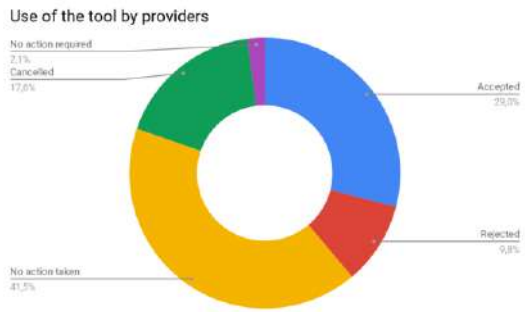

Figure 3– Use of the tool by providers

Action taken by providers

Although the proportion of interventions accepted by providers was low, these rates vary significantly when taking into account the course of action actually carried out by physicians (Figure 4).

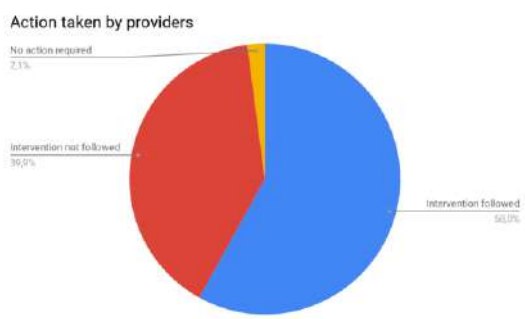

Figure 4– Action taken by providers

There were 112 interventions in which providers followed the pharmacist's suggestion, which means an actual acceptance rate of 58.03% (95% CI 50.73-65.08%), including 4 that were duplicated. Of those, 3 prescriptions had already been performed by physicians minutes before the intervention, which could be due to the simultaneous log-in to the EHR of both users or a parallel communication channel between them. Furthermore, in 8 cases the provider prescribed some of the suggested drugs but not all of them. Lastly, there were 4 interventions in which the pharmacist suggested to change the medication due to lack of stock in the PS, and 2 in which this communication channel was used to correct the registration of prescriptions in the EHR that had already been performed, either verbally or in an incorrect section of the EHR.

On the other hand, there were 77 interventions (39.90%) that lead to no action taken by the provider (that is, that the intervention was not followed). This includes three patients that were discharged on the same day, three interventions regarding lack of stock of a medication in which the prescription was not modified and one intervention that lacked the name of the drug omitted.

The remaining 4 interventions (2.07%) include the following: 1 to communicate that the PS would send a different medication because of lack of stock, 1 to remind the need for authorization by the financial entity prior to drug dispensation, 1 suggestion for clinical evaluation and 1 to register the communication with the nurse staff about the correct rate of infusion for a drug.

Interventions by Medical Department

As to the medical departments that received the interventions, Internal Medicine was the main recipient (38.86%, n=75), followed by Surgery (10.88%, n=21), Obstetrics (8.81%, n=17), Cardiology (6.22%, n=12), Pediatrics (5.18%, n=10) and Traumatology (5.18%, n=10) (Figure 5). The difference between the number of interventions by medical departments is probably related to the number of inpatients treated by each.

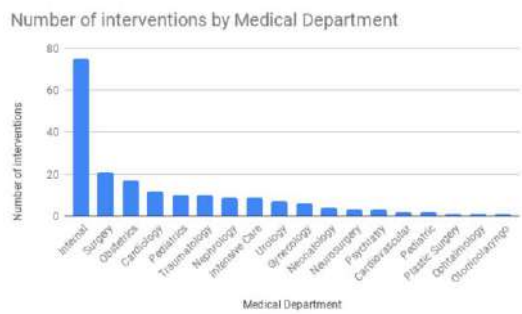

Figure 5– Action taken by providers

Interventions for medication omission

When analyzing all interventions for medication omission (117 out of all 193 interventions), 73 (62.39%) recorded the lack of prescription of a medication due to errors in the medication reconciliation process, with a total of 98 medications (1.34/intervention). The rest (44/117, 37.61%) were about suggestions of medication that was relevant to the current clinical context of the patient (e.g. potassium for hypokalemia).

Discussion

In this paper we describe the evaluation of a tool that allows pharmacists to register in the EHR and communicate to providers about potential errors in the medical prescriptions, either by omission of relevant medication, unjustified stop of medication or other reasons.

This tool was created mainly to optimize the medication reconciliation at admission, given the extensive evidence about the importance of this process [22,23]. However, when analyzing the results we observed that 37.61% of the interventions for medication omission were performed to register the lack of a prescription of a medication that was relevant to the current clinical context of the patient. In our

institution, the PS has a leading role in the medication cycle, having achieved validation rates close to 100%, which is why we find it very important to involve pharmacists in the improvement of the patient safety related to the pharmacological treatment.

On the other hand, the high use of the type of intervention *Other* of the tool provides evidence of the need of a formal communication channel between pharmacists and physicians. This type of intervention was mainly used to provide administrative information, to suggest improvements in the registry of the clinical information, to indicate the need of a clinical evaluation (e.g., corroborate known allergies) and, in some occasions, to indicate medication omission.

Also, it is worth mentioning that in one case this tool was used to register a telephonic communication carried out between the pharmacist and a nurse to provide information about the rate of infusion of a chemotherapy drug. This led us to reflect on the lack of existence of a formal communication channel between the PS and the Nursing Service, and the possibility to explore the need of such channel through inquiries to the stakeholders.

Another issue that is evident when evaluating the results is that the tool was not used properly (or at least not in the way it was expected according to how it was designed). Either by an error in the type of intervention selected by the pharmacists or by an incorrect selection of the action taken by the providers, the raw data shows a discrepancy between the action registered and the action taken. This could be improved by optimizing communication and training of the correct use of the tool. In any case, when we focus on the impact that the tool had on the actions taken by physicians, 112 interventions were accepted throughout the study period, representing 58% of all interventions.

Conclusions

Despite the discrepancy between the registry of acceptance of interventions through the tool and the amount of interventions eventually followed by providers (29.02% and 58.03%, respectively), it is clear that the functionalities of the tool are yet to be further exploited. The final number of interventions by the PS that were carried out by physicians during the study period is significant (193 in 85 days), and the rate of acceptance was high. It is worth mentioning that the existence of rejected interventions does not imply per se an error in the design and implementation of the tool or in the actions taken by pharmacists. They mainly represent a decision taken by providers based on their clinical judgement, which lead them to override the suggestions.

Furthermore, it is clear to us that the correct training of the staff involved in the process (namely, physicians and pharmacists) is critical in achieving our goals for improving quality of care and patient safety through the use of this tool.

Abstract

Telemedicine is an increasingly used strategy for providing care to patients. The prevention and treatment of Upper Respiratory Tract Infections (URTIs) during outbreaks still require new management approaches.

We aimed to describe patients' characteristics and the care process after the creation and implementation of a virtual care program for patients with URTI during the epidemiological outbreak.

We studied all consultations that took place between May, 21st, and September, 14th 2018 at Hospital Italiano de Buenos Aires (HIBA). After applying exclusion criteria 218 consultations were left for the analysis. Most patients did not need a referral to a care center for a face-to-face assessment. The consultation rate to the Emergency Department (ED) within 7 days was 11.92% (26/218) with a 95% CI of 7.94-16.99%.

This new approach in patient care has a great potential for relieving the overcrowding in EDs, decreasing waiting times and preventing the infection spread in waiting rooms.

Keywords:
upper respiratory tract infections; telemedicine

Introduction

Technological advances have a direct influence on the provision of health services, replacing in many cases the traditional ways in which Medicine has been exercised by offering remote medical services. Many doctors and health institutions are increasingly adopting the use of technology to provide care for their patients, either through websites, e-mails, chats, video calls, and/or mobile applications. The World Health Organization (WHO) defines Telemedicine as "the provision of health services by health professionals using information and communication technologies for the diagnosis, treatment, prevention of diseases, injuries, research, evaluation and continuing education, with the interest of taking care of the health of individuals and communities where distance is a critical factor". In many institutions in several countries, valuable experience in this field is progressively being acquired [1–5].

On the other hand, Upper Respiratory Tract Infections (URTI is defined as a term that includes several infectious diseases of the upper respiratory tract: rhinosinusitis, the common cold, pharyngitis/adenitis, laryngitis, and otitis media) are a reason for frequent consultation in hospitals throughout the world, both in adults and in the pediatric population [6], especially during the winter time.

Non-urgent consultations to the ED during the epidemiological outbreak contribute to a phenomenon known as *overcrowding* [7], and they overload the health system, negatively affecting patient care. According to a study performed in our institution, the overall prevalence of consultations for URTI at HIBA during 2015-2016 in our walk-in area was 12.01% with 95%CI 11.86%-12.16% (21,581/179,597). Management strategies for the prevention and treatment of influenza during the seasonal epidemiological outbreak are necessary to redirect patients to the outpatient setting [8].

In addition, the healthcare sector faces two apparently contradictory demands: first, to ensure equitable access to quality healthcare services, and second, to reduce, or at least control, the rising costs of these services.

Telemedicine could help meet these two demands by optimizing the use of existing resources (expertise and equipment) by means of telecommunications. Despite this, the use of Telemedicine for URTIs has not been thoroughly investigated. A tool that informs patients about the level of care required was reported to be widely accepted among users[9], but there is also evidence that the implementation of Telemedicine for the management of acute respiratory illnesses may increase health costs[10]. With this in mind, in this study, we describe the characteristics of the patients and the care process implemented for patients insured by HIBA's own Health Maintenance Organization (HMO) that consulted through the virtual URTI care program implemented in 2018.

Methods

Setting

Hospital Italiano de Buenos Aires (HIBA) is a non-profit organization with 165 years of history in Argentina. Its healthcare network includes a university hospital of high complexity that covers health care for outpatient, inpatients, emergencies, critical care, home care, chronic care, and medical and surgical specialties. It has its own medical insurance service (health maintenance organization), with more than 160,000 affiliates, and provides health services to 1,500,000 people with other health insurances. Annually, more than 45,000 patients are admitted to their hospitals, and 45,000 surgical procedures and 3,000,000 outpatient visits take place.

Since 1998, the HIBA has its own health information system (in-house) that includes the management of clinical and administrative information. It's Electronic Health Record (EHR) is an integrated, modular, problem-oriented and patient-centered system, used in the different clinical scenarios (ambulatory, hospitalization, emergency center, and home care) [11,12].

As part of the information system, an integrated Personal Health Records (PHR) called POPES is available to all outpatients since 2007. PHR allows patients receiving medical care in the hospital network to access and verify clinical and administrative information, and to interact with the health system. Among its main functionalities, the PHR allows users to update their personal information, share information, manage scheduled appointments, view test results, check, order and buy prescribed medication, and the possibility to consult with the healthcare team through Telemedicine tools, and it has a messaging service for communication with the general practitioner" At present, POPES has approximately 400,000 registered users [13].

Study Design

This study is an observational, descriptive, and analytical study of a retrospective cohort in the HIBA.

All patients included in this study were adults (defined as >= 18 years of age at the time of consultation) insured by HIBA's HMO, who consulted via the URTI virtual attention program between May 21st, 2018 and September, 14th, 2018.

Patients were followed-up for 7 days from the date of the virtual consultation for consultations to the ED and/or hospitalization.

The URTI program was publicized from May, 2nd 2018 through different institutional communication channels: HIBA TV (an internal television channel that displays short videos in waiting rooms), e-mails, Health Portal, HIBA's Intranet, and brochures distributed in the hospital (Figure 1).

It was initially designed to provide virtual attention to adults aged 18 to 65, insured by HIBA's HMO (a restriction due to administrative issue), with a Patient's Portal account, without risk factors (defined as: chronic pulmonary conditions -COPD, asthma , cystic fibrosis, bronchiectasis, tracheostomy-, chronic heart failure, chronic kidney disease in dialysis, chemotherapy treatment in the prior month, transplant, hospitalization in the prior month, pregnancy, and / or immunosuppression) that self-registered for attention for URTI symptoms. Providers could choose to refer patients older than 65 years old and/or with any of the stated risk factors to the ED, or decide to go through with the consultation if they judged the patient to be fit for it –e.g: mild asthma.

The service was implemented on May, 21st 2018, and was made available on business days from Mondays to Fridays, between 9 A.M. and 9 P.M. The consultation was registered in the Electronic Health Record (EHR) using a predetermined structured form designed for this project. The variables included in this form are used as secondary datasets for the description of the care process implemented.

The virtual attention system consisted of a video conference with video, audio and chats as functionalities to optimize effective communication (see Figure 2). The attending doctors could create and send to the patient's health portal a PDF certificate of care, indicating the prescribed hours of rest.

Figure 1– Advertising leaflet

The teleconsultation service implemented was designed in-house and embedded in the EHR and the PHR. Its development was based on the premise of not needing the installation of any software, besides Google Chrome. With that in mind, we used the Web-RTC (Real-Time-Communication) framework for the transmission of high quality and performance audio and video, a signaling service built with WebSocket and HTML-5 for the front-end and access to peripherals. This project required a server, developed in NodeJS with socket.io for establishing connections, and a gateway TURN/STUN in order to offer this service without compromising the security of the hospital network. We carried out iterative cycles of development and testing until we obtained a satisfactory final version for both desktop and mobile devices.

Figure 2 - Teleconsultation service embedded in the EHR and the PHR

The research project was approved by the Institutional Research Protocols Ethics Committee. The anonymity and confidentiality of the information were guaranteed. There were no potential risks for the patients involved in this study.

The quantitative variables are presented according to the distribution as means and standard deviation (SD), median and interquartile range (RIC) or 25-75 percentiles. The categorical variables are presented as absolute frequency and relative frequency (percentage). The rate is presented as prevalence, with its respective 95% confidence interval.

Results

During the study period, 434 virtual consultations were performed. We excluded those that were not effective (due to interruptions or other technical issues that precluded effective connection), patients that did not meet inclusion criteria and those with incomplete records of the consultation in the EHR (due to missing data on the care process). After the exclusions there were a total of 218 consultations for the analysis (Figure 3).

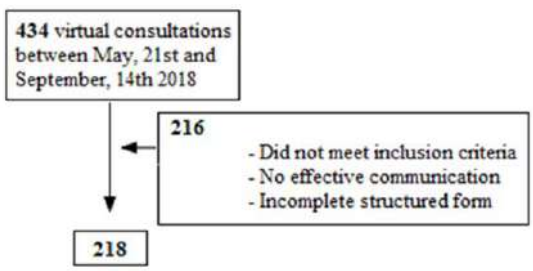

Figure 3– Flow chart of included patients

The most frequent causes of communication failures were:

- *Other reasons for consultation, not related to URTI symptoms*: request for test results, electronic order request for laboratory testing and urine culture, request for proof of blood type, information about flu vaccination, information about preparation for fecal occult blood, peripheral facial paralysis (one patient, who was referred to the ED), skin rash, dermatitis, request for a medical certificate of good health for work.
- *Technical failures in communication:* the patient initiated the communication but never answered the doctor's video call, technical issues with audio and/or video, interruptions in communication, patients with hearing loss, logistical problems when doctors changed shifts.
- *Non-compliance of age:* adult patients registered requesting attention to their children < 18 years old, patients under 18 (referred to a pediatrician), caregivers of patients > 65 years old registered to request attention to their patients.

It should also be noted that, within the subgroup with effective communication, we accomplished to overcome distance barriers for 1 patient from Bariloche (1,000 miles away from Buenos Aires) and 1 patient abroad in Chile.

The frequency of consultations had little variation during each month of the study (see Figure 4), and they were distributed as follows: 6 in May, 57 in June, 59 in July, 65 in August and 31 in September. The service provided was limited to business days between 9 A.M. and 9 P.M., and the daily distribution of consultations was as follows: 23.4% (51) Tuesdays, 21.6% (47) Wednesdays, 20.2% (44) Thursdays, 18.8% (41) Mondays and 16.1% (35) Fridays.

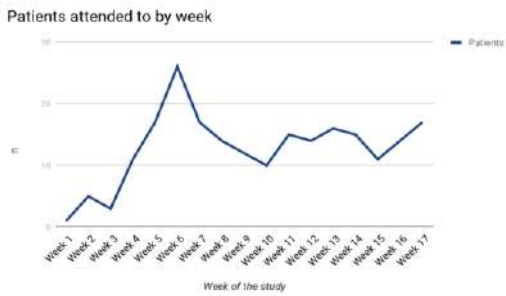

Figure 4– Distribution of frequency of patients attended to, according to date

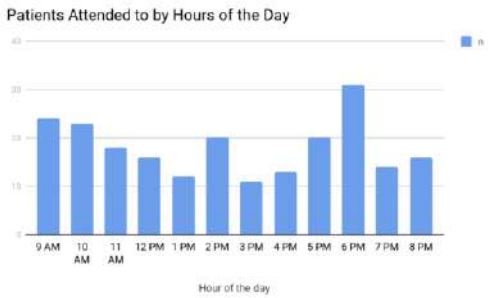

Figure 5– Distribution of frequency of patients attended to, according to time of day

The busiest range of hours was from 9 A.M. to 12 P.M., with 65 out of 218 consultations (global percentage 29.82%, see Figure 5), although the period of highest usage was between 6 pm and 7 pm.

The patients had a mean age of 46.6 years (SD 16.1), and 72.0% (157) were female. Table 1 shows patients' characteristics, including age, gender and other relevant clinical information recorded prospectively in the structured form. 206 patients carried out 218 consultations (10 patients consulted twice, 1 did so 3 times and 1 consulted 4 times).

Table 1– Patients characteristics

	n=218
Age, in years *	46.6 (16.1)
Female	72.0% (157)
Chronic diseases	
Chronic pulmonary conditions	4.6% (10)
Congestive Heart Failure	0.5% (1)
Immunosuppression	1.4% (3)
Dialysis	0% (0)
Chemotherapy in the last month	0% (0)
Transplant	0% (0)
Pregnancy	0.9% (2)
Non-planned admissions in the prior month	0.9% (2)
* mean (standard deviation)	

The data on the care process registered in the EHR are detailed in Table 2. The most frequent presumptive diagnoses were influenza and pharyngitis, with a combined 66.1%. Most patients (86.7%) were prescribed with symptomatic treatment. The vast majority of patients solved their consultation by this means, without the need for referral to a care center for a face-to-face assessment.

Table 2– Consultations and patient attention process

	n: 218
Dyspnea	5.1% (11)
Fever	39.0% (85)
Cough	72.9% (159)
Presumptive diagnosis	
Bronchitis	12.4% (27)
Pharyngitis	20.2% (44)
Influenza	45.8% (100)
Rhinitis	12.8% (28)
Sinusitis	2.8% (6)
Tracheitis	6.0% (13)
Symptomatic treatment	86.7% (189)
New virtual consultation suggested	8.7% (19)
Consultation in walk-in care center suggested	10.6% (23)
Referral to the walk-in care center	5.5% (12)
Referral to ED	6.4% (14)
Ambulance dispatch	-
Doctor home visit scheduled	0.5% (1)

The patients were followed up for 7 days from the time of the virtual consultation in order to estimate the consultation rate in the ED. Only 14 patients were referred by physicians to the ED, but a total of 26 patients consulted the ED, representing a rate of 11.9% (95% CI 7.9-17.0%). 23 of them did so for reasons related to the virtual consultation –e.g.: pharyngitis, laryngitis–, and 3 for unrelated reasons –diverticulitis, back pain.

In the follow-up period, there were no hospitalizations for any of the participants.

Discussion

Based on our work, we deem this new care strategy to have great potential during the seasonal outbreak: it could help prevent hospital *overcrowding*, reduce long delays inattention (or at least offer the possibility of waiting at home), avoid unnecessary referrals, and limit infections in waiting rooms. In accordance with previous studies, we consider that Telemedicine and e-health systems will have a growing role in the care process, bringing information and services to patients wherever they are [14] and allowing professionals to have greater degrees of mobility.

Users of this system were mostly young patients, which could be related to the fact that they are more frequently active and busy during work hours, or that they are more keen on choosing this specific channel for addressing low complexity health issues. This also explains why the levels of comorbidity burden were low. Older population may use this system with less frequency due to technological barriers (smartphone, computer or tablet required) and/or their preference for personal contact with caregivers.

It is also interesting that 72% of patients were female. This is clearly in relation to the population targeted in this project: patients insured with HIBA's HMO, which consists of an inverted population pyramid with over 70% of women.

It should be noted that some of the users displayed a certain resistance, since there were very few registered patients in the first weeks (perhaps due to insufficient advertising), and so did some of the providers, who expressed doubts or fears on Telemedicine during training sessions. It is clear that technological advances are shaping new paradigms in the relationships between individuals. Some authors mention advantages over the usual practice of Medicine, such as avoiding the need for transportation to a health institution, cost savings for the health system and time-saving for doctors (since video consultations are much shorter than the conventional ones [10]).

The elevated number of consultations during this first experience with a teleconsultation system for instant treatment suggests that healthcare users are willing to use new alternative strategies to conventional ones, even considering the selection bias inherent in the study design, since it was directed to adults over 18 years old, insured with HIBA's HMO, with an active account in the patient's health portal. It is also noteworthy that there were many consultations aborted due to technical inconvenience. Even though we were unable to account for all of these issues, many patients that were contacted by telephone afterward reported connectivity problems, which is very usual in-home connections in our country.

We must highlight three findings derived from our study. In the first place, there is a need for Telemedicine for pediatric patients with this pathology, which could guide the population targeted for the use of this tool in the future. Furthermore, no patients with a history of transplant, chronic renal failure or chemotherapy in the last month have attempted to use the service, probably as a result of education as an important tool in the management of patients with these chronic diseases [15]. Third, there were many patients with no respiratory symptoms seeking medical attention through this channel, including reasons for consultation that could be solved or managed by a video call. On the one hand, this leads us to reflect on the effectiveness of existing communication channels that were designed to solve these issues [16]. On the other hand, it allowed us to consider that Telemedicine could play a bigger role in the health system, prompting us to begin a new project for implementing this tool as a medical triage, which will be published in due time.

As for presumptive diagnoses, the most frequent were influenza and pharyngitis. Accordingly, 86.7% of patients were prescribed symptomatic treatment, and the vast majority of patients solved their consultation by the means of Telemedicine, without the need for a referral to a care center. This is probably related to the fact that the most frequently reported symptom was a cough, without the presence of fever. This shows that URTIs are low complexity pathologies, which contribute to the unnecessary *overcrowding* of EDs, requiring a strategy to decentralize medical attention and educate the population on the right channels for consultation. The shift of the healthcare model towards preventive services is essential to successfully accomplish a person-centered healthcare system, leading to patient satisfaction as an essential component and an important indicator of the quality of care [17].

Although it would have been interesting to explore user satisfaction, adoption, and resistance, we lacked the time to analyze this aspect prior to implementation, which constitutes a clear limitation to our study. However, we plan on evaluating these aspects in future lines of work, along with many lessons learned from this experience regarding technical issues and usability.

Conclusions

We can conclude that the use of a Telemedicine tool with video conference for URTI symptoms was attractive and practical, both for patients and professionals. This new care strategy could help prevent *overcrowding* in high complexity health institutions, reduce delays in attention and avoid unnecessary referrals, all of which could have a significant impact on healthcare costs and patient and provider satisfaction.

Diagnostic Informatics: Its Role in Enhancing Clinical Excellence, Patient Safety and the Value of Care

Andrew Georgiou, Rae-Anne Hardie, Maria R. Dahm, Julie Li, Judith Thomas, Gorkem Sezgin, Ling Li, Johanna I Westbrook

Centre for Health Systems and Safety Research, Australian Institute of Health Innovation, Macquarie University, Sydney, Australia

Abstract

Diagnostic informatics encompasses the role of information technology in key areas of the diagnostic testing (pathology and medical imaging) process, including the selection of appropriate tests and interpretation and follow-up of test results. We present three case studies employing diagnostic informatics methodologies to demonstrate their potential use and value in health services research: (1) Data analytics applied to diagnostic data linked with patient outcome data as a means of enhanancing the monitoring of the quality and appropriateness of diagnostic test choices; (2) Business process modelling which can help to highlight healthcare processes in the diagnostic pathway as a means of improving safety and performance, and (3) Consumer involvement in the diagnostic research process to assist in the establishment of person-centred test result management systems. The case studies provide evidence of the role that diagnostic informatics can have in improving the quality and safety of patient care.

Keywords:

Diagnosis; Quality; Safety.

Introduction

Diagnostic testing, (laboratory medicine, anatomic pathology and medical imaging), is an essential part of healthcare systems. Diagnostic testing generates information that is crucial to the prevention, diagnosis, prognosis, stratification of risk, and treatment of disease [19]. Whilst diagnostic testing may account for a small (less than 5%) proportion of most hospital budgets, there is evidence to show that laboratory services influence 66% of clinical decision making [8]. Despite the importance of laboratory and medical imaging in clinical care, diagnostic testing and its impact on healthcare processes has been an overlooked area of health services research [2].

Diagnostic error involves the failure to either establish an accurate and timely explanation of a patient's diagnosis, or communicate the explanation to the patient [15]. Diagnostic error poses a serious risk to patient safety, with major studies showing that it contributes to approximately 10% of patient deaths and 6-17% of hospital adverse events [15].

Factors which can contribute to diagnostic error include: problems with collaboration and communication among clinicians, patients and their families; lack of infrastructure to support the diagnostic process; and inadequate attention to understanding the problem and its causes. [15]. Failures can occur across a number of areas in the diagnostic process beginning with a failure to engage with a patient, to order the correct or appropriate test, follow up test results with the patient, or gather, integrate or interpret the necessary information, which can result in diagnostic errors [5]. Existing evidence has shown that over 40% of patients leave the hospital before all test results are finalised, 9.4% of which were deemed actionable by independent review [18]. The failure to follow-up test results can lead to missed diagnoses, delayed treatments, unnecessary healthcare utilisation and preventable harm [4]. Effective solutions must engage all stakeholders to arrive at decisions about who needs to receive the test results, how and when the results are communicated, and how they are acknowledged and acted upon [10].

We use the term *diagnostic informatics* to define the role that information technology plays in generating, gathering, integrating, interpreting, and communicating clinical test data and information. The diagnostic informatics landscape encompasses key areas of the diagnostic process, starting with the selection of the appropriate test/referral to address a clinical question, the quality and efficiency of the analytical process, and finally the interpretation, communication and follow-up of test results (including engagement with patients) and their impact on enhancing the value of care and patient outcomes (see Figure 1).

Figure 1. Diagnostic informatics landscape

Major areas of diagnostic informatics research can thus include the study of the choice of the appropriate laboratory/medical imaging request, the quality and efficiency of the analytical process, and the interpretation and follow-up of test results and their impact on patient care outcomes. Information and communication are a key component of the whole diagnostic process. The aim of this paper is to demonstrate how diagnostic informatics research can be used to inform decision-making and improve health outcomes. We outline three case studies to illustrate the application of diagnostic informatics research to the effectiveness of healthcare:

1. **Data analysis and linkage**, the impact of electronic ordering on the rate of potentially unnecessary repeat tests for older hospital inpatients.
2. **Organisational workflows**, the use of Business Process Model and Notation (BPMN) techniques to model and simulate crucial test result management and communication workflows in the diagnostic process.
3. **Patient/consumer involvement in the co-development of research approaches**, where consumers are partners in the development of the research process.

Case studies

Case study 1: Using data linkage to study repeat testing amongst older hospital patients

Aim

The aim of this study was to determine whether electronic provider ordering of laboratory could contribute to a reduction in potentially unnecessary repeat tests.

Methods

A retrospective study investigated 1,367,015 laboratory tests from 55,979 admissions of inpatients aged 80 years and over across three metropolitan hospitals from New South Wales, Australia, between 2014 and 2016. Data from the pathology service laboratory information system (Omnilab v9.4.2 SR10 updated to v11.1.1 SR23 in 2016), containing laboratory test information, and the patient administration system (Cerner PowerChart v2010.02.16), containing admission information, were linked by matching de-identified patient medical record number, gender, date of birth, hospital, and date-times of laboratory tests and admissions-discharges. The linked dataset was used in the analyses. The five most frequently utilised laboratory tests were identified and used to investigate repeat testing. The proportion of repeats were reported for electronic and paper-based test orders.

Results

The most frequently utilised laboratory tests for older inpatients aged 80 years and over were Electrolytes-Urea-Creatinine (EUC), Full Bood Count (FBC), Calcium-Magnesium-Phosphate (CaMgPhos), C-Reactive Protein (CRP), and Liver Function Test (LFT). The total number of tests by the ordering method (paper or electronic) are shown in Table 1. Among EUC, FBC, and LFT tests, there were more repeat tests among paper-based orders compared to electronic orders. The reverse was true for CaMgPhos and CRP tests. (Table 1).

Table 1. Proportion of tests which are repeats of a previously conducted test during a patient's admission, shown by paper-based or electronic ordering of tests

Test		Repeat Tests (%)	Total (n)
EUC	Paper	82.1	7,474
	Electronic	78.3	236,883
FBC	Paper	80.6	6,662
	Electronic	77.6	231,170
CaMgPhos	Paper	68.5	5,070
	Electronic	70.6	121,125
CRP	Paper	67.2	4,460
	Electronic	72.0	85,915
LFT	Paper	63.5	4,085

The repeat test interval (i.e., the time between successive repeat tests) was shorter for paper-based orders (examples of two of these tests, FBC and CRP, are shown in Figure 2). The difference in the cumulative proportions of repeat-tests between electronic and paper ordering became progressively smaller with increasing time between the repeat tests. Similar time-trends were observed for all of the top five tests.

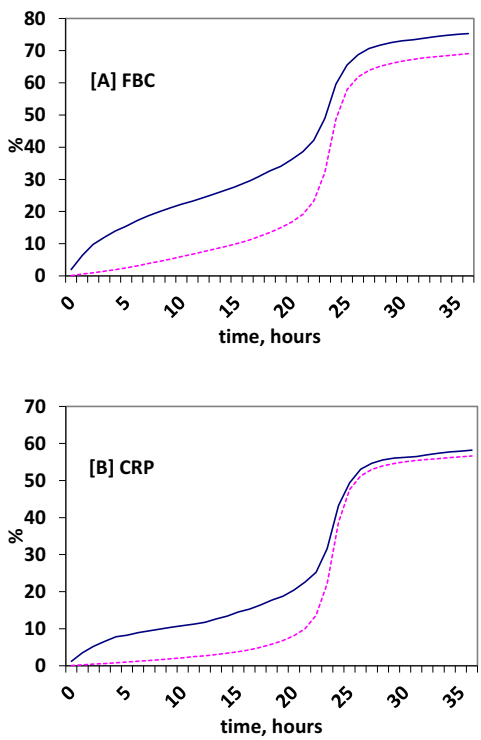

Figure 2. Cumulative proportions of repeat testing (horizontal axis) as a proportion of all test orders, by time (vertical axis; hours) for two analytes. Time intervals up to 36 hours shown. (A) Full blood count (FBC) (B) C-reactive protein (CRP) (Solid line=paper, dashed line=electronic)

Discussion

This study showed that paper-based orders were repeated with shorter time between tests when compared to electronic orders. This observation is similar to the study by Li *et al.* [14], which also found shorter time between repeat tests in paper-based test orders among paediatric intensive-care unit patients. Guidelines outline the minimum repeat testing intervals for a meaningful change to be observed as: 12 hours for EUC and FBC tests, 36 hours for LFT and CaMgPhos tests, and 24 hours for CRP tests [13]. Although repeats before the suggested minimum retest interval were observed for all tests, paper-based orders had a higher proportion of repeats with shorter intervals between tests when compared to electronic orders. Potential reasons for this difference as proposed by Li *et al* included: (1) duplicate order alerts were provided in the electronic ordering system, notifying clinicians that an identical test had already been ordered within 24 hours for the same patient; and (2) clinicians could more easily see existing test orders and results in the electronic ordering system, thus leading to better self-regulation of ordering decisions [14]. This study provides valuable information on the differences between electronic and paper-based laboratory test orders on repeat tests. The findings suggest that electronic ordering can potentially reduce potentially unnecessary short-interval repetitions of tests.

Case study 2: Using Business Process Model and Notation (BPMN) techniques to model communication workflows in the diagnostic process

Aim

The aim of this study was to model communication workflows in the diagnostic process.

Methods

In order to form an in-depth understanding of the context in which a system (e.g. electronic test result management) operates, we created a generic high-level process model for test-results management. The model was developed using the Business Process Model and Notation (BPMN) standard [16], a technique which uses structured analysis to diagrammatically represent business processes using standard symbols to provide insights into the complexity of healthcare processes. Models were created with the Bizagi Modeller freeware application.

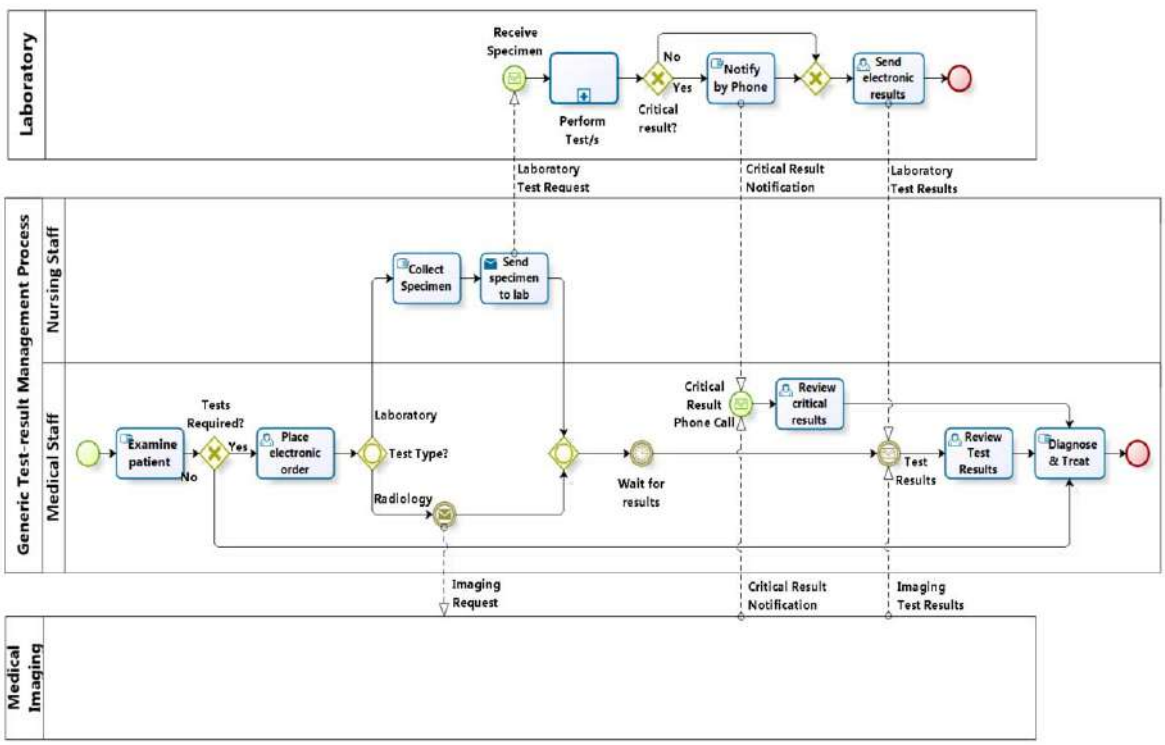

Figure 3. High-level process model for test results management developed using the Business Process Model and Notation (BPMN) standard

Results

The BPMN 2.0 standard allows processes to be represented using '*pools'* (which can be divided into multiple *'lanes'*) to clearly identify which participants perform each '*activity'*. This is demonstrated in Figure 3 as a high level process model. Three 'pools' are represented, namely the laboratory, medical imaging and a clinical department (represented by a medical staff 'lane' and a nursing staff 'lane'). Medical imaging is represented as a 'black box' i.e. only the message flows into and out of the pool are represented. In contrast, the laboratory and clinical department are modelled as 'white boxes' where all activities related to the process are visible. Following the arrows from the start (green circle event) of the process shows the sequence flow of activities (blue rectangles). The process pathway deviates based on the decision outcomes of questions posed at each gateway (yellow diamond).

The model in Figure 3 depicts the interaction between the pool containing the process of test result management by medical and nursing staff in a hospital test setting, with the pools of laboratory and medical imaging processes. Diamond shaped *'gateways'* depict decisions in a process where one or more

alternative paths may be taken (e.g. is a test required, or is a result critical). Circular shaped '*events'* (e.g. receiving a specimen, waiting on results, or calling through a critical result) can be used to indicate pertinent events in the process including (but not limited to) the start or end of a process, time related events or instances where messages are sent/received.

Discussion

The BPMN model highlights the value of using structured analysis to visualise healthcare processes. The technique allows proposed changes to processes to be modelled to determine their impact on existing workflows. As more data are collected, it will be possible to use BPMN to run theoretical process simulations.

BPMN enables business processes to be visually represented for ease of understanding and analysis. It can thus aid in enhancing the design and evaluation of evidence-based interventions, such as test result management tools/interventions (including electronic decision support aids) to consider how they impact on existing communication processes. This is particularly important for the laboratory notification of high-risk test results to the appropriate and responsible clinician, for immediate clinical action. Other clinical scenarios that have applied BPMN techniques include modelling clinical pathways [17; 20], for process improvement [1; 6; 20], for pre/post implementation workflows [9] and in genetic testing processes [6].

Case study 3: Engaging consumers in the analysis of diagnostic studies

Aim

The aim of this study is to involve consumers in the diagnostic informatics research process to assist in the establishment of person-centred test result management systems.

Methods

Consumer-focused research is a critical element in the development of person-focused care and shared decision making, which can contribute to improvements in the safety and quality of care. Health consumers can be defined as previous, current, or potential patients and their carers accessing healthcare services [11].

A core component of our research strategy was the establishment of a Consumer Reference Group which engaged consumers as partners in the research process. The value of research increases when consumer participants are familiar with how research is designed and undertaken [12]. Meaningful engagement of patients as partners in the research team requires the provision of adequate preparation and training for their research roles [3], which are achieved through capacity building activities and workshops. These hands-on learning activities ensure that the patient/consumer is involved in all phases of the research project.

Consumer representative organisations provided input during the development of our research proposal. We held a stakeholder forum to launch the project, where key recommendations were identified to address threats to patient safety resulting from failure to follow up test-results.

Informed by the stakeholder forum, we conducted semi-structured interviews with a diverse purposive sample of clinicians, radiology and laboratory staff, and patients within three NSW Emergency Departments in Australia. Consumer (including through interviews with patients) and clinician perspectives positively shaped the direction of the research study [7]. Interview results were used to compare current work processes and gauge patients experience of the test-result management cycle. Re-iterative qualitative thematic analysis was conducted.

Results

Ten consumers formed a Consumer Reference Group (CRG) and ranked themes (previously identified in interview analysis) according to their chosen order of importance. The CRG then analysed (in an interactive qualitative data analysis workshop with members of our research team) the two topics with the highest ranking: 1) 'Transitions of care' (how and if results move from one healthcare setting to another including procedures related to patient discharge); and 2) 'Access' (whether and how a person can have access to their results).

Discussion

This innovative, consumer-driven approach engaged consumers/patients in inclusive research which provided rich insights into consumer experience and expectations in test-result management. Moving forward, consumers will be invited to contribute to the preparation of research publications, including contributions of intellectual content and critical revisions of the manuscript. Dissemination of the study findings via academic and policy publications will inform future directions for research in this area.

Figure 4. Consumer reference group and research team

Enhancing consumer contribution through inclusive research has required, and continues to necessitate, a rigorous, open, negotiated, and interactive process. Ensuring consumer/patient involvement during all phases of the project, including the inclusion of consumers in data analysis, represents a step towards research that is co-produced with consumers. Our consumer engagement strategy helps build capacity by assisting consumers in developing relevant research skills which will enable them to effectively navigate and inform outcomes-based research.

Conclusions

Diagnostic informatics requires an innovative and inter-disciplinary approach to enhancing clinical excellence and quality care through the incorporation of outcomes-based approaches to monitoring and measuring diagnostic quality. These approaches include the building of robust communication workflows and evidence-based electronic decision support systems, and the establishment of shared decision-making through consumer/patient involvment.

The three case studies outlined above demonstrate how diagnostic informatics can be used to answer key research questions. In Case 1, linking diagnostic data with patient outcomes uncovered valuable information on differences

between electronic and paper-based laboratory test orders and the impact of electronic ordering on repeat tests. This evidence can contribute to the development of decision support tools to promote appropriate and safe test ordering. Case 2 demonstrated how business process modelling can be used to visualise healthcare processes in the diagnostic pathway, helping to optimise design through the identification of potential problem areas and the modelling (and simulation) of interventions. The ability to identify and explicate health care processes provides a valuable means of enhancing the design and implementation of digital systems, thus providing a valuable connection for the development of research tools identified in Case 1. Finally, Case 3 showcased the importance of consumer-driven analysis and interpretation of study findings, which allowed us to identify consumer-perceived barriers, leading to the development of person-centred, safe and effective test result management systems. A better understanding of diagnostic informatics as an integral part of the diagnostic process is crucial to the future quality and safety of patient care.

Acknowledgements

This work was supported by National Health and Medical Research Council, Partnership Project Grant number 1111925 with partners including NSW Health Pathology and the Australian Commission on Safety and Quality in Healthcare. We also acknowledge and thank all participants who participated.

Ethics approval was granted by the Human Research Ethics Committee of the relevant Local Health District, ratified by Macquarie University. All relevant site-specific assessments have been approved.

Possible Usages of Smart Contracts (Blockchain) in Healthcare and Why No One Is Using Them

Alain Giordanengo[a,b]

[a] *Department of Computer Science, UiT The Arctic University of Norway, Norway,*
[b] *Norwegian Centre for E-health Research, University Hospital of North Norway (UNN), Tromsø, Norway*

Abstract

Security, privacy, transparency, consent, and data sharing are major challenges that healthcare institutions must address today. The explosion of the Internet of Things (IoT), the enactment of the General Data Protection Regulation (GDPR), the growing trend of patients self-managing their diseases, and the eagerness of patients to share their self-collected health data with primary and secondary health organisations further increase the complexity of these challenges. Smart contracts, based on blockchain technology, can be a legitimate approach for addressing these challenges. Smart contracts define rules and penalties in an agreement, enforce those rules, and render them irrevocable. This paper presents a state-of-the-art review (as of May 2018) of the possible usages of smart contracts in healthcare and focuses on data sharing between patients, doctors, and institutions.

Keywords:

smart contracts, healthcare, blockchain, trust

Introduction

Since the enactment of the General Data Protection Regulation (GDPR) in May 2018, the security, privacy, transparency, and consent for patient-owned medical data have been at the forefront of the concerns of healthcare institutions. The explicit consent of patients for processing health data and the transparency notice explaining what data will be collected, how it will be collected and patients' rights to full access to their health data [1] have greatly affected healthcare information systems.

In addition to the data generated by healthcare institutions, patients are increasingly active in managing their diseases by collecting health data using mobile devices and sensors [2]. Sharing patients' self-collected data with medical systems has a positive effect on disease management [3], and patients are eager to participate [4].

Blockchain technology is receiving extensive publicity in healthcare and has promised great improvements, such as smart healthcare management and patient empowerment [5]. Smart contracts implemented using blockchains, sometimes referred to as Blockchain 2.0, are protocols permitting the verification and enforcement of legal agreements between two or more parties and rendering them irrevocable. Interest in smart contracts has been growing ever since the creation of Ethereum, the first blockchain-based solution that integrated smart contracts, which was publicly released in 2015. Smart contracts can allow patients to manage access to their health records, secure data exchange, and ensure the privacy of those exchanges [6].

This paper presents a state-of-the-art review of the possible usage of smart contracts in healthcare, their objectives, and their limitations, with a focus on data sharing, and discusses why no one is using them in a real situation today.

Methods

Scientific and grey literature search

The author followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) methodology to perform a scientific and grey literature search. Figure 1 shows the keywords and the search query selected by the author. Three peer-reviewed online databases were searched: PubMed, IEEE Xplore and Web of Science, together with Google Scholar. The author tailored the search query for each online database according to its specific functionalities. The search query was limited to the metadata fields: title, abstract and keywords.

---

smart contracts[Title/Abstract/Keywords] AND
(clinical[Title/Abstract/Keywords] OR
healthcare[Title/Abstract/Keywords])

Figure 1: Search query and keywords used for the scientific literature review.

The author imported all the results from PubMed, IEEE Xplore and Web of Science, as well as the results displayed on the first page of Google Scholar, to Rayyan [7], an online tool that facilitates the review process. The author chose Rayyan based on its lack of cost and flexibility compared to other tools [8]. The author first excluded results based on their metadata fields (title, abstract and keywords) using criteria listed in the next section. The author then reviewed the remaining results for inclusion based on the full texts.

Inclusion and exclusion criteria

The papers needed to meet several criteria to be included in this review. The papers needed to do one of the following:

- Describe a model or an implementation using smart contracts in a healthcare-related situation;
- Illustrate an idea for, or the potential effects of, smart contracts in healthcare systems or medical workflow.

Systematic or literature reviews that provided sufficient information regarding smart contract usages in healthcare were also included.

Papers focusing on the blockchain technology stack or smart contract algorithms, but without illustrating their uses in a clinical setting, were excluded.

Studies reported in languages other than English were excluded.

Data categorisation and data collection

The content of the papers has been organised according to a taxonomy defined by the author for presenting an overview of the usage of smart contracts in healthcare. The categories comprise the following:

1. *State of the presented work*: the part of the life cycle in which the described work is positioned (e.g. proof-of-concept [POC], prototype, production);
2. *Objective*: the situations in which the smart contracts can be used and what their goals are, or what challenges they are addressing;
3. *Content of the smart contracts*: the data or information that the smart contracts contain;
4. *Technology stack*: the frameworks, components, software, or standards on which the smart contracts rely on;
5. *Concerned Actors*: the actors affected by the introduction of the presented work in healthcare (e.g. electronic health records vendors, clinicians, patients);

The author used these categories to evaluate and analyse the included papers. Each included paper was expected to address at least one of these categories.

Results

Reviews on literature

Figure 2 shows the selection of articles. In total, forty-three articles were identified from the literature search: thirty-three from peer-reviewed literature and ten from Google Scholar. Eight duplicates were identified and removed. The author reviewed titles, keywords and abstracts of thirty-five papers, and fifteen were excluded based on the criteria specified in the previous section, leaving twenty articles for full-text assessment. Ten further articles were identified for exclusion for the following reasons:

- Out-of-scope papers (8): five papers cited healthcare settings as potential examples but did not include them at any stage of their studies, while two others limited their trials to blockchain technology that did not involve smart contracts. One paper focused on metrics for assessing blockchain-based healthcare apps instead of describing a model or an idea.
- Inappropriate description (1): the description or testing of an idea included insufficient details that would permit solid reproduction of the claims made.
- Full article innaccessible for review (1).

Ten papers were included in the final collection and analysis.

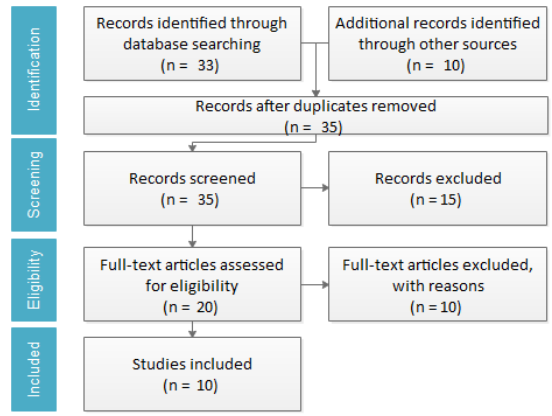

Figure 2: PRISMA flow diagram

Data extraction from included articles

The evaluation and analysis of the included articles (Table 1) are based on the categorizations described previously in the methods section.

State of the presented work

It is important to note that none of the nine studies (omitting one literature review) presented have reached the production stage. Of the nine presented studies, one is a model (i.e. a solution that is not entirely functional), three are POCs (i.e. demonstrating the feasibility of a concept) and five are prototypes (i.e. providing almost all features of an end product). None have been tested in a real-life situation.

Objectives of smart contracts, their contents and concerned actors

Six studies used smart contracts for managing data sharing. These studies concerned patients, medical workers and healthcare institutions.

- Dubovitskaya et al. [9] defined a prototype using smart contracts for exchanging data between patients and doctors and to manage access permissions. The smart contracts contain three types of blocks: 1) patient-defined permissions for allowing doctors to access or share patient- or healthcare-generated health data. The permissions can specify a data category, particular rights (read, write, and share) and a timeframe. They can also force the anonymisation of data. 2) clinical metadata, which contains all required information for accessing the corresponding data files stored off-chain (i.e. in a classic cloud solution). The clinical metadata also contains a hash of the data files to ensure the unforgeability of the data stored in the cloud. 3) patient private data directly attached to the chain by the patient, such as self-collected health data. This is the only prototype system that allows patients to exchange their data actively, without relying solely on data generated by healthcare institutions.
- Dagher et al. [10] proposed using six smart contracts as access controls for sharing medical records between healthcare and insurance providers. The first contract records the users and the mining operations. The second classifies users as patients, providers or third-parties. The third defines the relationships between users. The fourth defines the ownership of medical records, the fifth specifies the access permissions for those records and the last shares symmetric encryption

keys (SEK). Patients interact with the blockchain by changing the access permissions, while the providers use the SEKs to encrypt or decrypt medical records before sending or after receiving them via an off-chain communication channel.

- Azaria et al. [11] used several smart contracts in their data-sharing prototype for different purposes: 1) registrar contracts, which map participant (patient) identification strings (e.g. social security numbers) to their public signing keys to be used in a blockchain. These contracts also contain policies regarding the creation or updating of identities, and only certified institutions can generate them. 2) patient–provider relationship contracts, which allow patients to fine tune the access rights of their providers regarding any portion of their medical data. These contracts also contain data pointers and can be used between providers. 3) summary contracts, which contain the history of all contracts signed by all parties. For instance, they include all the patient–provider relationship contracts of a patient, who can consult them. They also act as a backup.
- Xia et al. [12] used smart contracts for sharing medical data between cloud providers and medical and research organisations. The smart contracts are used for three main purposes: 1) encrypting medical reports, 2) identifying actions performed on sent data, and 3) revoking access to violated data. The smart contracts contain a data sensitivity level, IDs of the owner and requestor (i.e. who is requesting the data), data IDs, permissions and the cryptographic keys.
- The POC defined by Ahram et al. [13] used smart contracts but for limited purposes compared to the previous studies. First, a smart contract ensures that a patient and only a patient is creating the initial version of their medical records during the first visit to a clinic. A second type of smart contract then ensures the update or transfer of the medical record by or to a provider.
- The POC by Saravanan et al. [14] used smart contracts for sharing health data with clinicians that has been self-collected using sensors. The contracts contain access logs and the shared health data. This solution requires patients to share their private keys with their clinicians off-chain before starting to use the solution.

Two other studies rely on smart contracts for improving medical trials. These studies concern researchers, participants in medical trials and research institutions.

- Benchoufi and Ravaud [15] proposed using two smart contracts to ensure the integrity and transparency of medical trials. The first ensures the irrevocability of the trial protocol by containing the protocol of the study and the statistical analysis plan and by defining the data monitoring committee. The second smart contract contains patient enrolment data (consent and information forms), data collection, trial monitoring, data management and data analysis. Using this approach, the authors claim that the reproduciability is improved and study reports and dissemination of results are impartial. Any public institution can monitor the flow and progress of a study and verify its validity.
- Nugent et al. [16] proposed similar usage of two smart contracts for improving the data transparency in clinical trials. The first is a regulator contract, containing clinical trial authorisation details, which is managed by public regulators (e.g. US Food and Drug Administration). The second is a trial contract, managed by the research organisations, which is used for storing trial protocols, consent forms and anonymised participant information.

The final study, by McFarlane et al. [17], focused on the adjudication of medical billing and the provision of medical access in case of emergency. In the first situation, a smart contract containing patient identification, institution denomination, and the debt owed would be issued. The smart contract would be auto-updated once the patient has paid the debt. In the second situation, a smart contract containing a secondary private key (derived from the original private key) could be issued by the patient to allow emergency services to access medical records, should the patient be unresponsive, have their mobile phone present and have configured emergency access to that phone by bypassing the lock screen. The second situation is only an early model, and no more details are given.

Technology

While a comparison of the different blockchain technologies is outside the scope of this article, it is interesting to note that none of the studies are interoperable, even if they use the same blockchain "family". This is due to the use of proprietary data types, with different types of rules and custom codes for managing the automatic execution of smart contracts. In addition, only one addresses interoperability issues by proposing the use of the Fast Healthcare Interoperability Resources (FHIR) specification to represent medical data.

Five types of technologies are used in these studies. Ethereum, a permission-less blockchain (i.e. any user can create and run code, and its execution relies on miners), was the most used (6 studies of 9), together with specialised libraries or languages that targetthis blockchain, such as Solidity (a contract-oriented high level language targetting the Ethereum Virtual Machine). One of the studies relies on Hyperledger, which is a permissioned blockchain. The authors of that study claimed that Hyperledger is more suited for sharing data than Ethereum [9]. It is permission-limited, and the impersonalisation and risk of data misuse due to the anonymisation of permission-less-typed blockchains both increase the likelihood of a Hyperledger system being used and remove the need to pay for transaction execution (mining). Another study relies on IBM blockchain, and one proposes the usage of ErisDB (renamed Monax in 2017 - https://monax.io/2016/11/08/eris-0120-release/) as well as Ethereum.

Conclusion and Discussion

This paper shows that smart contracts could be used in healthcare in different situations, from data sharing to the improvement of clinical trials. Two studies presented allow patients to upload their self-collected data into a blockchain and share it with their clinicians.

However, the small numbers of studies included (n=9, omitting a literature review) and the fact that none of them were at a commercialisation or production stage raise questions about the usability of this technology in real-life situations. A wider systematic review of blockchain technology, conducted in 2016, showed the same limited results, with only three articles examining smart contracts and no production-ready services [18]. Several possibilities could explain this situation in healthcare:

1. Blockchain will not change how medical records are stored. Blockchain is usable as a registry only, because inserting vast amounts of medical data, such as computed tomography (CT) scans, would render the Blockchain bloated and difficult to manage. The challenges of medical data storageing are the same, whether blockchain is used or not.
2. Blockchain technology is not necessary when trusted parties or regulators control the decision-making processes (e.g. creating smart contracts or mining), as in healthcare. Moreover, private blockchains are arguably only a shared database with at best a journaling of the data, which has existed since the seventies [19]. However, blockchain has proved its usefulness in decentralized situations in which parties cannot be trusted, even if some security issues remain unaddressed today [18].
3. Accessing encrypted patient data in the blockchain requires the healthcare institutions to use the patients' private keys (the public keys being used for encrypting the data). The sharing of a private key renders it public, and therefore not secure. In addition, this raises the question of trusted parties, described in point 2.
4. The GDPR states that patients have full access to their data [1], meaning that they have the opportunity to both manage the access rights and to move any portion or all of their data from one provider to another. Moving data between providers implies the deletion of data held by the old provider. However, it is not possible to delete anything from a blockchain without voiding its integrity and recalculating all the hashes.
5. Some of the actors cited are vapourware. For instance, ErisDB (or Monax, as it is now branded) provides no documentation nor access to a single piece of code, but still advertises its products. These practices increase doubts about the usefulness of the technology.
6. There are contradictions regarding the potential impacts of the costs of using a blockchain-based solution by healthcare institutions; some suggest that cost savings could be made [20] while others point out probable cost increases due to the nature of blockchain itself (e.g. computational power and storage increase due to data replication) [21].

Based on these considerations, the author believes blockchain-based technologies are not adapted and not ready yet for usage in healthcare, at the time this study was conducted (May 2018). Moreover, another study has suggested that the usage of these technologies is extremely immature and lacks public or expert knowledge, making it hard to form a clear strategic vision of its true future potential [22].

Abstract

Medical calculators play an important role as a component of specific clinical decision support systems that synthesize measurable evidence and can introduce new medical guidelines and standards. Understanding the features of calculators is important for calculator adoption and clinical acceptance. This paper presents a novel classification system for medical calculators. Metadata on 766 medical calculators implemented online were collected, analyzed, and categorized by their input types, method of presenting results, and advisory nature of those results. Reference rate, publication year, and availability of references were collected. We found the majority of calculators are likely not automatable. 16% of medical calculators present advisory results to clinicians. 83% of medical calculators provide references. We show a 9-year lag from publication to implementation of calculators. New medical calculators should be developed with EHR integration and the advisory nature of results in mind so that calculators may become integral to clinical workflow.

Keywords:
Medical Calculator; Clinical Decision Support Systems.

Introduction

Electronic health records (EHR) are becoming highly prevalent in hospital systems [1]. Clinical decision support (CDS) within EHRs is also ubiquitous. Technologies such as the SMART platform [2], the HL7 FHIR data interface [3], and CDS Hooks [4] are helping drive the development of CDS that can be used in any EHR system. At the same time, studies have shown quality, workflow, and efficiency benefits for users of decision support systems [5,6]; however, these benefits are not universal for all CDS [7,8].

Some CDS systems have medical calculators as a major component; therefore, it is important to understand medical calculator attributes. Medical calculators embody evidence-based medicine and are typically based on scientific literature [9]. Some medical calculators are embedded into EHRs and can be considered ubiquitous such as the automatic BMI calculation. The proliferation of technologies, such as the internet and EHRs, have obvious implications on the accessibility of patient data and access to medical calculators. While the majority of medical calculators are simple and straightforward, there exist many online, web-based medical calculators that may be provisioned within an EHR.

Workflow integration and dissemination techniques are common themes in literature examining CDS. Previous broad studies on CDS have identified workflow, adoption, effectiveness, and dissemination of knowledge as top challenges [10,11]. Appropriate integration of CDS has been problematic, with alert fatigue being well studied [12,13]. Recent studies have investigated the potential for automating calculation of medical calculators, highlighting the opportunities and challenges of doing so [14,15].

The appropriate provisioning of CDS was characterized by the "five rights": making the right information available to the right person, in the right format, through the right channel, at the right time [16]. The automatic provisioning of CDS can have a positive impact on important healthcare issues, such as patient safety [17], racial and gender disparities [18], and process adherence [19]. In addition, prior studies show that factors such as automatic provisioning of CDS tools [6,20] can impact the adoption and success of CDS. Moreover, the Kawamoto study [21] identified several important relevant factors driving CDS adoption that are applicable to medical calculators: a) automatic provision of decision support as part of clinician workflow, b) provision of recommendation rather than just an assessment, and c) computer-based generation of decision support.

Classification of medical calculators is an important topic that impacts provisioning techniques. There is no widely accepted standard classification of CDS, and no comprehensive taxonomy for medical calculators. Osheroff et al., proposed a generic CDS taxonomy based on user interface [16], while Berlin et al. developed a framework for the classification of CDS (the CDSS Taxonomy framework) [22]. Calculator inputs and outputs have not been well studied. Dziadzko et al. [23] classified a subset of online calculators by their specialty, calculation methods, and goal, but did not further describe the output modes of a calculator. Aakre et al. [15] studied the specific availability of the inputs of 168 clinical calculators within the EHR and classified them as easily extractable, extractable with advanced techniques, or not extractable, but did not provide a taxonomy to describe different input types and the impact those types have on automatic calculation. Of the existing literature, the Berlin et al. framework provides the most broadly applicable framework for assessing a CDS like medical calculators. Their Reasoning Method, Recommendation Explicitness, and Explanation Availability attributes are particularly pertinent to calculators due to their simple nature.

The importance of workflow integration and automation on CDS adoption is clearly defined in literature; however, current research does not address the specific contributions that the structure of a medical calculator may have on the ability to automate and integrate these types of CDS into EHR workflow. These currently unknown attributes of calculators may have a direct impact on medical calculator adoption. We expand the current state of CDS classification by identifying attributes that are unique to medical calculators. Their potential for automatic

calculation and delivery of advisory information to clinicians and calculator input and output modalities are important factors for clinical acceptance and workflow integration. We also examine literature references of calculators to determine availability and lag between publication and implementation of online calculators.

Methods

We performed an assessment of three currently available online services that provide access to medical calculators, consisting of two free services and one commercial service. These services are anonymously referred to as Service 1, Service 2, and Service 3, respectively. The two free services were the first two non-medical-specialty specific web-based services appearing in the top 10 "organic" search results using the term "medical calculator" through a Google search. The commercial service was selected due to its availability in the University of Missouri Health System (UMHS). In total, these three online medical calculator services contained 766 implemented medical calculator algorithms.

Input types were determined by performing HTML data scraping of the HTML input tag from Service 3. Each input was classified into a type by examining the HTML input type (radio, checkbox, number, or text), and whether the data was a discrete value, a logical computation of a discrete value, required interpretation or the opinion of a clinician, or were worded in such a way as to require data from a patient and be unlikely to be stored in the EHR. The resulting types were checked for completeness during classification of the entire set of calculators.

Calculator output types were determined by examining all calculators in the study. Each calculator page was opened and classified into one or more of the output type categories. Categories were added as new output types were encountered. The calculators' targeted user (physician or patient) was captured and their references were collected where available. The calculator type was also assessed by examining the input and output modalities and targeted user to arrive at a classification. Calculators that did not fall into an already encountered type were assigned to a new type.

Results

Using the CDSS Taxonomy framework, we accounted for Reasoning Method, Recommendation Explicitness, and Explanation Availability during our data collection. Data inputs, calculator outputs, and calculator references were documented for each calculator in the three services. Calculators were then categorized based on these factors.

Calculator Inputs

To provide a generalized guide for future calculator development, we examined the inputs necessary for medical calculators and generally classified them as follows:

1. Discrete Data Elements – these are atomic pieces of data stored in an EHR. For example, the rate of creatinine clearance.
2. Non-discrete Data Elements – inputs of a non-discrete nature can ask for medical opinions of providers, for example, the likelihood of a diagnosis.
3. Logical Computation on discrete data elements – a calculator that asks if a value is over or under a certain threshold, or within a specified range, requires logical computation to determine an input value. For instance, in a point-based calculator, assigning points based on age ranges falls into this category.
4. Obscure Data Elements – Data elements unlikely to be contained as structured data within an EHR. For example, the NIH Stroke Score requires the patient to identify the current month and his or her own age.

Calculator Output

For demand-driven calculators, the way in which calculator results are delivered (Recommendation Explicitness [22]) were considered germane in our review as they are related to the advisory nature of the calculator output. Advisory calculators suggest a diagnosis or recommendation, and non-advisory are assessment only, providing a probability, score, or discrete information result. We identified five different types of results display, classified as either non-advisory (types 3, 4, and 5) or advisory (types 1 and 2), with Table I showing the distribution of these.

1. Diagnosis - Calculator presents a potential diagnosis, for example the Duke Criteria for Infective Endocarditis [24] provides a definite, probable, or rejected diagnosis for infective endocarditis
2. Advice/Recommendation - Calculator suggests or recommends a specific course of action, such as the HEMORR2HAGES Score for Major Bleeding Risk [25] which suggests initiating therapy based on calculator results.
3. Probability - Calculator provides a probability of patient having or developing a condition. The APACHE II Score [26] provides a probability of mortality
4. Classification - Calculator classifies patient in one or more categories. For example, the Apgar Score [27] classifies infants as normal or requiring intervention.
5. Discrete Information - Calculator provides a discrete data value for provider to use. The BMI calculator provides the well-known ratio of body weight to height.

Kawamoto [21] indicated that the success rate for decision support use is substantially higher for CDS that provision a recommendation versus an assessment. We found that just 16%

Table I - Percentage breakdown of output types of calculators. Note that a calculator may present multiple output types.

	Service 1 (n=138)		Service 2 (n=498)		Service 3 (n=130)	
Output Types	**Count**	**Percent of total**	**Count**	**Percent of total**	**Count**	**Percent of total**
diagnosis	2	1.45	27	5.42	6	4.62
advice/recommendation	42	30.43	37	7.43	7	5.38
probability	23	16.67	41	8.23	4	3.08
classification	75	54.35	195	39.16	69	53.08
discrete data	33	23.91	249	50.00	56	43.08

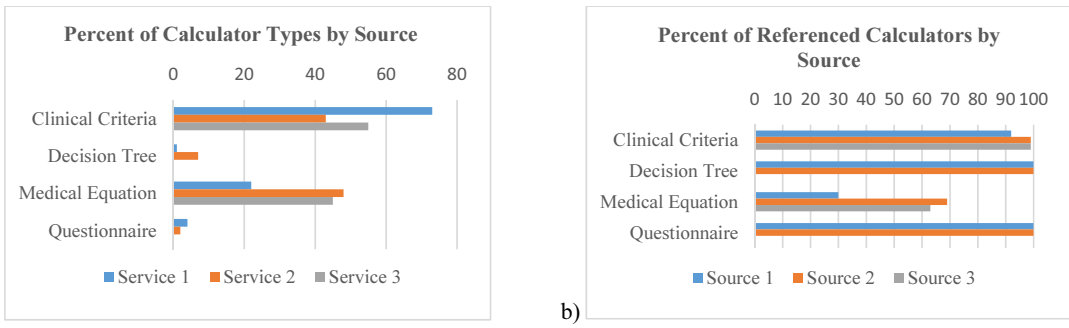

Figure 1 – Calculator Types and References by source. a) shows that Clinical Criteria and Medical Equations are the most popular types of medical calculators. In b) we find that Medical Equations are far less referenced than the other types.

(121/766) of calculators fall in the advisory category. With the majority of analyzed calculators not providing recommendations, there is a lower potential for significant adoption of medical calculators.

Calculator Categorization

Calculators in this study were analyzed and categorized into four major types:

1. Clinical Criteria – These are clinician facing calculators typically implemented as a scoring system. Answers to specific questions accrue points, with the total then looked up in a table to define the calculator output. These can require any combination of the four Input Types. For example, Total Cholesterol required by the ACC/AHA 2013 Cardiovascular Risk Assessment [28] accepts discrete data input. The Wells Score System for Deep Vein Thrombosis [29] asks for non-discrete data elements through questions such as "An alternative diagnosis is more likely than deep-vein thrombosis." The Multiple Myeloma Diagnostic Criteria [30] has input with logical computation on discrete data elements (M Protein: IgG > 3.5 g/L). The Head CT Rule for Minor Head Injury [31] requests obscure data elements such as "Inability to bear weight right after the injury as well as in the emergency department". Combinations of any of the input types may also be requested, as in the Metabolic Syndrome Criteria [32]: "Blood pressure >=130/>=85 or on blood pressure prescription"
2. Medical Equation – All inputs are Discrete Data Elements. The result of the calculator is found by computing a formula with the appropriate values. For example, the Cockcroft-Gault equation for estimating creatinine clearance is CreatClear = Sex * ((140 - Age) / (SerumCreat)) * (Weight / 72), where the value for Sex is 1 for male and 0.85 for female [33].
3. Questionnaire – Inputs can be any of the four Input Types and are designed to be answered either by a patient or in collaboration with a patient. A scoring system is usually employed, similar to Clinical Criteria. An example is the CAGE Questionnaire [34], which contains input prompts such as "Have you ever felt you needed to cut down on your drinking?"
4. Decision Tree – Inputs presented to users are dependent on answers to prior questions. A scoring system is used similar to Clinical Criteria. The PECARN Pediatric Head Injury/Trauma Algorithm [35] is an example of a decision tree.

Figure 1(a) shows the distribution of calculators by type across the three analyzed calculator services. Clinical Criteria calculators make up the majority of catalogued calculators. Because they can require Input Types other than Discrete Data Elements, additional steps may be required by the provider to search the EHR or other sources for relevant data and could reduce the likelihood of utilization. Medical Equations make up the next largest category. These are the only type that rely solely on Discrete Data Elements. Given the availability of EHR data, they can be automatically computed without interaction from a clinician. Questionnaires and Decision Trees make up a collective minority of the catalogued calculators. Both types are designed to be highly interactive and thus do not lend themselves well to automated computation.

Calculator References

The rate at which references were made available, for which types, and the accessibility of those references, were collected during calculator analysis. The availability and access to references fulfills a portion of the CDSS Taxonomy framework's "Explanation Availability of the Information Delivery axis" [22]. Clinicians can gain an understanding of the reasons behind a recommendation from the primary literature and is complimentary to the advisory content of medical calculators. The distribution of references by calculator type is presented in Figure 1(b). While the numbers of decision tree and questionnaire calculators were very small, we did note that Service 1 and Service 2 referenced 100 percent of these types. Clinical criteria calculators were referenced more than 90% of the time, with two services approaching full coverage. Medical equations were the least referenced type of calculator across the three services we analyzed.

We found that each of the three services presented references in distinct ways. One service listed references in citation style, while the other two attempted to provide URL links and categorization of the references. A primary concern uncovered in our analysis was the accessibility of the references. We conducted a detailed analysis of the largest calculator service that provided URL links (Table 2). A deeper analysis of the NCBI links showed that they all led to PubMed, a site which makes freely available basic information on articles, such as

Table 2 – Reference links provided by Service 2

Domain	Count
Internal Site Reference	47
Other URL	55
No URL Provided	65
www.ncbi.nlm.nih.gov	589

publication year and abstract, but not the full text. Lack of access to full text references could be an important factor in the adoption of newly implemented medical calculators.

An analysis of the publication year of the NCBI references supported a trend towards older publications (Figure 2), with the median publication year being 2002. Growth of implemented calculators follows an exponential curve until 2006. In the same year, there is a change in the rate of medical calculator implementations. Because this analysis represents a single point in time snapshot of medical calculator implementations as of March 2015, and implementation dates of online medical calculators are not available, we can only hypothesize that the reason for the change in calculator implementation rate is a lag from publication to implementation of approximately 9 years. Studies of medical research publication to widespread practice implementation show a similar lag of 17 years [36] to 24 years [37].

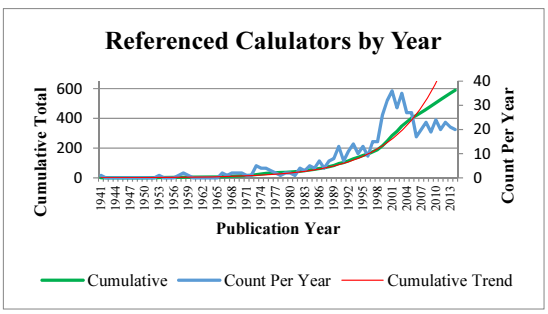

Figure 2 – Number of referenced calculators by year.

Discussion

Our analysis shows that less than half of available medical calculators lend themselves to fully automatic calculation of results, with past research indicating that the adoption of CDS increases with automatic provisioning [21]. The ability of a calculator to have its results displayed automatically is rooted in the decisions made during the research that produced the calculator publication. While any calculator may be included in provider workflow at the "right time", only a minority of calculators could automatically provide the resulting answer without requiring a clinician to manually input data that may already be available in the EHR. Medical equations are the single type of calculator capable of providing the result without the interaction of the user- this is due to the inputs requiring only discrete, structured data. Clinical criteria may be automated but may be challenging to develop due to the varying types of inputs that could be required. The other types of calculators (e.g. decision trees and questionnaires) are less suitable for automatic calculation due to their interactive nature. Thus, as new predictive models are developed, careful consideration should be given to the type of calculator that could be implemented. Medical equations and clinical criteria could be the preferred implementation if adoption and dissemination are desired for the model.

The advisory nature of current medical calculator outputs is also not consistent with prior studies that suggest recommendations lead to better adoption [21]. Only a small percentage of the calculators we studied (16%) provisioned results in an advisory fashion. Two of the most active forms of delivering medical calculator results included suggesting a diagnosis, and dispensing advice or recommendations for treatment. While we surmised that many factors play into the ability to provide advisory results, e.g. validation studies, liability, and confidence, it nevertheless is a factor related to adoption and should be considered in the development and publication of new predictive models.

Finally, 83% of implemented medical calculators in this study provided reference materials. The high rate of reference availability could prove a useful method of introducing new evidence-based medicine directly in the clinical workflow as embedded medical calculators; however, the inaccessibility of full text references may be problematic. It requires further study to determine whether or not reference availability would have an impact on perceptions of calculator credibility. The noted median year of publication of medical calculators was 2002, which highlights a potentially missed opportunity to leverage EHR deployed CDS as a means to introduce new evidence based medical literature.

Conclusion

This paper presents a taxonomy of medical calculators that can be used to inform future research in medical calculators and predictive algorithms. Researchers ultimately may be best positioned to impact the future of CDS adoption by becoming more cognizant of the types of data used to build these models, and the advisory nature of the results, and by being conversant in the fundamental structure of a medical calculator. These decisions may influence the speed at which new predictive models are implemented and delivered as automatic decision support within EHRs. EHR vendors and implementers should take note of the five rights of CDS, relevant usability and automation concerns, and disparities between different levels of clinical experience to design calculator workflows that are deployed automatically to end users. As CDS becomes more accepted as part of the delivery of medicine, evidenced by recent opinion [38] and the creation of "npj Digital Medicine" [39], insights into the issues surrounding integration of CDS into clinical workflow will help drive adoption of new technologies. We believe that future medical calculators will go beyond regression analysis and include more complex data, longitudinal data, and data from outside the EHR. Techniques such as deep learning, explainable AI, and big data technologies will make available more decision support that is based on discrete data in an EHR and can be automatically provisioned as medical calculators. Such disruptive and cutting-edge research will radically change medical practice in the coming decades, and contributions in this area must continue to push the comfort zones of the medical community. Building a solid understating in this area, as the collective research on medical calculators does, is necessary to prepare for such a future of digital medicine.

Abstract

Lean management applied to healthcare aims at creating maximum value for patients by reducing waste and waits. It puts the patient's needs center stage, emphasizes employee involvement and continuous improvement. To realize this, visual tools such as the huddle board or the patient board are implemented in hospital wards. The boards are currently realized by whiteboards or flipcharts, which leads to duplicated data entries and loss of information. The objective of this work is to introduce a concept for digitalizing the patient board and integrate with a hospital information system (HIS) for improved data availability. Data on appointments, personnel planning and master patient data can be directly accessed from the HIS database. A digital patient board has several benefits: data can be collected from information systems, making it obsolete to record information several times. Even more functionalities, in particular, those supporting the communication between a patient and a healthcare team can be included by means of a digital board which improves patient involvement.

Keywords:

Health Communication, Hospital Information Systems, Patient Care Management

Introduction

To reduce costs, healthcare providers try to improve their outcomes while simultaneously achieving greater efficiency. One prominent method is lean management; it promises improved quality, capacity, and safety while limiting costs [1; 2]. Lean is a management philosophy that helps to create maximum value for patients by reducing waste and waits. It puts the patient's needs center stage, focuses on employee involvement and continuous improvement [3]. Originally developed for Toyota Production Services, lean has been applied to various industries and is now conceptually described as "an integrated socio-technical system whose main objective is to eliminate waste by concurrently reducing or minimizing supplier, customer, and internal variability" [4].

Visual means such as the huddle board or the patient board are used as tools to implement lean principles into practice [5; 6]. The patient is placed in the middle of all processes. By means of a patient board, be it a flipchart, whiteboard or a customized markerboard, installed in a patient's room, each patient is continuously informed about the course of the stay. On that particular board, a patient's needs and requests regarding the treatment process can be recorded manually during consultation with a doctor (for example, the date of discharge). In addition, the patient can also see what time the nursing staff will check the next time, who is responsible for him or her on a particular day or which examinations will take place on the current day. This information board creates transparency for the patient. Daily objectives defined by physiotherapists, physicians or nurses motivate to do suggested exercises continuously.

There are commercial tools available to support patient communication such as the communication boards from ID Signsystem [10] which are not digital solutions, but customized markerboards. MyCareBoard is a digital whiteboard distributed commercially by the company Lincor [11]. This board is developed for inpatients. It shows the latest laboratory data, provides access to social media tools and shows contact persons for the day. MyCareBoard provides many functionalities that go beyond the lean principle which renders the interaction much more complex. Since the inpatients in our collaborating hospital are often above 60 years, we believe that – in contrast to MyCareBoard - our digital patient board should focus on the provision of relevant information and on a well-defined set of functionalities.

Sehgal et al. found out that whiteboards placed in patient rooms have the potential to improve teamwork, communication and patient care [12]. They can improve patient experience and coordination of care between patients, their family members and hospital staff. Dry-erase whiteboards were used at the bedside but led to frustration for nursing staff, nursing leadership, hospital administrators and patients. Studies showed that one major reason is that these whiteboards fail because pens are unavailable when needed [12].

The use of a whiteboard version of a patient board was evaluated in a project at the Biel hospital center [4-7]. It was found that patients appreciate the visual representation of their daily routine and the planned appointments shown on the patient board. Some weak points were that data must be recorded several times on the different boards, in the HIS and on the patient board. Furthermore, data protection was not given since the current board is placed visibly to all visitors in the patient room.

To overcome these limitations, we introduce a concept for digitalizing the patient board and integrating it into the hospital workflow. Furthermore, we introduce our prototype for a digital patient board. The objective of a digitalized patient board is to increase data availability for patients, improve patient involvement, patient experience and provide a means for asynchronous information exchange and communication with a patient.

Methods

Development Process

Requirements were assessed in discussions with the leading nurses, the head of the nursing department and an IT manager of a Swiss hospital. In an iterative process accompanied by stakeholder discussions, a concept was developed to replace the current patient board realized as a whiteboard by means of a digital solution meeting the above-mentioned requirements. The interfaces to existing information systems were analysed. Finally, a prototype of a digital patient board was implemented considering the requirements from the orthopedic ward. Feedback on the system was retrieved in discussion with nurses and patients (see the section on usability test results).

Lean Management on the Partner Hospital

The hospital *Spitalzentrum Biel* involved in this work adapted the Seattle model of a lean hospital. Among other methods, they apply lean in their orthopedic and gynecology ward. Each ward is split into four zones with a zone comprising 4 patient rooms. In the daily personnel planning, nursing staff is assigned to the single zones. Over the day, nurses only address tasks within the assigned zone. Every hour, they go through the bedrooms in their zone and address the patient issues.

The lean principle is applied to support planning and communication among others by implementing three different boards (flowboard, huddle board, patient board). They are available as whiteboards on which hospital staff can write relevant information. The flowboard is located in each zone of a ward and is used by caregivers. They meet to plan their hourly rounds to the patients and allocate tasks. This information is written on the board. All professional groups of all zones meet twice a day at the huddle board to discuss the daily routine on the ward. The huddle board supports the communication and planning of the tasks in the ward.

The patient board is placed in the patient rooms. By means of a flipchart/whiteboard, each patient is informed about the course of his or her stay. A mobile care trolley was made available to the nursing staff for the hourly rounds. This is a mobile workstation for care to avoid unnecessary interruptions in the working process with patients as well as long distances. It contains a laptop and the most important materials as well as medications [7].

Results

In this section, we introduce the concept for digitalizing the patient board and integrating it with the system and process landscape of a hospital. Further, we describe the functionalities and components of our prototype of the digital patient board.

Requirements

A main requirement for digitalization of the patient board is to provide the same content as the one available on the existing whiteboard patient board, but in a digital format. Information should be accessible through a web application running on two devices: on a touch screen placed in the patient room and a tablet application accessible through a tablet. Nurses, physicians and patients interact with the touch screen. They should be able to enter and modify data. Wherever possible, relevant data items have to be retrieved from existing information systems and shown on the patient board. The information should be displayed in a suitable way for patients and health professionals.

The tablet version is only designed for use by patients. It should enable the patient to enter notes on the daily physiotherapeutic goal and to ask questions. Furthermore, the patient should have access to responsible care providers, appointments, daily physiotherapeutic objectives and the specified requests and needs. Data security has to be ensured in both devices.

Concept

Our concept for digitalizing the patient board and integrating it with the information system environment consists of several devices (Fig. 1).

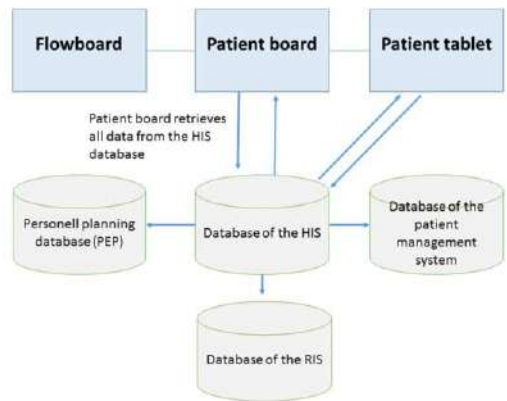

Figure 1: System overview: The patient board is the central data access screen. It is connected to the database of the hospital information system. A subset of the data is available through the patient application using a patient tablet.

The **patient tablet** with patient application is designed for use by patients during their stay at the hospital and allows, for example, accessing the individual daily, physiotherapeutic goal and a progress line.

The **patient board** is a web application accessible through a touch screen located in the patient room. It provides data access for doctors, nurses and patients.

The **patient portal** is an application for patients to be used inside or outside the hospital, mainly providing information on the stay.

Table 1 summarizes the type of information that is available through the different devices. Figure 1 shows the interactions between the different devices (flowboard, patient board and patient tablet) with the HIS and connected information systems. In this work, we are focusing on the digital patient board. However, the flowboard is included in the concept since it is currently under development.

All relevant data shown on the patient tablet or patient board is retrieved and stored in the HIS and is accessed by the different devices listed above. The information shown on the patient board is taken from the HIS database which in turn has interfaces to other databases. For example, from the personnel planning system PEP, the responsible physician and nurse and their period of service, are taken. This information can be shown on the digital patient board in order to select the responsible physician according to the shift planning. In future, additional boards that allow showing the result from shift planning directly on the patient board can be integrated. From

the radiology information system (RIS), scheduled radiology examinations of a patient are collected. The patient master data and case data are taken from the patient administration system. In future work, we will also digitize the flowboard that will also be connected to the patient board and HIS.

Table 1: Information available on different devices

Device	Information provided
Flowboard	Patient ID, surname, first name, patient room number, upcoming examination (where, when) shown in a flow chart
Patient board	Date, surname, first name, date of birth, language, responsible physician and nurses, upcoming examinations, goals, medication, admission date, discharge date
Patient tablet	Responsible physician and nurses, upcoming examinations, physiotherapeutic goals, request and needs from the patient

Patient Board and Patient Application

The electronic patient board was implemented as a web application, specifically implemented for the orthopedic ward of the collaborating hospital. We developed the patient board in two languages (French and German). Languages can be added easily in future, addressing the fact, that inpatients might neither speak German nor French.

When the application is started, the functionalities differ slightly depending on the platform used and access rights. Accessed through the touch board (referred to as patient board in Figure 1) by health professionals, data can be manipulated. More specifically, patient master data can be accessed and individual data records such as the therapeutic goal of the patient board can be modified. Functionalities of the touch screen application for the nurses and physicians include:

- Entering dietary restrictions, responsible care providers, patient needs,
- Specifying physiotherapeutic goal,
- Changing mobilisation schema (Figure 3),
- Entering discharge date,
- Retrieving examination and treatment appointments from relevant information systems.

The system can only be accessed by authentication with a password or patient barcode.

When data is accessed by a patient through a patient tablet, the individual progress is shown on the patient board; questions and needs can be formulated and stored for indirect communication with the healthcare team. In this way, the patient is provided with a platform for recording requests that cannot be addressed immediately by the care team. Contact persons of the healthcare team are listed on the screen. Additionally, the patient application displays a progress curve based on the mobilization scheme and daily goals of the physiotherapy. The display can be personalized so that a patient only sees data that is of importance for him. This ensures that patients are not overloaded by information. In order to make entries in the patient tablet app, patients must authenticate themselves with an integrated barcode scanner. The scanned bar/QR code is compared to the tablet UUID stored in the database and assigned to the patient. Figure 2 shows a screen of the patient application.

Figure 2. The digital patient board shows a progress line with respect to the mobilization progress, daily goal (Tagesziel), needs (Bedürfnisse), responsible nurses and clinicians, or appointments. Elisabeth Brönnimann is a fictitious character.

Figure 3: Mobilisation schema

Usability Test and Evaluation Results

To assess the usability of our digital version of the patient board in its appearances and for the different user groups (tablet vs. touch screen and patient view vs. health professional view), we performed a usability test. Nurses and potential patients have been interviewed. With "potential patients" we refer to persons that were not inpatients at the time of evaluation but are likely to become one day. They were recruited from the authors' social and work environment.

At the beginning of the test, patients were introduced to the topic of lean management and the general idea of the patient board. Afterwards, they were confronted with the app running on a tablet and a set of six tasks which had to be solved. The task included: creating, sharing and deleting a note, scanning a barcode, asking a question, opening the daily goal view and the progress bar.

Nurses assessed the patient board application that we opened in a tablet. Their tasks comprised: specifying the type of diet, adding and removing employees, specifying a mobilization goal and treatment phase, specifying a physiotherapeutic objective, adapting the date of discharge, and answering patient requests.

All participants were asked to think aloud while performing the tasks. A questionnaire with 11 statements and a 5-item Likert scale had to be completed afterwards (see Figures 3 and 4). The statements addressed usability issues (ease of use, understandability etc.) and layout.

18 potential patients and six nurses were involved in the usability test and completed the questionnaire. All participants were able to solve the tasks. The age distribution of the patients is as follows: age group 18-24 (four users), 25-44 (three users), 45-64 (seven users), 65-79 (four users).

The layout and design were well received by the potential patients. They felt comfortable while using the app and

confirmed that they could deal with the app intuitively. 72% claimed that they would be willing to use the application. The overall feedback was rather positive. The complete results from the questionnaire answered by patients are shown in Figure 4.

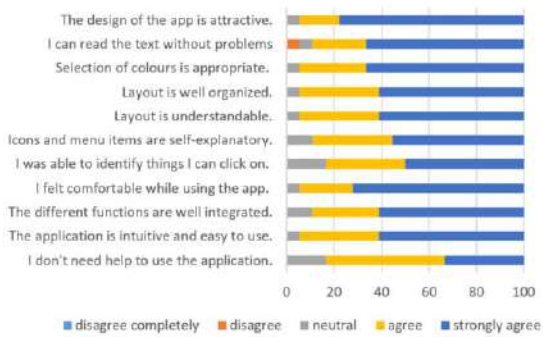

Figure 4: Evaluation results for patients (values in %)

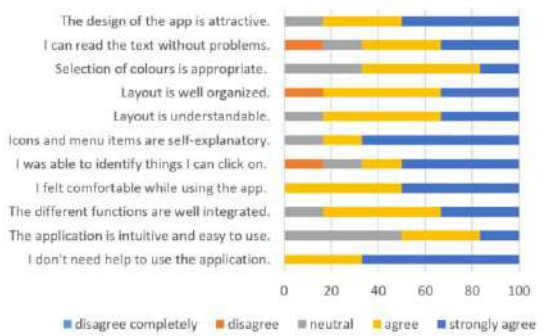

Figure 5: Evaluation results for nurses (values in %)

Compared to the patient-user group, nurses were more critical and had problems with some tasks (see Figure 5). For example, 50% of the nurses did neither agree nor disagree with the statement that the app can be used intuitively. One person had problems in dealing with the app, in particular with identifying things and reading text. However, most of the nurses confirmed they had not needed help to use the application.

Discussion

Benefits of the Digital Patient Board

Improving patient experience and coordination of care between the patients, their family members and staff is important for good outcomes in clinical care. In this paper, we introduced a concept and first prototype for a digital patient board integrated into the information system environment of a hospital. The usability test showed that patients and nurses are aware of the potentials of a digital patient board. Studies showed that patients appreciate having key information organized and available to them at a glance, leading to an increase in patient satisfaction scores [9]. Our digital patient board can facilitate in the future, consistent, standardized, and transparent communication among patients, caregivers in hospitals, medical centers and long-term care facilities.

Our implementation of a digital patient board provides features that are currently not provided by the whiteboard version, but that improve the communication between patient and healthcare team. In particular, the patient is better involved in the care process by having the opportunity to ask questions through the board. Based on the information shared by the patient, employees can respond directly to their respective needs. The patient always has an overview of his treatment and goals in mind.

One open challenge is to decide for an appropriate degree of transparency: since the interest and intellectual capacity of patients differ, the amount and kind of data displayed for the patient has to be considered carefully so as to avoid misunderstandings. Initial interviews with hospital staff show that the need for information also depends on the hospital and wards.

Another important issue is data integrity and data separation. Data integrity is ensured by the user logins and role management i.e. nurses will see more information and have more interaction possibilities when accessing the patient board with their credentials than patients.

The data flow via the corresponding interfaces between information systems in hospitals and the patient board will in future allow employees to dedicate themselves directly to communicating with the patient without having to re-enter existing information such as responsibilities or appointments on the patient board. Waiting times for the patient are reduced, employees are relieved and data integrity can be guaranteed. The economic effect still has to be proven in corresponding evaluations.

The functionalities of the patient board as tested in our prototype have been integrated into a mobile version of KISIM. KISIM is the HIS of the cooperating hospital developed and distributed by a Swiss software company CISTEC AG (http://www.cistec.ch/). KISIM mobile will provide access to the above-listed functionalities of the patient application. The data will be retrieved and stored in the KISIM database.

Problems of the Usability Test

There are some issues that influenced the usability test results. Nurses were not only focusing on their role as nurses but partially provided feedback from a patient perspective, i.e. they made comments on things that they assume to be not intuitive or understandable for patients instead of focusing on their role as nurses.

Another issue is that the “potential users” were not hospitalized and were recruited from the authors’ environment. Regarding usability, we consider these persons as representative since we selected persons randomly not requesting specific technical skills. However, people might conceive things differently when they are really inpatients. We tried to balance the age groups of persons involved in our test and could not determine differences in the feedback depending on the age of the user. As mentioned earlier, the inpatients of the collaborating hospital are older than 60 years. A field study has to be performed to ensure that inpatients can deal with the systems without problems.

A comparison between the whiteboard version and the digital version was not performed. Since the digital version of the patient board contains the same information as the current markerboard version of the patient board, we believe that the information is at least understandable to a similar extent. However, we did not verify this within our usability test.

Future Extensions and Integration with other Digital Boards

As mentioned in the concept section, we envision to digitize additional lean boards. There is already one commercial

product available that digitizes the huddle board (http://www.cistec.ch/abteilungsboard/). It supports an interactive shift scheduling in a ward. Additional functionalities of that board are:

- Providing an overview of the rooms and beds as well as the patients.
- Information from the patient record can be displayed directly on the board (configurable).
- Shift planning: By integrating the planning information from the PEP into the board, the employees of a shift are automatically displayed. These can then be assigned to the patients.
- Planning entries/exits.

The board has been implemented in one Swiss hospital [8] and has been in use since July 2018. We are currently digitalizing the flowboard. Once this is completed, all three boards can be integrated ensuring the best possible data integration and reuse. Questions concerning storage and remarks from patients in the HIS could help in understanding communication problems among patients and healthcare staff.

Conclusions

Lean management is going to be implemented in hospitals to better deal with available resources. In its current implementations, however, optimization potentials exist that could be addressed by means of digital solutions. We introduced our concept for a digital patient board as one crucial component of the lean hospital. The usability test confirmed good usability. Data can be automatically retrieved from information systems.

In future, in particular, the patient tablet as one out of several devices of our concept can be equipped with additional features, such as menu selection, or features for patient education. However, it has to be ensured that patients only see content that is relevant for them and which they can handle. We believe that the standard version of the digital patient board should focus on the information provided by the current patient board. Advanced users should be enabled to use additional functionalities.

Acknowledgements

We would like to thank all the persons involved in the usability test. Further, we thank the collaborating hospital and staff for the productive meetings and helpful comments.

Abstract

Neonatal screening and ongoing follow-up of children with sickle cell disease are essential to reduce the mortality caused by this disease. To ensure care continuity, it is essential to include in the patient's record the history and details of biological tests. Thus, it is necessary to provide a Laboratory Information System for electronic management of biological test prescription and results, and the laboratory system must integrate well with Health Information Systems. In this paper, we propose a Laboratory Information System for the management of biological tests for the neonatal screening and healthcare of sickle cell disease in Senegal.

Keywords:

Clinical Laboratory Information Systems; Anemia, Sickle Cell; Neonatal Screening

Introduction

Large amounts of data pass regularly through Senegal's health system between medical services and biological laboratories. This data includes on one hand the tests issued by the physicians and on the other hand, the test results produced by the laboratories. In addition, there is data specific to laboratory activities such as sampling data, the test results, and the test reports, etc. This data is usually recorded in paper documents and is accessed manually. This situation also leads to recurrent back and forth by patients or their carers between medical services and laboratories. Thus, the labs face enormous problems related to (i) collection, storage and processing of test prescriptions and results, (ii) data security, and (iii) possible impaired data integrity because of the frequent use of archives. It then becomes necessary to implement a Laboratory Information System (LIS) integrated into existing Health Information Systems (HIS) to overcome all these difficulties.

The purpose of the LIS is to manage the laboratory's workflow, including processing, storing, and managing biological analysis data in order to provide accurate results for clinical decisions [1,2]. In Senegal, the integration of a LIS with an HIS represents a new scientific and organizational dimension in the local medical practice. Indeed, despite several initiatives including the National Medical Information System for Senegal (SIMENS) project [3], a modular HIS, initially designed for medical services in health facilities of level three in the sanitary pyramid of Senegal [4,5], a LIS has never been proposed.

In this article, we propose a laboratory information system for the management of screening tests for sickle cell disease and all other tests (hematology, biochemistry, parasitology, and bacteriology) necessary for proper monitoring and good management of positively screened patients. The LIS is designed as a module of SIMENS and is called SIMENS-LIS4SC (SIMENS LIS for Sickle Cell) and is integrated with the HIS of the Center for Research and Ambulatory Care of Sickle Cell Disease (CERPAD) in the Saint-Louis region of Senegal. CERPAD aims at proposing a model for neonatal screening and early healthcare of sickle cell adapted to Senegal's public health system. Indeed, sickle cell disease is a major public health problem occurring in approximately 300,000 births annually worldwide [6]. According to a systematic review on sickle cell disease for children under five years od [7], both the highest prevalence and highest mortality of sickle cell is in Africa, and there is a need for national comprehensive newborn screening to identify patients, and to develop holistic care programs to provide therapeutics and education for families and children with the disease. In Senegal, there are no published studies on sickle cell prevalence. Few local and specific studies, such as one in Senegal, [8] reveal that sickle cell disease mainly concerns children and adolescents.

In the results, we cover the first phase of the project, which began in April 2017. The health services involved were the maternity wards of the Saint-Louis' Regional Hospital Center (CHRSL) and the reference health center of the city of Saint-Louis. We present the different interfaces designed for managing the biological test data of the CERPAD laboratory. We illustrate the system contribution in terms of quick and easy access to statistical data for decision-makers through a reporting and dashboard module. A preliminary evaluation was also conducted to show the LIS assessment by the different CERPAD actors involved in the laboratory tests processes.

Methods

The neonatal screening program included every newborn with the consent of their parents. Specially trained midwives and gynecologists informed parents about the process. Materials collected included for each newborn, a blood drop sample and an information sheet regarding the baby's medical data, the parents' marital status, contacts, and socio-professional status. In addition, for newborns suspected of having sickle cell disease or homozygous C after the initial screening, a second venous blood sample was collected for detailed analysis.

The initial blood sample was used to perform hemoglobin typing by the isoelectrofocusing method. The second sample was used for performing capillary electrophoresis of hemoglobin, to identify and confirm the sickle cell status. The center followed monthly newborns with a major sickle cell syndrome profile (SS, SC, SE, SDPunjab, SOArab, SLepore, Sβ°thalassemia, Sβ+thalassemia) or a CC status during systematic visits. They also received emergency care during acute attacks or other complications related to the disease.

Recommended during the follow-up for diseased patients, mandatory biological and radiological examinations evaluated systematically and periodically the patients' health state. These examinations' objective was to detect complications in early stages in order to propose preventive treatment before any organ deterioration or the appearance of functional repercussions. A doctor from the HIS could also prescribe these examinations during the patient consult and could send patients directly to the nurse for sampling. Samples were then passed to the lab technician to trigger the biological test process of sample sorting. The biological examinations were proteinuria (after 24h), blood count and reticulocyte level (every month from birth), serum iron, ferritin, lactate dehydrogenase, and irregular agglutinins (every year since birth), and micro-albuminuria and creatinine (every year from 5 years old). The radiological examinations were transcranial ultrasound (every year from 2 years old), abdominal ultrasound (every year from 5 years old), retinal angiography, and cardiac ultrasound (every year from 10 years old). Radiological examinations were performed in an external department to CERPAD and were not yet taken into account in the SIMENS-LIS4SC.

An application dedicated for data management of laboratory tests for sickle cell disease screening and healthcare was implemented. It became a part of a module integrated in SIMENS, acting as a laboratory information system and connected to the HIS module of SIMENS dedicated to sickle cell neonatal screening and healthcare. The SIMENS-LIS4SC had two main inputs (neonatal screening test request from maternity wards and biological test request for the diseased patient follow-up and healthcare from the physician) and one output, which were the test results integrated in the patient record. The application was implemented using an Agile development process [9]. We used PHP and the ZEND 2 framework to develop the LIS, as these technologies were already a part of SIMENS. For data management, we used the MySQL relational database management system. We worked with a medical and medico-technical team of doctors, nurses, laboratory technicians, biologists, and administrative secretaries who were very involved in the software design. Regular meetings made it possible to clearly identify needs, discuss the various user profile requirements, present intermediate results to gather opinions and suggestions, and define the following work, etc. To guide the design of new features and interfaces, workflow schemes and other essential information were regularly shared.

As a preliminary evaluation, we gathered the opinion of 9 users using a qualitative form including 18 questions. These users included a secretary, nurse, technician, biologist, and physician using the LIS for almost 2 years. For each question, users had to answer using a 4-value scale (fully agree, partially agree, partially disagree, fully disagree) and were allowed to give no opinion.

Results

Workflow

Figure 1 shows the proposed workflow for laboratory tests management of sickle cell neonatal screening, follow-up, and healthcare. The maternity wards intervened in the sampling phase for the newborn screening, the secretary while creating the patient's record, and the nurse for filling the sample data from the maternity wards. The nurse could have taken samples at the CERPAD center if necessary, for instance when the physician prescribed additional biological tests for the diseased patients follow-up and healthcare. When the samples were transmitted to the laboratory, the technician performed some checks before completing the tests and filling the results. Then, the biologist interpreted, validated and sent the results to the secretary for printing.

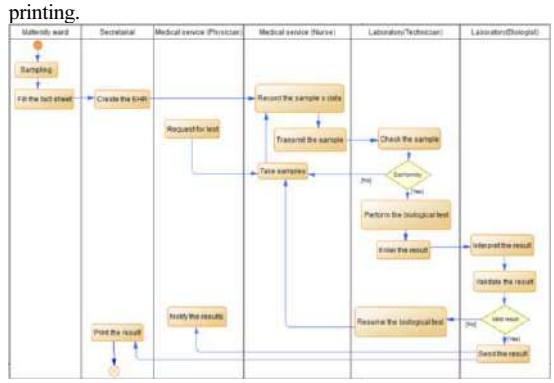

Figure 1– Workflow of Laboratory Tests Realization

The SIMENS-LIS4SC

In this section, we focus on the LIS interfaces that highlight the management of the sickle cell biological test data within the CERPAD for the neonatal screening and healthcare. Any of the identity data in screenshots does not refer to any real patient.

First, the screening process consisted for the secretary, to create a record in the Electronic Health Record (HER) for the patient based on his information sheet data from the maternity ward. The secretary was also responsible for recording biological test requests, such as hemoglobin screening as shown in Figure 2.

Figure 2– Screening Test Request from the Secretary Interface

Then, the nurse filled the data related to the samples (Figure 3) taken on the patient before sending them to the laboratory technician who performed the verification.

Figure 3– Sample Data Entry by the Nurse

Verification step shown in Figure 4 consisted of checking the state of the samples, the conformity of the material used, etc. In the event of a problem, the technician could request through SIMENS the resumption of the samples concerned.

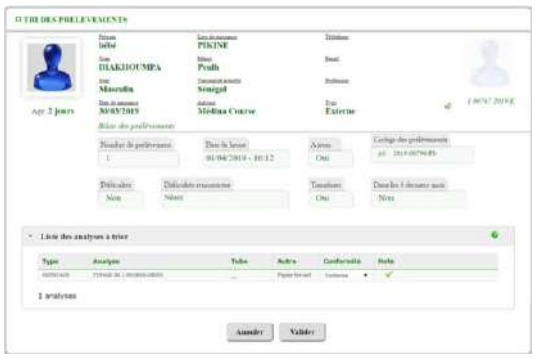

Figure 4– Samples Checking by the Technician

The technician was also responsible for recording the results of the biological tests as shown in Figure 5.

Figure 5– Test results entry by the technician

Finally, the biologist interpreted and validated the results for printing. The results were integrated into the patient's EHR. The secretary could access the results and print them as shown in Figure 6 for transmission to physician and newborn's parents.

Figure 6– Example sickle cell screening result print

In addition to accessing the laboratory test results directly in the patient record, the physician could prescribe complementary tests directly during the consultation. The Figure 7 shows how the SIH alerted the physician about the mandatory exams to prescribe for the follow-up of the diseased patient.

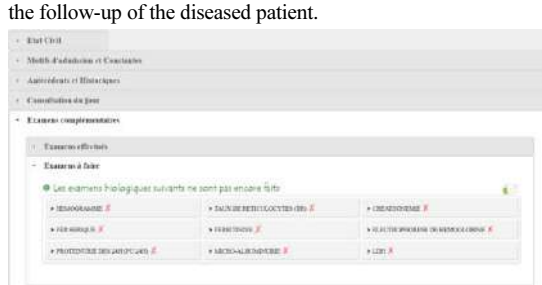

Figure 7– Complementary Tests Prescribed by the Physician

Example of Statistical Data on the Screening Tests

The neonatal screening program started in April 2017 with a two-month experimental phase. This phase also made it possible to test and maintain the SIMENS HIS and LIS modules for sickle cell disease screening.

Table 1– Summary of the screening from 06-2017 to 08-2018

Period	AA	AC	AD	AS	CC	SC	SS	Total
2017-06	226	10	0	23	0	0	0	259
2017-07	236	5	1	22	0	0	2	266
2017-08	48	1	0	6	0	0	0	55
2017-09	146	4	0	13	0	0	0	163
2017-10	286	5	0	29	0	0	1	321
2017-11	245	2	0	29	0	0	0	276
2017-12	261	7	0	21	1	0	0	290
2018-01	308	6	0	26	0	0	0	340
2018-02	251	7	0	30	0	0	0	288
2018-03	216	6	0	31	0	0	1	254
2018-04	208	2	0	19	0	1	0	230
2018-05	174	6	0	16	0	0	0	196
2018-06	219	3	0	19	1	0	0	242
2018-07	241	5	0	23	0	1	2	272
2018-08	43	0	0	1	0	0	0	44
Total	3108 (88.90%)	69 (1.97%)	1 (0.03%)	308 (8.81%)	2 (0.06%)	2 (0.06%)	6 (0.17%)	3496

Table 1 shows the evolution of the data over time and their distribution according to the various screened sickle cell profiles, covering a period of 15 months from June 2017 to August 2018. 3496 newborns were screened during this period. 3180 (green columns) of them were healthy and non-carriers. 316 (orange and red columns) were carriers of the gene Hemoglobin S. Among carriers, we had healthy carriers (AS) and diseased patients (SS, SC, SE, SDPunjab, SOArabe, SLepore, Sβ°thalassemia, Sβ+thalassemia). In this first phase, we found 8 (red columns) diseased patients of SS profile.

The figure 8 shows a dashboard of the distribution of (1) the overall screened newborns between internal and external status, (2) the diseased patients between gender and (3) the diseased patients according to SS, SC and CC profiles.

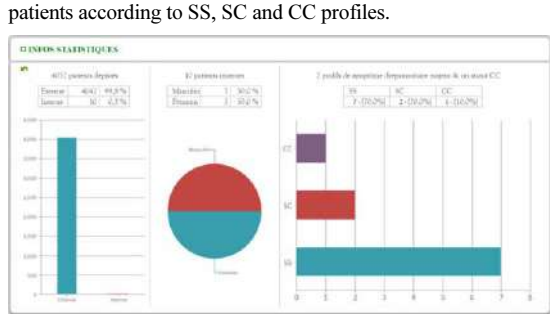

Figure 8– Patients Distribution According Internal and External Status, Gender and Sickle Cell Diseased Profiles

Table 2– Evaluation results and analysis

The system facilitates my work										
The system improves the quality of my care									**Key:**	
The system improves our ability to coordinate continuity of care									Fully agree	
The system improves medical information sharing									Partially agree	
The system improves decision-making									Partially disagree	
The system is easy to use									Fully disagree	
When using the system, the number of clicks is acceptable									No opinion	
System's response time is acceptable										
System's session opening is acceptable										
The system preserves patient's security and confidentiality										
The system is reliable										
The global quality of the system is excellent										
The information in the system is exhaustive										
The information in the system is quickly available										
The information in the system is relevant										
The information in the system is quickly available when needed										
The form and layout of the information in the system is acceptable										
The information in the system allows me to make decisions										

The figure 9 shows a dashboard of the distribution of only validated results by the biologist of the overall screened newborns between (1) gender, (2) sickle cell all profiles and (3) ethnic groups.

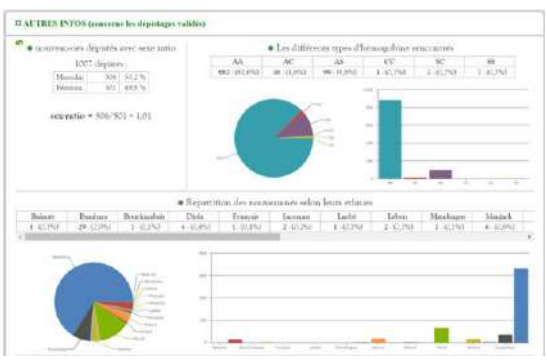

Figure 9– Patients' Distribution of Validated Results, According to Gender, Sickle Cell All Profiles, and Ethnic Groups

Evaluation of SIH SIMENS-LAB

The qualitative evaluation yielded very good results (see table 2). All users found that the system was easy to use, reliable, secure, and that it facilitated their work. Moreover, most of them considered that it was able to improve the quality and the continuity of care, and, to a lesser extent, the decision-making process. Decision-making seemed to be the weakest point of the system, though, with two users finding that the system did not improve decision making, and 3 expressing no opinion.

Discussion

In this section, we discuss the related works on Laboratory Information Systems which have various features :

- The automatic validation of analysis results, which consists in checking the plausibility of the results by confronting them all with a certain number of previously defined parameters in the system. In some laboratories in Europe, it is necessary to validate more than ten thousand results per day. The system ensures the same quality of validation throughout the day. For example, Valab software is a reference application in biological validation [10].
- The management of electronic medical records, sampling, data capture, validation, printing of results, and rapid communication of test results to connected health centers are executable tasks with e-Chasqui. This system is designed to support the national network of anti-tuberculosis laboratories in Peru. It improves the quality of care and ensures effective follow-up of TB patients [11,12].
- The management of HIV testing, treatment of HIV-positive patients, and patient data security is achievable through the NETLAB system. It is a software developed to improve the treatment of HIV in Peru. It manages 100 different diseases for which the National Institute of Public Health and the network of health laboratories in Peru provide test prescriptions and results. It ensures, among other things, the communication of laboratory results, in complete confidentiality to laboratory staff, health providers, and patients living with HIV [13].

In addition, there are other large-scale solutions for performing more complex tasks than in the examples mentioned above. For example, Delphic is a SIL for end-to-end information management for hospital and community labs. It covers all phases of the laboratory work process. It is adaptable to various laboratory environments and fully customizable, making it ideal for multi-laboratory organizations [14]. The BK-LIS is a LIS for patient data management of laboratories in health facilities in Vietnam. It is designed for the management of Hematology, Biochemistry, Immunology, Microbiology, Urine, Endocrine, and Cell Analysis.[15].

As far as we are concerned, information systems are being implemented especially for sickle cell disease, the most common genetic disease in the world. It is generally found in all continents but, the highest prevalence rates are observed in Africa. Thus, the Laboratory LARTIC (Support Laboratory Research and ICT) of the Faculty of Medicine of Antsakaviro of Madagascar in collaboration with the NGO Fight against Sickle Cell Disease in Madagascar, France and the Faculty of Medicine of Antananarivo have set up the openMRS-Sickle-Cell, an application based on OpenMRS for the network fighting against sickle cell disease in Madagascar. In Madagascar, where the prevalence of hemoglobin S trait carriers is estimated at

approximately 2,000,000 distributed in highly endemic areas that are often remote and almost inaccessible, the system allows the centralization of clinical data of patients screened and followed up [16].

In the context of CERPAD where we developed our LIS, we could design a system from scratch for systematic neonatal screening and ongoing follow-up of patients. We integrated social specificities of the West African region, such as the genetic roles played by ethnic groups, in a long-term multidimensional database for research purposes. This research should allow a better characterization of the disease taking into account the socio-demographic and environmental parameters in Saint-Louis of Senegal.

Conclusion

SIMENS-LIS4SC fulfills several functions allowing the realization of the different laboratory tasks for biological tests related to the management of sickle cell disease. It allows the laboratory to take advantage of the automation of tasks. The SIMENS-LIS4SC also makes data entry, reporting and archiving much easier within the CERPAD. Physicians can quickly access results and analysis reports interpreted and validated by the biologists, which greatly speeds up diagnosis and improves treatment. This system also provides efficiencies and decreases patient expenses by reducing the number of redundant tests. Researchers can use the data collected to carry out clinical, epidemiological, and social studies.

The SIMENS-LIS4SC is reusable in other sickle cell screening programs. It is also adaptable for any other disease screening and could extend to hospital level, by adding relevant tests.

Acknowledgements

This work is part of the SIMENS project which is supported by the African Center of Excellence in Mathematics Computer Science and ICT (CEA-MITIC), the Pierre Fabre Foundation, and the Senegalese High Study and Research Ministry through the Scientific and Technic Research Impetus Funding (FIRST).

Portable Health Clinic: An Advanced Tele-Healthcare System for Unreached Communities

Rafiqul Islam[a], Yasunobu Nohara[a], Md Jiaur Rahman[b], Nazneen Sultana[b], Ashir Ahmed[c], Naoki Nakashima[a]

[a] Medical Information Center, Kyushu University Hospital, Fukuoka, Japan
[b] Grameen Communications, Dhaka, Bangladesh
[c] Department of Advanced Information Technology, Kyushu University, Fukuoka, Japan

Abstract

The Portable Health Clinic (PHC) system endeavors to take healthcare facilities along with remote doctors' consultancy to the doorsteps of the unreached people using an advanced telemedicine system. Thus, the necessity of having physical healthcare peripheries specially in the developing countries can be mitigated. The PHC system promotes preventive healthcare by encouraging regular health checkups so that diseases can be prevented as well as their severity can be mitigated, leading to a reduction on healthcare expenses. Thus, the number of patients along with excessive workload on existing healthcare human resources can be minimized. The current project in rural Bangladesh alone has served more than 41,000 people so far by the PHC system and a simple analysis of this data shows some significant findings on regional health status. A simple expansion of this program, covering a wider service area, can produce a big data to reflect the whole country`s health profile.

Keywords:
Preventive Healthcare, Telemedicine, Triage

Introduction

Healthcare facility is a basic right for all human beings. Unfortunately, the shortage of qualified doctors and health workers, insufficient medical facilities and lack of healthcare awareness remain as some major obstacles for ensuring a standard level of healthcare service in the developing countries [1, 2]. Under this circumstance, telemedicine with preventive healthcare could be considered as a key to overcome this situation. Keeping this in mind, the Portable Health Clinic (PHC) system has been developed as an advanced telemedicine system for the rural communities in Bangladesh [3, 4]. This system, also called "Doctor in Box", enables bringing healthcare services to the doorsteps of the rural communities at a affordable price (Figure 1).

Nowadays, the prevalence of non-communicable diseases like Diabetes Mellitus and Hypertension has increased to a cautious extent. Being a developing country, Bangladesh is not an exception. From our studies, we have learned that not only the urban people, but the people in suburban and rural areas are equally affected by these diseases. These diseases and the consecutive complications can be effectively prevented by taking cautions beforehand. Prevention is more important in countries like Bangladesh because of the limited ability of people to spend on health bills and the absence of provision from government. Preventing such diseases to occur or diagnosing it at early stage can help people to save substantially on medical bills. For this, regular screening of health status is important which can be facilitated by the PHC. Thus, the PHC system has been developed in a preventive healthcare approach with a special focus on non-communicable diseases [5, 6]. One of the main obstacles for ensuring basic healthcare service in developing countries is the poor doctor-patient ratio. According to World Health Organization (WHO), where it requires at least 12 doctors for standard healthcare service to every 10,000 populations, Bangladesh have just 4 doctors. However, it is not that easy to increase the number of doctors in a short period of time. When it is not easy to improve this doctor-patient ratio by increasing the number of doctors alone, decreasing the number of patients is very important. The PHC system also aims to contribute in improving this doctor-patient ratio by introducing preventive healthcare to reduce patients by advance intervention to the problem.

Figure 1. Portable Health Clinic ("Doctor in Box")

The PHC system made it possible to provide primary healthcare services to the doorstep of the rural communities through a telemedicine system. However, to ensure better consultancy by the remote doctor, accurate and a wide range of diagnosis reports of the patient are required to be available to the remote doctor. Unfortunately, most of the developing countries do not have enough quality diagnosis laboratories in the rural areas with qualified pathologists for producing reliable reports. Therefore, this work introduces a new module to the PHC system called the "Tele-Pathology" system that enables rural laboratory technologists to gain assistance from a remote professional pathologist using an online tele-healthcare system and receive the verified report from the pathologist [7]. This involves a very simple technology using available devices like a camera and microscope, and it can be easily replicated.

While providing this primary healthcare service in rural Bangladesh, a huge need of eye care services was identified.

Considering this demand in rural Bangladesh, this work also added another new module with the PHC system called the "Tele-EyeCare" system for ensuring eye care services [7].

The main objective of this work is to improve the PHC system and expand the service scope so that it can respond to the wide range of demands of rural patients with quality consultancy aided by accurate diagnosis. Addition of Tele-Pathology and Tele-EyeCare modules will contribute significantly in this direction.

Methods

PHC System Structure & Operations

The PHC system consists of 4 components: 1) PHC box with various medical sensors, internet enabled tablet pc and printer, 2) health worker 3) online dataserver for sharing and preservation of health data and 4) remote doctor call center (Figure 2). The health worker brings this PHC box to the patient to measure the vital information and upload this data, along with the medical history of the patient to the online server using the system application (app). The remote doctor gains access to this data and makes a video call to the patient for further verification. Finally, the doctor produces an online prescription and preserves it in the server under the patient`s personal file. Then, the health worker prints the prescription from the server and passes to the patient with detail explanation instantly (Figure 3). The whole process to serve one patient takes about 15 minutes excluding doctor`s consultancy time.

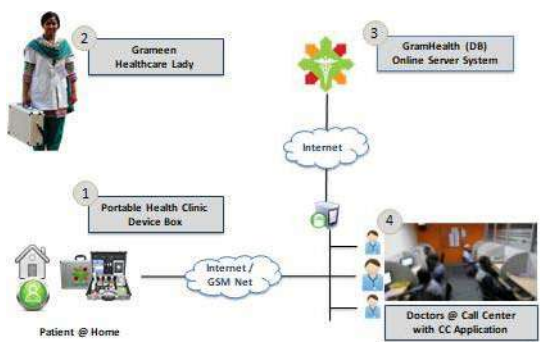

Figure 2. PHC System Structure

The PHC system introduces a triage process based on the concept of "B Logic" for the people of Bangladesh. It classifies the subjects under investigation in four categories, namely, (i) green or healthy (ii) yellow or caution (iii) orange or affected and (iv) red or emergent, based on the gradual higher risk status of health [8-11]. The subjects under orange and red are primarily diagnosed as in the risky zone who need doctor`s consultancy. However, the major part of the subjects who are diagnosed in the alarming zone (yellow) can be served by the trained health workers without medication and they can be prevented from shifting to the risky zone (orange and red) being under the guided lifestyle. This reduces the pressure on the doctors, enabling them to focus on the risky patients who deserve better attention.

Tele-Pathology System

The Tele-Pathology module of the PHC system enables the rural diagnostic centers operated by laboratory technologists (diploma) for producing quality pathological report with the support of the qualified remote pathologist (Figure 3). At present, this system is capable of a blood hematological (CBC) test, routine examination of urine, routine examination of stool and a skin scarping test. In this system, the rural laboratory technologist (1) collects the sample, prepares the physical report, produces the test slide, (2) takes a number of microscopic images of the slide with varying positions and then (3) uploads the images along with the physical report to the online server. The remote pathologist then (4) diagnoses the sample based on the microscopic slide images with the reference of physical report, finalizes the pathology report and preserves to the online server.

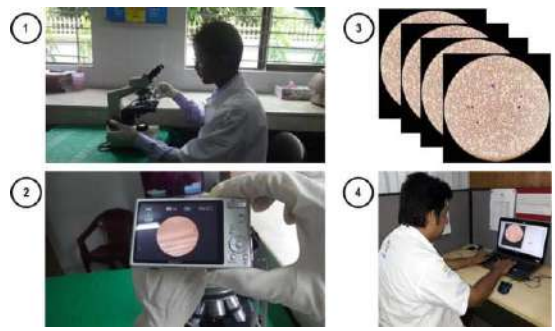

Figure 3. Tele-Pathology System

In case a pathological report is required by the call center doctor (physician), the doctor can gain access to the report from the online server for preparing a prescription. If needed, the laboratory technologist can also download this report to deliver to the patient.

Tele-EyeCare System

The Tele-EyeCare module of the PHC system ensures primary eye care services for the rural communities. This module has added a Digital Fundus Camera to the PHC box for retinal imaging (both Mydriatic & Non-Mydriatic) of the patients. This enables the health workers to have a better view of the retina and the peripheral for identifying the problem with certainty. Thus, the trained local health workers check and classify the patients as per severity of the problem. Low risk patients with simple complications are served by the health workers. However, in case of doubtful cases, the patients` vital information, initial primary checkup reports and ophthalmic images are shared with a remote ophthalmologist using the online server (Figure 4).

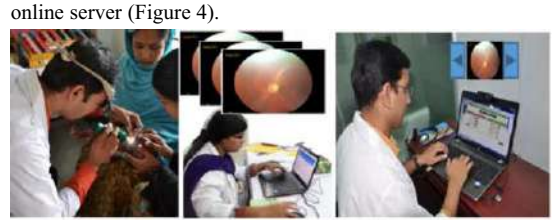

Figure 4. Tele-EyeCare Service System

The ophthalmologist then checks the initial primary checkup reports produced and shared by the local health worker, investigates the ophthalmic images, directly talks to the patients over video conference system, reconfirms their status and finally, provide online prescriptions. If needed, the ophthalmologist can ask for further investigation of the patient by the health worker and can also provide glasses prescription with the support of the health workers. Thus, this system enables to provide basic eye care to the ordinary patients by the health workers and special care for the critical patients by

professional ophthalmologist who really deserve special attention.

Village Service Delivery Model

In village service delivery model, preferably one female health worker works in a village as she can gain better access to the female patients due to privacy reasons. Usually, she uses a local village medicine shop (pharmacy) as her service point for daily service and general village patients come there for PHC service (Figure 5). However, she also visits door to door in case of elderly or disabled patients, pregnant women, emergency patients or special on-call service.

Figure 5. Village Service Delivery Model

Urban Service Delivery Model

Although, it was developed for the low income rural communities, it is found equality useful for the urban, rich, and aged community for home delivery service. The main clients are aged people who are suffering from non-communicable diseases like hypertension and diabetic that need regular checkups. Although, they are financially rich but as it is difficult for them to visit hospital regularly due to physical stress, trouble to arrive at doctor`s appointment at expected time, traffic congestion, etc. So the PHC home delivery service is offered to the pre-registered urban patients and the health workers visit the patients as per schedule.

Personal Health Record

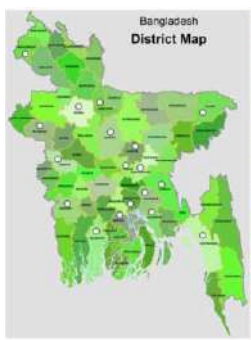
The PHC system preserves all medical data of the patients in the online server so that the doctor can refer previous data in need. All checkup data, pathological reports, medical histories and prescriptions are preserved sequentially. Also, all the patients are provided with their respective user id and password for their access to their personal, health record which is maintained with high security and privacy (Figure 6). They can change their profile information but only monitor the health records with graphical representations.

Figure 6. Personal Health Record & PHC Prescription

The prescriptions produced in the PHC system are unique in shape and format considering the targeted patients of the rural communities (Figure 7). It contains both the measured health data in the left side and doctor medication with advice on the right side. As most of the patients do not understand the significance of digits, it shows all health data with corresponding color sign. The same four colors of the triage system (green, yellow, orange and red) are used against each data point so that they can easily understand the severity of any particular item.

Results

The PHC healthcare services have been offered in 18 districts of Bangladesh at more than 70 service points all over the country (Figure 7). Until April 22, 2018, the number of patients served by the PHC system in Bangladesh alone was 41,949. Besides, the PHC activities are also continued in Cambodia, India, Thailand and Pakistan under the supervision and management of local partners.



As on April 22, 2018					
Year	Total Checkup	Health Status			
2010	377	103	15	248	10
2012	6,412	1,056	4,035	1,084	237
2013	13,277	1,595	6,781	4,301	546
2014	5,288	1,004	2,278	1,659	326
2015	5,547	1,330	1,429	2,016	772
2016	7,007	1,875	1,614	2,255	1,069
2017	2,853	366	800	868	361
2018	1,188	95	410	325	121
Total	41,949	7,424	17,362	12,756	3,442
		24,786 (61%)		16,198 (39%)	

Figure 7. PHC Service Statistic in Bangladesh

The diagnosed major diseases found in PHC healthcare services are hypertension (1,944), diabetes (1,365), anemia (647), and ophthalmic problem (138).

The Tele-Pathology service started in 4 rural diagnostic centers under 4 districts (Barisal, Bogura, Manikganj and Thakurgaon) of Bangladesh. So far, this system has served patients with a total of 1,610 Hematological (CBC) reports and 918 Routine Examination of Urine using remote pathologists.

The Tele-EyeCare mobile service has recently started in 1 rural center called “Vision Center” in the Nator district of Bangladesh on a test basis. So far, it has already served 2,410 checkups for 2,046 patients using remote ophthalmologists. Soon this service will be extended to other parts of the country.

Discussion

Out of a total 41,949 PHC healthcare patients, 61% (24,786) was green and yellow patients who were served by the health workers alone. The rest of the patients 39% (16,198) were served by doctors who needed medication. So, the PHC system can reduce the work load of a professional doctor by 61% that can be managed by local health workers. Thus, the best use of the valued resource of a doctor can be ensured and only the people who really need expert`s consultancy can avail it.

Due to its easy operation, a huge number of health data can be collected by the PHC system and this big data can be used for countrywide disease pattern analysis. For example, this research has found some significant differences of health parameters in different areas. In one area, we have found a

significantly small number of anemic cases among the adult women compared to the rest of the country. In another area, we have identified very high urine protein compared to the rest. Thus, the detail analysis of this data may show some significant findings including environmental issues.

Similar to the shortage of physicians, there is a huge shortage of ophthalmologists and it is just 0.063 ophthalmologist for every 10,000 populations in Bangladesh. The Tele-EyeCare module of the PHC system can highly contribute to ensure the best use of this valued resources for dealing with complicated cases and manage ordinary cases by health workers. For the further advancement of the Tele-EyeCare system, a new development has been started using Artificial Intelligence (AI). It will use ophthalmic image recognition technology with the aid of neural network and deep learning for automatic diseases identification. This will facilitate both the village health workers and ophthalmologists for better and prompt services.

Conclusions

At present, the PHC tele-healthcare system offers a unique opportunity for ensuring better healthcare service covering primary healthcare, eye care and pathological services to the unreached rural communities. However, this modular system will gradually be expanded in other healthcare service areas to cover common healthcare issues based on the local demand. Now, we are working on an Obs & Gyne module and Dental Care module to be added soon to the PHC system.

The concept of the PHC system came from the local demand of Bangladesh. However, since most of the developing countries are facing the same problem and having similar situations, an easily replicable PHC system can be in good use there. So far, this system has been replicated in India, Pakistan, Cambodia and Liberia with some localizations. However, there is still plenty of opportunities for further improvement of the system and expansion of the service to the other parts of the world.

Since the aging communities are increasing in the developed countries, they are also facing a similar crisis of doctor shortage in their rural areas. Therefore, there will arise a huge demand of PHC services in the developed countries as well [12]. To address this demand, the PHC system can be further improved with the aid of technologies. One of these attempts is to include Bluetooth enabled medical sensors so that the measured vital data from the sensors will be automatically transferred to the online server to avoid typing error from manual data entry [13]. Also, there is a requirement to develop the PHC box as an integrated unit so that it will be low cost, handy and light weight for easy operation by a rural health worker.

[b] Institute of Computer Engineering, TU Braunschweig, Germany

Abstract

With regard to the growing number of older adults, it needs smart solutions for fall prevention. Especially at geriatric institutions, the risk of falling is very high and frequently leads to injuries, resulting in serious consequences. We present the Inexpensive Node for Bed Exit Detection (INBED), a comprehensive signaling system for fall prevention. The INBED system is based on a wireless sensor network infrastructure via IEEE802.15.4 and highly-specialized open hardware in-house developed wearable. The device, which will be attached to the patients, can detect several types of movement. Occurring events are forwarded to the nursing staff immediately by using the self-organizing and scalable network including wide area network integration. The system can help to relieve the staff while the personal freedom of movement and privacy of patients is increased. With this development, the energy-efficient, simple and intuitive mechanisms of proximity communication can be combined with broadband benefits.

Keywords:
Accidental falls, Accident prevention, Geriatrics.

Introduction

As a result of demographic change, the number of people to be cared for, and thus also the challenges and demands on health care, are increasing. Falls in older adults are frequent and fatal events with mostly serious consequences for the individual as well as considerable financial expenditures for the society.

For geriatric wards the average fall ratio per 1000 bed days is more than twice as high as on other clinical wards, which has been validated by the German quality report benchmark in geriatric health care from 2007 [1]. This can be significantly higher if you look on specialized clinical departments such as gerontopsychology wards. A large part of the falls occurs as a result of getting up in the immediate vicinity of the bed [2]. Usually high fall risk patients are encouraged to call the nurses for help if they wish to get up, this directive is not always followed (e.g. due to cognitive impairments). The situation in outpatient areas are similar and again most of the falls occur during rising events for transitions.

The increased falling risk of older adults is mainly caused by chronic diseases and predisposing factors like gait and balance disorders [3]. Furthermore, dementia and motor deficits patients fall twice as often as patients with normal cognitive abilities [4]. One of the most common consequences for elderly fallers is the femoral neck fracture [5]. The incidence among the over-65s in Germany for such an injury is 600 to 900 fractures per 100,000 people per year [6]. Beside the mental and physical strains, fall events are associated with immense consequential costs. The estimated overall annual costs of treatment of fall-related hip fractures in German hospitals and rehabilitation centers are up to 2.77 billion Euro [7; 8].

We designed in several iterations a highly specialized Wireless Sensor Network (WSN) system in different architectures to recognize an attempt to leave the bed for fall prevention. On the one hand, the system should not restrict the patient's movement. On the other hand, it has to recognize potential fall risks in a timely manner, so that an active intervention by nursing staff is possible to maintain the patient's care and safety. Furthermore, the diversity of clinical structures is quite challenging. Other more practical issues are the availability and amount of power sockets, the type of communication infrastructure (Wi-Fi, Ethernet, etc.) and individual restrictions of the specific country (e.g. hygiene requirements, care regulations or patient protection laws, limitations of the use of protocols e.g. Bluetooth or Zigbee). Hence, the following objectives for the development of the INBED fall prevention systems are:

- Development of a reliable and cost-effective solution for a sensor-based bed-exit/rising detection system (primary function) based on initial research results with different sensor prototypes.
- Recognition of restlessness conditions of patients prior to a rising attempt (optional primary function), so that the nursing staff can intervene immediately.
- Detection of falls (secondary function) and provision of virtual risk areas, such as stairs (secondary function).
- State-of-the-art technological concept, focusing on a minimal price for the end customer without reducing the quality of the overall system or individual functional areas.
- Creating an adaptive, scalable and modular communication infrastructure to include the wearables at a ward.

Related Work

In the last years, several studies showed a positive impact of bed exit systems on the fall rate of older adults [4; 9]. Currently, there are two main types of systems available. Distinguished in body worn and ambient variants, they can occur in different forms, e.g. mattress pad systems, ground pressure mats, infrared systems or garment clipping sensor systems [10]. Those systems have advantages and disadvantages depending on the symptoms of the patient and the surrounding. Hygiene requirements that demand special cleaning can exclude the use of system components if they cannot be cleaned to rule. The false positive alarm caused by objects like mobile dining tables, suit cases or by the patient's restlessness leads to dissatisfaction of the nursing staff. Furthermore, one of the main reasons for an

increased risk of falling is dementia [4] which often involves underweight and restlessness [11] whereby the reliable functionality of the system can be affected as well.

For example if a patient weighs under 50 kg, proper function of pressure sensors is not guaranteed so that mattresses or ground pressure mats (cf. [12]) are useless. In addition, mobile dining tables or suitcases can lead to false positive alarms by standing on such floor sensors, which can affect a discontent of the nursing staff. Moreover, special cleaning procedures of nursing and/or clinical facilities can lead to the exclusion of such system components. Having this in mind, the implementation of a proper fall prevention system should be suitable to diagnoses and symptoms of the particular patient condition. This is also in line with the National Institute for Clinical Excellence findings; *"To be effective, they [Bed-Exit Alarms] need to be implemented with care and with a clear understanding of their limitations"* [10].

In general, video monitoring would be a proper solution but besides legal restriction relating to the usage of camera recordings in public, the basic acceptance is an important field. The acceptance of cameras surveillance impartial is quite low in a major group (in general under 50 percent) (see [13; 14]).

In recent years the Peter L. Reichertz Institute for Medical Informatics have worked on the field of fall prevention by developing several prototype systems. This led to first clinical study with the aim of measurement of the reduction falls on a geriatric ward, by close monitoring with a portable proprietary sensor system (www.shimmersensing.com). For this purpose, a bed exit alarm with this wearable was developed as a core component, which reliably detects rising attempts [9].

With the results and experience of this first clinical trial and close collaboration of various clinicians and nursing staff, we were able to further improve the system and adapt it to the conditions of clinical use. Last but not least, this includes the development of various hardware-software-components for the implementation of an adaptive, scalable and modular overall system for fall prevention, which will be presented in this paper. In addition, compared to existing solutions the INBED system is highly cost efficient and comprises the specific requirements of clinical use cases.

INBED system

The first version was tested within a larger 15-month study. For this iteration of the system, we designed the base station using an Arduino with an Atmel ATmega168 micro controller unit (MCU) and a Bluegiga WT11 Bluetooth module. If regular messages from the sensor are missing or the sensor detects a rising attempt, it triggers an alarm and the base station activates the nurse call. For each patient, one pair, that can easily be connected to the nurse call system at bedside, is needed [9].

The wearable part on the fall prevention system was the Shimmer sensor system. Via Bluetooth connection, a variety of receivers can be used to integrate the new modality into the clinic's system. Porting the algorithms to the hardware was straightforward. The Shimmer device provides enough resources, making it possible to detect additional states of the patient [15].

With the gathered information and data from the 2012 study, we could determine new challenges of the clinical everyday life and master them through further development of the system.

In order to cover all requirements, we decided to develop our own scalable system with a wearable core component, the INBED, in close cooperation with the clinical partners. The wearable itself is a small, affordable wireless sensor board based on an ATmega2564rfr2 System on Chip where the MCU as well as the transceiver unit are fully integrated on a single chip combined with a Bosch BMX055 Microelectromechanical systems. In Figure 1 the board can be seen, including an image of a coin scale and in comparison, with the relay node.

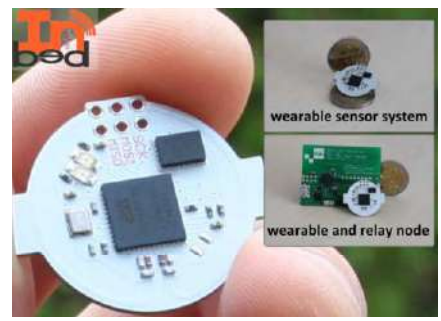

Figure 1– Current INBED wearable board with relay

The ATmega2564rfr2 includes both a low-power 8-bit MCU based on the AVR enhanced RISC architecture as well as a fully IEEE 802.15.4 compliant radio transceiver for the 2.4 GHz ISM band. To reduce the costs, a simple PCB dipole antenna is used. For the sensing part we used a small footprint Bosch BMX055 9-axis sensor module (3-axis accelerometer, 3-axis gyroscope, 3-axis magnetometer). The BMX055 is connected to the ATmega2564rfr2 via Inter-Integrated Circuit (I2C)-bus. By using the accelerometer, the BMX055 implements the option of a free fall detection which can trigger an interrupt. However, many other interrupts can be configured to trigger on several events, e.g. thresholds. Hence, by extensively using the pre-configurable interrupts, the energy efficiency of the entire wearable can be increased as reactive programming models can be applied.

The wearable is powered by a standard CR2032 battery. Thus, the cost overhead and efficiency limitations when using voltage regulators is excluded. To guarantee that the voltage level never undershoots the required level for reliable operation, the ATmega2564rfr2 integrates mechanisms like brown-out detection and a battery monitor. The voltage can be sensed continuously to allow an early notification when a battery runs out of energy.

All components are mounted on a 2-layer PCB with the dimension of 20mm diameter plus two 1mm wings and 6mm in height. The wearable detects several patient related movement events, like rising attempts, and sends a signal to the nursing staff immediately, using a relay node based on IEEE802.15.4. Finally, a signal processing base station (Raspberry Pi 3) to create a modular communication network. The base station provides an alarm which is displayed (optical, acoustical or haptic) on the user interfaces (hardware-enhanced mobile phone) and the staff terminals [15].

Overview and Scenario

The main goal of the INBED system is to inform the nursing staff about pre-fall patient movement events in appropriate time, that they can help the patient to get up and assist the walk (e.g. for the toilet) and prevent falls.

For the application of the system the INBED wearable will be attached to the patient's upper leg on the upper half of the thigh. This position is optimal to detect rising event by angle changes of the legs without affecting patient's comfort to much. Furthermore for a functional system, relay nodes have to be positioned

on the ward at strategic points, like patient rooms, at a maximum distance of 20m from one another to form a suitable network for data transmission and node locating. Finally, the base station has to be set up. It should be equipped with some patient information and at least with system information, which relay nodes is where at the ward and which wearable node is in circulation.

For a better description of the system and its functions, we will use a fictional but typical clinical scenario described in Figure 2.

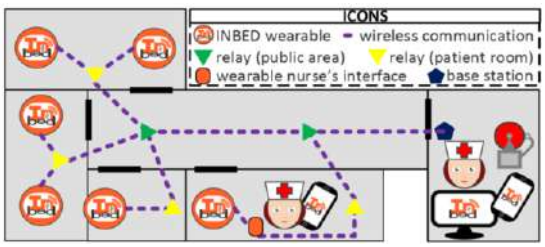

Figure 2– Floor plan of an exemplary ward with installed INBED system

The setting: The initial situation is to serve a regular geriatric ward. Here, the focus should be on patients with the following characteristics: high fall risk, motor functional deficits, sensory restricted, basically self-sufficient. In case of problems (pain, urgency) these patients are advised to contact the nursing staff to reduce the risk of falls. But in the majority of cases this instruction is ignored. Hence, in this scenario the patients are equipped with INBED wearables, which has been attached to the thigh by means of a regular band aid, at admission on the ward. A relay node has been installed in the rooms where the patients are located, as well as at certain distance on the ward floor, and at strategic points in the ward, like exits, elevators or public common area and the drug delivery. The base station is located in the nursing room and connected to the ward Wi-Fi. Ward internal mobile devices are available as an interface for the nursing staff. The model from Figure 2 can be assumed as a regular station. The overall system deploys an IEEE802.15.4 communication network and is therefore not dependent on external infrastructure. The network is structured as a tree with the base station as root node, relay nodes as intermediate nodes and the INBED wearables as leaf nodes while the wearables for the nursing staff can join the tree at any point. In every patient's room lays at least one patient, wearing an INBED device. The nurse's room is equipped with alarm interface devices, like a ward computer and the internal ward patient alarm system. Moreover, the simplified communication paths of the system can be seen, including broadcast communication of the wearables to fix patients room relay nodes as well as the unicast communication between the relay nodes and the base station. As can be seen one nurse is close to a patient, equipped with a smart phone including a system interface, which is utilized as a mobile relay node.

The procedure: A typical scenario might be, that a patient will wake up in the night e.g. due to a strong urinary urge. The patient begins to move in bed, due to a certain degree of physical restlessness is associated with the urge to urinate. This unusual high variance of the movement of the patient triggers a restlessness event. The event message is sent via a broadcast and received by the patient room relay node (nearest node). For each generated event alarm by the wearable will send various encrypted and pseudonymized information. These are information about the origin (ID of the sender), the nature of the incident (code of the event) and logistic data for the processing or function provision (battery voltage, etc.). While the INBED wearables send their messages via omnidirectional broadcast, the relay nodes forward their messages via directed unicast towards the base station.

A message contains message prefix, which shows the state of the current message within the system structure (new or already known), event identifier, device ID (wearable device), battery voltage (wearable devices), first relay node that received the massage (ID) and received signal strength indicator (RSSI) of the first receive. If the message is received by the base station, the contained data will be stored in a database which provides the information on several nursing staff devices (e.g. smart phones).

This alarm is displayed prioritized with the database's join information, affected patient, room, event type. The event is displayed via the ward computer as well as on the mobile devices of the nursing staff. Moreover, both acoustic or haptic alarm were optionally used. While the nursing staff is often quite busy and ignore restlessness warning and decides to continue with the current work, the restlessness warning can be deactivated via all interfaces. Further restless warning will be triggered by the system and notified by the staff, if the urge to urinate persists. In doing so, the nursing staff obtains knowledge about the urgency of an intervention on the patient.

With increasing urgency, the patient decides to go to the toilet without contacting the nurses. This triggers a rising-up-event which is distributed according to the restlessness event. At the base station, the rising-up alarm will be triggered with a higher priority compared to the restlessness alarm. Due to multi-morbid and motor-functionally restrictions of geriatric patients, the rising from reclined position will usually take some time (cf. [12; 14]). With the information about the patient's attempt to get up, the nursing staff is called to go to the patient as soon as possible. The alarm cannot be cancelled via application buttons.

When the nursing staff arrives at the patient, they can take care of his/her needs. By measuring the signal strength of the wearable's signal, the proximity to the nursing staff, can be estimated. Then an existing alarm will be switched off when staff is near an alarming device. Figure 3 shows the overall functions of the whole INBED system.

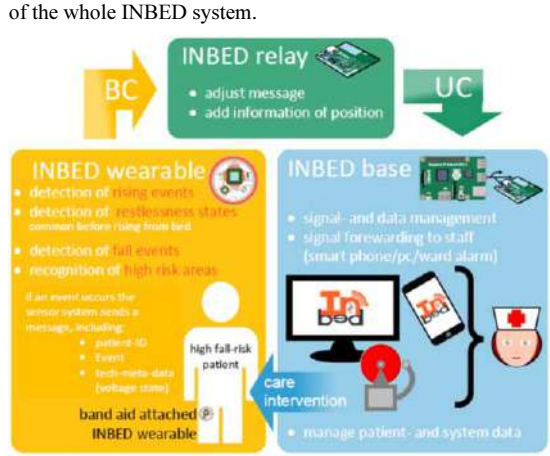

Figure 3– INBED system functionality diagram

Communication and Energy Efficiency: The past ten years research show a widespread of IEEE 802.15.4-based communication in small range Personal Area Network and for sensor communication [16; 17]. However, during the first bed-exit

study an intuitive shortrange one-on-one Bluetooth communication of the wearable part to the base station, that triggers an alarm via nurse call were used. The unidirectional communication via the already installed, analogue and functional nurse call system allows only alarm triggering and not the raw data transmission. The follow-up system consists of commercial-of-the-shelf components on an open hardware-design. This enables short-range communication via its own modular, intuitive and highly energy-efficient IEEE802.15.4-network and is therefore largely. Its own network provides additional side-effects, such as indoor tracking or risk area detection. Due to the bidirectional connection, an adjustment of thresholds while operation is possible [15].

Testing: The functionality test of the entire system was performed under real conditions, with all components. Three test subjects (m=1, w=2, age=28±3), for three trials per subject and event were equipped with an INBED wearable before different scenarios have been investigated. The test cases include both, intended triggering of events (e.g. by standing up, falling, restlessness, error triggering) and testing of the normal case without explicit supervision. For the tests the wearable was attached to the upper front of the thigh as described before.

To underline the suitability for daily use the test series were performed in a clinical environment. For the validation of rising detection, the test subjects started from a lying position and slowly began to rise. Finally, they stood up and get out of the clinical bed, as can be seen in Figure 4. The first three phase images show the approach to the edge of the bed and the beginning of the uplift of the upper body. The phase images four to six show the overcoming of the bed edge with the body and the final raising to the standing position (#7).

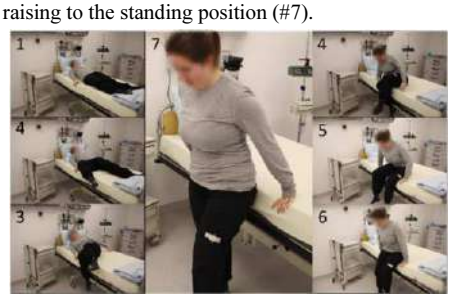

Figure 4: Procedure of a general rising out of bed, represented by seven phases.

We also validated the detection of fall events with six subjects (m=2, w=4, age=28±3), for five trials per subject, as well as restlessness events with two subjects (m=1, w=1, age=26±1), two nights with four wearables per subject, and the corresponding alarms. It should be mentioned, that these sequences of falls were exemplary but representative fall event in clinical environments like the rising before. Within the Figure 5 the raw acceleration data of the three axes are shown, as well as the restlessness counts at the bottom of the diagram and at the point when the interrupt occurred a dotted line can be seen. The counts of the diagram are weighted by the kind of the movement related to the intensity of the motion itself (calm motion = 1, stronger/quicker motion = 2).

The rise up is complete with the final standing of the subject. Thus, a measurement of a fixed period of time is not practical. In the shown case, the recording is about ten seconds long. The restlessness is transmitted after about one second and after about three seconds the rising was transmitted as an alarm.

For the fall test it can be said that the procedure is more or less the same as can be seen at rising with the slight difference that the trial isn't ending by standing but by a subject fall. While a fall the slight decreasing acceleration (near 0.4g) can be followed by high g peak by subject impact.

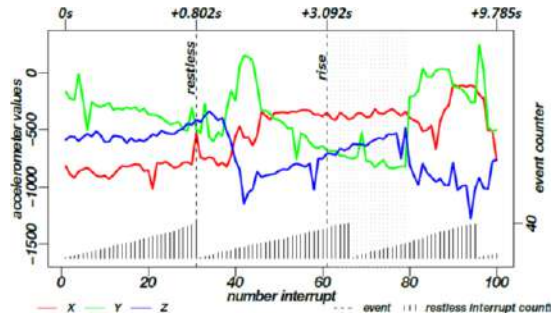

Figure 5– Diagram of the recorded INBED data during rising (raw triaxial acceleration data lines) – in lower area the restlessness counter lines - dashed line show the triggering of the alarms (restlessness and uprising) - grey dotted lines represent standing

For the test of restlessness events, the subjects went to a lying position and then turn from side to side. The recording of the uprising or falling test process differs from the restlessness in terms of duration, this is due to the functional determinism of rising. The recordings of the restlessness measurement are about 35 seconds long for the test trials. The triggering of the corresponding event is expected during the repeated rotation process. Within the tests the actual alarm triggered after about 20s under described circumstances. But it has to be mentioned that the trials aren't representative for every "real" geriatric patient hurry.

Prior to the test runs, we performed a learning phase based on collected data of rising events from different subjects within a cross-validation. According to the person's movement, interrupts are trigger the wearable to wakes up. Subsequently it reads out information about the three axes and the type of interrupts, e.g. if restlessness occurred. Due to the constant restlessness caused by the subject's movements, the INBED node does not have the opportunity to let the restlessness count decay again, by fading. Thus, the count is reset only after reaching the restless threshold. Besides the more detailed described tests above, further trials have been performed.

The testing of the main feature, the rise detection, was evaluated by a comprehensive assessment with 224 different subjects (mostly young students with knowledge of the functionality). The measurement was totally anonymous by means no subject meta data was stored. All subjects were placed in a laying position on a regular hospital bed like height cot.

Parallel to the described testing, several overall system interviews and demonstrations, for health care professionals and clinical IT experts, were done to improve the system and the system settings.

To test the communication features, as well as the energy-efficiency we investigated the communication range of the wearables. Therefore, INBED wearables were equipped with batteries and iteratively moved remoter away from a relay node. On average a communication range of 25m is reached for line of sight while about 15m-25m are usual in a common building structure. The different results are related to the specific structure of the sending path's obstacles, like walls, water pipes or power lines.

Results

For the main functionality the rising detection a sensitivity of 100% in total only slight differences in detection speed were mentioned (few seconds) could be achieved. Within the learning process we identified an angle threshold of 63−117° in sagittal axis.

For the fall events, an optimum value for the free fall phase is ≤ 0.4g and for the impact variance of ≥ 1.3g. However, problems were encountered, while heavy stomping gait pattern and individual steps can also be detected as a false-positive fall.

Within the restlessness detection tests no false-positive events were recorded. Any larger movement (e.g., rotation) seen in the reference camera footage has also been recognized by the INBED system as restlessness event and any documented false-positive rising was be detected by the system, as well.

To evaluate the energy efficiency of the nodes, we assume a battery power of 230mAh, a clock frequency of 8MHz of the MCU and a standard room temperature of less than 20°C. In "worst-case", which means a continuous transmission of a fixed message every 0.9s, the INBED wearable lasts about 52 hours (approx. 200,000 transmissions). The "best-case", where only life-sign messages occur, results in more than 19 days lifetime for the wearable.

Conclusion

The main functionality, the rising detection showed a high sensitivity (100%) for the tests. The specificity, under controlled circumstances, is also high (no false-positive while tests), but real clinical conditions will show reliable results. Former study results are promising (see [9]).

For the restlessness test a high specificity could be measured as well, but the arranged tests are maybe not that expressive, cause no older adult subjects were included for now, which may lead to inaccurate movements. Within a future study we will assess the specificity under real conditions.

The fall test results show quite good sensitivity in heavy falls, but the final sensor system setting can lead to false-positives while heavy gait or subject bumps. A strong bump of a patient, e.g. at a table, is interpreted with high probability also as a fall. However, this can be clarified by the staff by asking. In addition, such a strong impact can also lead to injury, hematomas, which may need treatment. The sensitivity is limited for short height falls, e.g. out of low-floor bed.

By a hybrid approach, both the advantages of short-range, e.g. energy efficiency, as well as the benefits of larger bandwidth of Wi-Fi from the base station can be used [15].

The further integration of other sensors, e.g. gyroscope is planned. Another goal is to further optimize internal processes by adding the possibility to adapt individual configuration values remotely. As the INBED system is operational in our second clinical long-term study, this time as a multi-centric and randomized study within two geriatric wards, starting soon.

Transforming Nursing Documentation

Melinda L. Jenkins[a], Avaretta Davis[a,b]

[a] *Division of Advanced Practice Nursing, School of Nursing, Rutgers University, Newark NJ, USA,*
[b] *Veteran's Health Administration, Washington DC, USA*

Abstract

Graduate nursing education is positioned to transform nursing documentation so that it more fully describes nursing assessments, diagnoses, interventions, and outcomes to measure improvements in care. Learning to document with structured nursing terminology is an integral part of "Information Technology for Evidence-Based Practice", a required online course taken by all students in the Rutgers Doctor of Nursing Practice program. Beginning with SOAP and terminology required for billing, students create a clinical note adding elements of the Nursing Minimum Data Set, using Clinical Care Classification terms. Next, students are asked to select a nursing-related clinical practice guideline, electronic clinical quality improvement measure, and a screening tool that applies to their encounter note. Then, they identify Patient Reported Outcome Measures as well as improvement activities in the CMS Quality Payment Program. The course is well-received; many graduate students now face changes in documentation and electronic tools and can predict future evolution.

Keywords:

Terminology, Reference Standards, Nursing Informatics, Graduate Nursing Education

Introduction

Clinical documentation by Advanced Practice Nurses is useful to measure and improve the quality of care. Graduate nursing education is positioned to transform nursing documentation so that it more fully describes nursing assessments, diagnoses, interventions, and outcomes. As electronic health records evolve, optimizing clinical documentation will demand linking clinical notes to structured terminologies to power essential utilities such as clinical decision support, reports for value-based payment, and efficient information exchange with consumers and other providers. This paper presents a method of teaching documentation using structured nursing terminology, blending it with medical documentation required for billing, and connecting it with clinical guidelines, quality measures, patient-reported outcomes, and population health. Examples of students' exercises are included.

Learning to document with structured nursing terminology is an integral part of "Information Technology (IT) for Evidence-Based Practice", a required online course taken by all students in the Rutgers Doctor of Nursing Practice (DNP) program. The course is designed to meet one of the American Association of Colleges of Nursing's DNP Essentials: IT competencies for the improvement and transformation of health care [1] and the American Organization of Nurse Executives' recommended information management and technology competencies for nurse leaders [2]. It illustrates the use of 3 of the 4 nursing care elements in the Nursing Minimum Data Set: Nursing Diagnosis, Nursing Intervention, and Nursing Outcome [3].

Furthermore, it promotes the goals of the Nursing Informatics Working Group of the International Medical Informatics Association [4] to:

- Educate/inform nurses regarding electronic health record standards
- Promulgate standards that enable representation of nursing-related measurements
- Educate/inform nurses regarding nursing-related measurement standards

Many advanced practice nursing curricula continue to teach the Problem-Oriented Medical Record and Subjective, Objective, Assessment/Diagnosis, and Plan (SOAP) format developed by Weed [5,6]. However, in early publications, Weed wrote, "…all narrative data presently in the medical record can be structured, and in the future all narrative data may be entered through series of displays, guaranteeing a thoroughness, retrievability, efficiency, and economy important to the scientific analysis of a type of datum that has hitherto been handled in a very unrigorous manner" [5, p.599].

For many years, SOAP notes documenting history, examination, and medical decision making have provided the foundation for billing using Evaluation and Management (E & M) codes developed by the Center for Medicare and Medicaid Services (CMS), appropriate to the level of care provided in a patient encounter [7]. While CMS has recently proposed consolidating encounter payment levels, the SOAP format will very likely continue to be standard practice [8]. Most SOAP components can be captured with SNOMED-CT (Systemized Nomenclature of Medicine – Clinical Terms), a reference terminology recognized by the American Nurses Association [9]; many nursing terminologies are also mapped to SNOMED-CT [10].

Structured Terminology: CCC

Beginning with SOAP and terminology required for billing (history, examination, International Classification of Diseases, Tenth Revision (ICD-10) coded diagnoses [11], Current Procedural Terminology (CPT) coded medical interventions [12], and E & M codes [7]), DNP students in the Rutgers IT course are asked to create a clinical note that adds elements of the Nursing Minimum Data Set, as captured by Clinical Care Classification (CCC) terms [13]. CCC coded nursing terminology has a four-level framework that consists of 21 care components within 4 healthcare patterns (Health Behavioral, Psychological, Functional, Physiological), 176 nursing diagnoses, 804 nursing interventions with 4 action types, and 3 potential outcomes (Improved, Stabilized, Deteriorated) for each nursing diagnosis.

Each student's note should include expected outcomes as well as a plan with five categories of interventions, as indicated for each diagnosis: Medications, Procedure/Lab/Radiology orders, Care coordination/Referrals, Patient Education and Patient self-management assignment, and Follow up/next visit. CCC nursing terminology is ideal for the documentation of expected outcomes and Care coordination/Referrals, Patient Education and Patient self-management assignment, and Follow up. Within the electronic health record, CCC captures nursing's contribution to care by mapping nursing interventions to patient outcomes.

A brief example of a student's note follows:

S. "Though I have not fallen for years, I feel unsteady at times." Meds: Carvedilol, 40 mg extended release PO qd. History of myocardial infarction 5 years ago. No surgeries. Last eye exam 2 months ago. Lives alone in a small house with stairs.

O. Vital signs: BP: 110/80, HR: 70, RR: 16, T: 98.6. Thin white woman, age 81. Alert and cooperative. Wearing flat shoes with good tread. Labwork WNL. Cardiac and Neuro exams WNL. Gait WNL. Fall risk score = 14

A. Hypertension (ICD 10: I11.0), Safety-Fall Risk (CCC: N33.6.1)

Goal: Improve Fall Risk

P. Refill medication (RxNorm: 860524) [14], Teach Environmental Safety (CCC: N42.1), Monitor/Follow up 2 weeks (CCC: N42.0)

Outcome: Fall Risk Improved

Clinical Guidelines, Quality Measures, Screening Tools

Next, students are asked to select a nursing-related clinical practice guideline that pertains to the documented scenario. Students are instructed to find a relevant guideline from their own practice or from a search of the literature or from ECRI Guidelines Trust [15]. An appropriate guideline for this patient encounter is from the American Geriatrics Society [16, 17].

After this step, students are asked to identify nursing-related electronic Clinical Quality Improvement (eCQI) measures from CMS that are related to the encounter. Advanced practice nurses are eligible clinicians for eCQI. They should revise their encounter note if necessary to include key data elements for the measure chosen. CMS Measure CMS139v7 is appropriate for this encounter [18]. It is the "percentage of patients 65 years of age and older who were screened for future fall risk during the measurement period." It matches National Quality Forum (NQF) measure number 0101.

Students are encouraged to search for a reliable screening tool related to the guideline, and appropriate for electronic documentation. In this example, one appropriate Fall Risk Screening algorithm is STEADI, that combines subjective and objective information [19]. Other appropriate screening tools include the Morse Fall Risk Scale [20] and the Get Up and Go Test [21,22]. The students have the opportunity to revise their encounter note to include data elements required for screening.

PROMIS/HCAHPS/ Health Status Indicators/MIPS

Students are asked to describe two or three Patient Reported Outcome Measures (PROMIS) that relate to the encounter and to explain why they picked these PROMIS measures [23]. In this example related to falls, a possible PROMIS measure might be a Mobility or Physical Function measure from PROMIS Item Bank v2.0. There are several brief checklists, available in both English and Spanish, that may be incorporated into electronic documentation. Students are asked to describe implications and opportunities that use of PROMIS brings to their practice. Ideally, the tool would be used during the patient assessment, with a follow up test to assess outcome after nursing intervention.

PROMIS individual patient measures are then compared with the institution-level Medicare Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) measures with which students working as RNs may be more familiar [24].

To address population health, and demonstrate the type of data freely available online, Students are asked to go to the County Health Rankings and Roadmaps website [25], select a state and a county, then compare two or three of its health status indicators with CDC-defined peer counties. Then each student describes the most likely improvement activity that nurses may perform to address the chosen indicators. Students are taught to explore the improvement activities in the CMS Quality Payment Program to find a related activity, if possible [26]. If not, students describe an alternative and feasible nursing intervention on the Merit-based Incentive Payment System (MIPS) list.

Conclusion

Overall, the student response to these assignments has been very positive, and many of their comments highlight the learning that has taken place. Some examples follow:

- The material is very different than the research & clinical courses we usually take, so it's refreshing.
- I did not care for health information technology prior to taking this course, and after taking it, I have discovered there are infinite resources and systems aimed to improve quality of healthcare; it was quite fascinating actually.

- This course has made me want to branch out and incorporate informatics into my career.
- I am so interested in IT changes happening in my workplace now, and while reading the textbook would jot down notes to discuss with my committee and hopefully we can do a hospital wide study about something related to nurse/provider perception of the new EMR, and patient engagement in the e-portal.
- Taking a course that gave insight as to how health data is entered, processed, managed, and accessed is essential to professional practice. It has helped me rethink EHRs and how something as simple as entering vital signs can later be accessed to analyze treatment protocols.

Evidence is emerging that standardized structured nursing documentation supports accurate and complete information in practice, data reuse and sharing, and improved efficiency, business analytics, and care quality [27]. It is imperative to provide a strong background in clinical informatics to graduate nursing students who will become leaders as expert clinicians and administrators. This course shows clearly how standardized nursing terminology is applied to determine the contribution of nurses in important measures related to patient outcomes.

Future plans for the course are to continually update it with clinically-relevant readings and assignments, and to incorporate evolving standards, such as the National Library of Medicine Value Set Authority [28] and assessment tools linked to Logical Observation Identifiers Names and Codes (LOINC) coding [29]. The goal is to transform documentation of nurses' work so that it will be recognized in measures related to quality of care and payment.

Developing a Safety Case for Electronic Prescribing

Yan Jia[a], Tom Lawton[b], Sean White[c], Ibrahim Habli[a]

[a] Department of Computer Science, University of York, York UK,
[b] Bradford Royal Infirmary and Bradford Institute for Health Research, Bradford UK
[c] NHS Digital, Leeds UK

Abstract

It is now recognised that Health IT systems can bring benefits to healthcare, but they can also introduce new causes of risks that contribute to patient harm. This paper focuses on approaches to modelling and analysing potential causes of medication errors, particularly those arising from the use of Electronic Prescribing. It sets out a systematic way of analysing hazards, their causes and consequences, drawing on the expertise of a multidisciplinary team. The analysis results are used to support the development of a safety case for a large-scale Health IT system in use in three teaching hospitals. The paper shows how elements of the safety case can be updated dynamically. We show that it is valuable to use the dynamically updated elements to inform clinicians about changes in risk, and thus prompt changes in practice to mitigate the risks.

Electronic Prescribing, Medication Errors, Patient Safety

Introduction

Many countries have promoted Health Information Technology (HIT) as a primary means to improve the safety and efficiency of healthcare delivery. For example, the US government and European Commission have initiated policies to promote the adoption and use of HIT [1]. In the UK, several funding programmes have been launched to drive technology use within the National Health Service (NHS) [2]. One of the main types of HIT being targeted is Electronic Prescribing Systems (EPS) that involve "*the use of computing devices to enter, modify, review, and output or communicate, drug prescriptions*" [3].

There are many potential benefits associated with EPS, e.g. reduction in prescription errors as a result of fewer illegible orders, easier repeat prescriptions and better ability to track prescriptions [4]. However, the introduction of EPS also introduces new causes of risks, for example alert fatigue [5]. In order to realise the benefits of EPS, thorough risk assessment must be conducted. This should enable hospitals to evaluate whether the EPS will achieve safer care by reducing current clinical risk and also controlling the new risks associated with the introduction of the new technology.

In many engineering domains the use of a Safety Case (SC) is an established practice [6]. A SC is a structured argument, supported by evidence, that a system is acceptably safe in its context of use [7]. The SC is a risk management tool, providing rationale for accepting a system into service and enabling the relevant stakeholders to make informed decisions. The SC is particularly useful when it is produced at the same time as the system is designed and deployed, as it can help to inform design decisions and potential changes to the clinical workflows [8].

Previously, we reviewed the notion of hazard for HIT [9] and implemented a tool-supported methdology called the Safety Modelling, Assurance and Reporting Toolset (SMART) [10]. In this context, hazards are conditions or behaviour that can be observed at the level of the clinical system, and which have a clear link to patient harm, e.g. wrong medication. In this paper, we use SMART to support hazard analysis and develop a SC for an EPS deployed in three teaching hospitals. This paper focuses on three areas:

- Safety analysis: modelling causes and consequences of hazards, and hazard controls;
- Safety case: the use of the Goal Structuring Notation (GSN) [11] to present a safety argument, reflecting the hazard controls and risk acceptance;
- Through-life safety: an initial analysis of those aspects of the SC that are static, and those which can benefit from being updated dynamically.

Our approach involves proactive safety analysis, prior to deployment of EPS. In addition, we present a rationale for dynamically updating the SC, to support through-life safety. We refer to this as a Dynamic Safety Case (DSC) [12].

Methods

Setting: The study was undertaken in three teaching hospitals based on a large-scale HIT system, with a focus on the prescribing process as part of medication management. Figure 1 is an abstract model of the medication management process, of which prescribing is the first step, and the scope of our study.

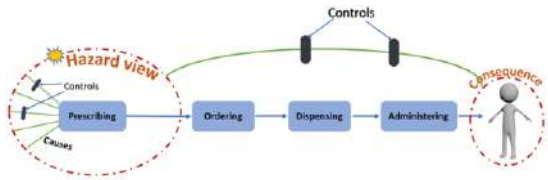

Figure 1 – Abstract Model of Medication Management

Data collection: a qualititve reseach method is used in this study. Data was collected from multi-disciplinary workshops (eight in total), which were organised to perform the hazard identification and risk analysis for the EPS. There were 3 clinical consultants, 2 nurses, 2 pharmacists, 2 safety engineers, 2 researchers and 2 systems engineers (representing the EPS supplier) involved in the workshops.

Data analysis: A combination of Software Hazard Analysis and Resolution in Design (SHARD) [13] and Systems Engineering Initiative for Patient Safety (SEIPS) [14] were used to stimulate the indentification of hazards, their causes and consequences, and the controls associated with the hazards. SHARD is suitable for identifying hazards and casuses of hazards from a software perspective, e.g. missing data, but it does not address complex interactions between software systems and humans. SEIPS provides a framework for a comprehensive consideration of work system design, which includes five elements: *person*, *tasks*, *technology and tools*, *environment* and *organisation*, and its impact on care processes and outcomes. This helps to address the interactions of software system and humans in a complex socio-technical context. Thus the two methods are complementary. The results of using SHARD and SEIPS are recorded using bow-tie diagrams. Finally, GSN was used to represent the safety arguments for EPS based on the results and findings from the workshops.

Results

Six main findings were identified, which are reported in this section.

The importance of a clear process model

To ensure the safe implementation of HIT systems, it is important to understand how HIT systems are used to support the clinical activities. As such, the first step was to define a clear process model to reflect the relationships between EPS, as a HIT system, and prescribing, as a clinical activity. During this task, one challenge arose, which is to what level of granularity the prescribing process should be modelled, e.g. a more detailed IT centered view, including "right click for more medication options", or a more abstract clinical activity level, such as "choose right medication". As a result of considering both the validitiy of the processes and the emphasis on clinical context for hazard identification, the multidisciplinary team constructed the clinical process model to describe the flow of clinical activities and decisions, linked to the specific functions in the EPS, as shown in Figure 2. This also reflects well established health informatics approaches to evaluating HIT systems, that HIT interventions should be clinically- and problem-driven rather than technology-driven [15]. As is shown in Figure 2, the "sign" clinical activity in this model is associated with the "sign medication" function in the EPS. This model provides an understanding of the interaction between a HIT system and its clinical activities which is necessary before being able to identify hazards.

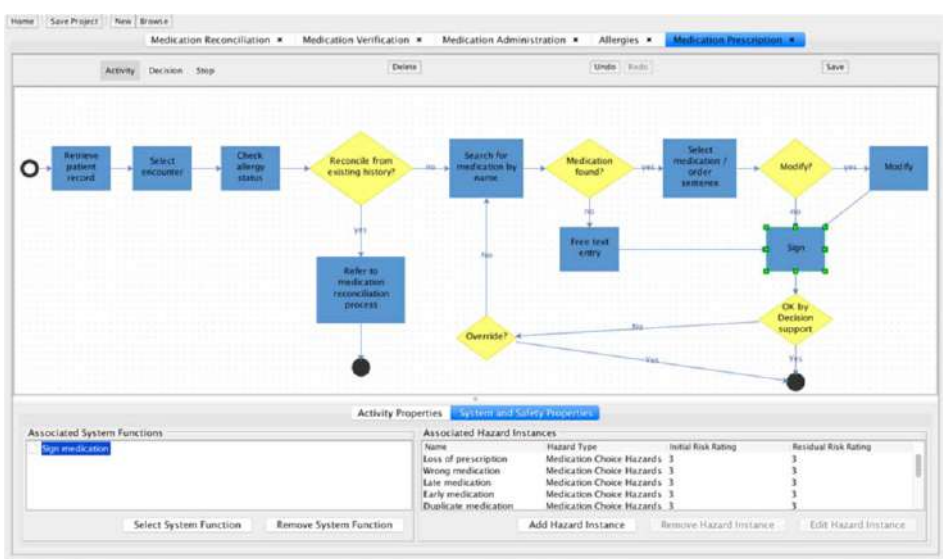
Identifying hazards in complex clincal settings

The most critical step in achieving and demonstrating the safety of HIT systems is to conduct a systematic process to identify potential hazards during the product development and then engineer them out or reduce their likelihood [16]. In order to carry out a thorough and proactive hazard identification, we first agreed on an overall hazard categorization based on the five rights in medication safety [17], producing five general categories:

1. Wrong patient selected in prescribing phase
2. Wrong medication dose prescribed
3. Wrong medication route prescribed
4. Wrong medication time prescribed
5. Wrong medication choice

Each hazard category can be refined further. We do this using the failure classes defined in SHARD, which provides a structured approach to the identification of potentially hazardous behaviour in software systems. By applying these failure classes (*omission*, *commission*, *early*, *late* and *incorrect*) to the hazard category 5 - *wrong medication choice*, defined above, we identified seven specific hazard cases, *loss of prescription*, *unintended medication*, *wrong medication*, *late medication*, *early medication*, *duplicate medication* and *adverse interaction*.

For brevity, the rest of the paper focuses on the wrong medication choice category, but the method described above would apply equally well to the other hazard categories.



Fgure 2- Prescribing Process in SMART

Modelling the causal chains (technical and non technical)

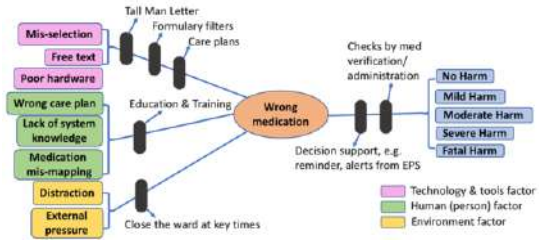


Figure 3 – Bow-Tie for Wrong Medication

In order to mitigate the hazards, it is important to identify their causes so we can identify effective controls. In a socio-technical system, it is important to recognise both technical and non - technical factors. Therefore, we used the SEIPS model to guide us to think systematically. The use of the SEIPS model both helps to identify causes of the specific hazard, and the controls. For each hazard, there are a range of controls that can counteract causes of the hazards, and others that can influence the consequence of the hazards. Figure 3 illustrates the causes and consequences and the controls related to the *Wrong Medication* hazard, arising out of the analysis workshops.

In Figure 3, we can see that there are 8 identified causes that contribute to *Wrong Medication* during prescribing (the left-hand side of the bow-tie). Among them, three causes belong to the technology factor (*technology and tools* in SEIPS), which is related to the EPS deployed in the hospital. A well designed EPS should have the ability to mitigate the causal factors, for example by integrating Tall Man Letter to make it noticeable or striking out inapplicable options when the prescribers are selecting medications. Another three causes are categorised as human factors (*person* in SEIPS). These causes can be controlled by providing education and training to clinical practitioners. The last two causes are work environment factors (*environment* in SEIPS). They are related to the local organisation and policy. These factors should be controlled by providing guidance or procedures by the local organisation, e.g. to close the ward at key times.

The classification of causal factors is useful, as recognising that different causal factors belong to particular categories helps to find the right control. It also helps to make the causes of hazards explicit and reveal the weak points of the system. For example, considering *Wrong Medication*, it seems that the organisation should also seek to reduce the pressure on clinical practitioners, e.g. by reducing the un-necessary and non-clinical related workload (*environmental* factor).

Difficulty of determining severity

Turning to the right-hand side of the bow-tie, we consider the consequences of the hazards. In the workshops, we found it very challenging to assess the potential harm concerning a particular hazard. For example, consider the *Wrong Medication* hazard; the medication type, the profile of the patients, the complexity of the clinical conditions and the state of the clinical setting would lead to different consequences.

In addition, we found it difficult to map the consequence of medication errors to severity of harm. From our literature review, we discovered that it is very hard to find information to make such connections. Studies such as [18] and [19] either just give a severity classification without a detailed description of how they mapped their patient results to the severity, or they focus on error types and their causes, but do not identify the severity of the patient outcome. Further work is needed on how to categorise the severity of harm and give concrete examples how to map the consequences (patient outcomes) to different severities. In order to illustrate this, we present examples of patient harm in Table 1 using the World Health Organization (WHO) severity classification [20]. This table is intended to be illustrative but refining and expanding it, e.g. by considering different aspects of human function such as vision and respiration, might aid in future hazard and risk assessment.

Clear arguments, the essense of reasoning

Based on insights gained in the workshops, we employed GSN to represent the safety argument for the EPS in three teaching hospitals. Figure 4 shows the top level of the safety argument and reflects the use of a Hazard Log to record information about all the hazards. A Hazard Log is a standard safety management tool for recording and tracking information about risks, used in other sectors, e.g. aerospace, but also applicable in healthcare and required by the NHS HIT standards [7; 21].

Table 1– Examples of Severity Classes

Severity	None	Mild	Moderate	Severe	Fatal
Summary	No symptoms (detected)	Symptoms short-term, requiring minimal intervention	Harm or loss of function may be long-term, requiring intervention	Life-saving intervention needed; long-term harm or permanent loss of function	Death caused or brought forward by the incident
Examples	Paracetamol given instead of priadel (loss of therapeutic effect)	Nausea, vomiting or diarrhoea from overdose of epirubicin	Digestive problems including ulcers and internal bleeding	Blindness due to prescribing a diuretic to patients with low blood pressure	Weekly dose of methotrexate given daily
	Use of antibiotics to treat viral infections (NB reduces utility of antibiotics)	Forgetting to specify maximum daily dosage for an "as required" drug	Hypotension due to overdose of lisinopril	Lung damage and possible sepsis giving oral treatment to patient with dysphagia	Ten times overdose of insulin
		Accidental sedation due to prescribing diazepam not diltiazem	Dyspepsia and ulcers from overuse of non-steroidal anti-inflammatory drugs for arthritis		Haemorrhage from incorrect use of warfarin

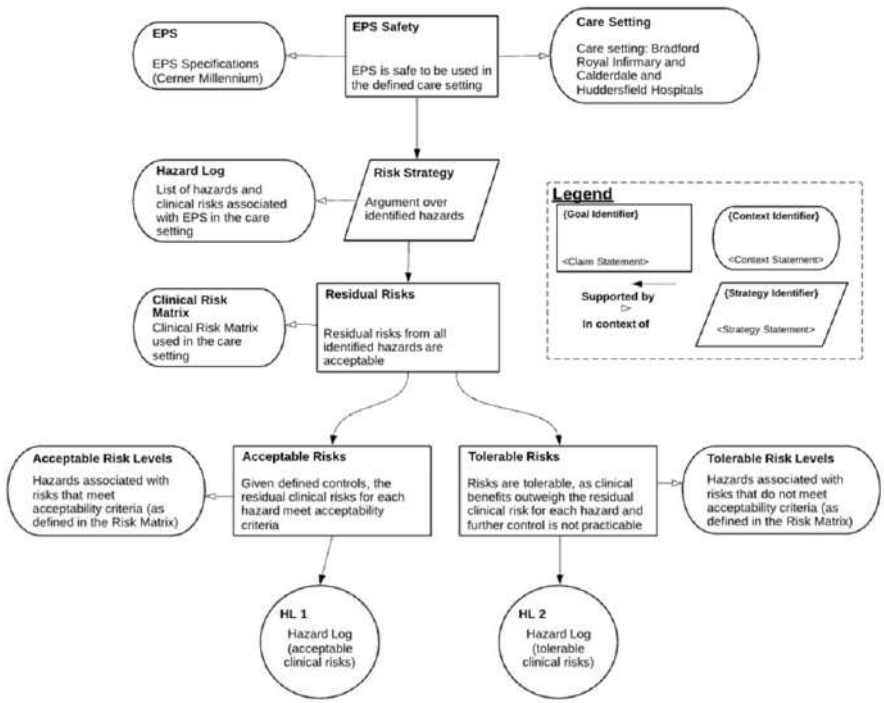

Figure 4 – Top level of the GSN for the EPS for the three Teaching Hospitals

It is often infeasible to eliminate risks, so the claim **Residual Risks** shows that the risks left after implementing the controls are acceptable and/or managed in the context of the Risk Matrix used at the hospitals; this breaks down into two sub-cases:

- Residual risks meet the acceptability criteria
- Residual risks do not meet the criteria, but can be accepted due to the clinical benefit

Evidence to support these claims can come directly from the Hazard Log.

For example, the risk of the "*Wrong Medication*" hazard has been reduced to an acceptable level, given the seven controls identified in Figure 3. The controls and risks are set out in the Hazard Log. Alternatively, we could have expanded the GSN argument further, replacing solution HL1 with more detailed sub-arguments for each hazard. For the "*Wrong Medication*" hazard, the solutions at the bottom of the argument would be evidence about the effectiveness of each of the controls.

The evidence about the controls on the left of the bow-tie is generated from analysis of the error records, which are derived from chart review, automated review of electronic records, review of incident reports, review of self-reporting, patient and staff interviews, and from direct observation [22]. For example, in order to assess whether the controls – Tall Man letters and Formulary filters – are effective, we should interrogate the error rates related to mis-selection of medication and free text.

Dynamic Safety Cases

It is well established that the safety of critical services is a dynamic property [23]. In healthcare, this dynamism is often attributed to variation in the health and care services, and their underlying systems, as well as in the environments within which they are deployed. Although variation can be seen as a negative attribute, e.g. a sign of noncompliance, increasingly more emphasis is placed on the necessity of variation to enable, and sometimes empower, people and technologies to adjust and adapt to ensure continuous safe care. The ability to adapt and adjust is a key enabler for resilience in healthcare [24]. Unlike traditional SC, which often remain static and are only updated in a reactive manner, both the justification and evidence base of the SC for a complex process such as prescribing should evolve based on real-time data that is collected, proactively, from diverse sources, particularly covering and combining clinical, organisational and technological factors.

The SC described in this paper will be extended and integrated with a new dynamic risk model and uncertainty assessment algorithms, based on Bayesian Networks, for proactively computing the confidence in, and updating the reasoning about, the safety of the medication services based on real-time data. This will be combined with a set of update rules triggering the provision of actionable suggestions to clinicians in response to changes in the services, clinical settings, the safety argument or the confidence in that argument. Thus clinicians will be able to take risk reduction action, i.e. adding new controls, based on leading indicators/precursors of problems before they develop into potential errors and patient harm.

Discussion

The paper summarises our work to date on developing a full SC for the entire HIT system in the three hospitals. Our results so far show that having a clear model of the medication process aids analysis, both in identifying hazards and their controls. In particular the clincal process models enable the workflows to be analysed at a level which is understandable by the users of the EPS, and which is also clinically meaningful.

The use of the bow-tie to model the causes and consequences of a hazard in the precribing process gives a direct visuliation of how a hazard is controlled, what can be the potential causes of this particular hazard, what consequences there can be for the patient through this hazard and what kind of controls we have to mitigate the hazard. This is a very useful basis for hazard and risk assessment. We see an opportunity to use this approach to improve analysis of medication safety, particularly assessment of risk, beyond just EPS, and this is an area for future research.

Further, we have shown how to use GSN to construct an explicit argument to justify the safety of EPS use in the context of the wider medication management system. The SC rests on evidence, some of which relates to the controls identified in the bow-tie diagram. SC are predictive, and the evidence is usually based on analysis prior to operation. A first step in making the SC representative of actual use of EPS would be to update the evidence to reflect the effectiveness of the controls, as they change over time. Ideally we would use this to show that the EPS plus controls is better (in terms of patient safety) than the previous manual system. However it is hard to obtain data that shows what happened before introduction of EPS, and hence to make such comparisons. In contrast, in future, it will be possible to see whether or not the controls are effective and the extent to which the risk is reducing over time, e.g. the frequency of over-riding alerts and error rates relating to mis-selection and free text are going down. Thus the SC can support management of risk through life, rather than just being a tool for deciding whether or not a system can be deployed. This is a key area of our future work, and should lead to development of DSC.

Conclusions

Management of risk associated with HIT systems is challenging as the technology is used in a complex socio-technical setting, and the staff using the systems are often under significant pressure, due to the volume of work, or the need to respond to patients' symptoms very quickly. We have presented our approach to assessing the safety of HIT systems, based on work on EPS in three UK hospitals, which draws on accepted practices in other domains, which we believe helps address the problems of managing safety in a healthcare setting.

The work enables causes and consequences of hazards to be analysed more directly than is possible with a purely statistical approach. Further, it enables the role and effectiveness of risk controls to be assessed. The work reported here is part of an ongoing research programme that will enable dynamic control over safety risk, by updating the evidence in the SC from analysis of operational data.

Abstract

Cancer is a major public health challenge in low and middle income countries (LMICs). In this paper, we describe work in progress to develop functionality within an open-source electronic medical records system to support safe and standardized cancer care in low-resource settings. We engaged cancer care providers from LMICs to elicit and prioritize requirement, and following a rapid application development approach we developed chemotherapy prescription and documentation functionality within OpenMRS.

Keywords:

Developing Country; Electronic Health Records; Neoplasms

Introduction

Cancer is a major cause of mortality and morbidity worldwide. As of 2018, there are an estimated 14 million cancer cases and 9.6 million cancer deaths worldwide, according to the WHO [1]. Cancer causes more deaths than HIV/AIDS, Malaria, and Tuberculosis combined.

The cancer burden is heaviest in low and middle income countries (LMICs) where it is fast replacing infectious diseases as a leading public health challenge. Sixty percent of cancer cases and over 70% of cancer deaths are occurring in LMICs. Yet cancer has not been receiving the needed attention and priority, e.g., in the form of funding. Cancer receives only 2% of the funding that is put towards other diseases in LMICs [2].

Leveraging health information technologies such as electronic medical record (EMR) systems in oncology in LMICs can contribute to the improvement of cancer care outcomes through improved care coordination, standardization of treatment, facilitation of guideline adherence and computerized clinical decision support (CDS) [3]. Cancer is a complex family of diseases and cancer care is also complex. There are hundreds of cancer types, each with different risk factors, prevention strategies, presentation, staging, investigations and treatment approaches, including chemotherapy, radiotherapy, and surgery [4]. In addition, health care systems in LMICs are varied, often with limited availability of cancer care specialists and services such as radiotherapy and pathology [2; 5]. Medical errors, e.g., in chemotherapy administration, are common in such complex care environments [6] and the lack of standardization of care affects outcomes. Lack of good quality data for research and planning is also a major challenge for cancer care in LMICs [3; 7] that EMRs could help address.

Unfortunately, adoption of EMRs in oncology in LMICs remains low. For example, the majority of EMRs in Africa are implemented within HIV/AIDS care programs, and only 27% in non-HIV related programs [8]. There have been few reports on EMR implementations in cancer, e.g., in Rwanda [7], but these implementation projects are still in their infancy.

The complexity of oncology is a factor in this low EMR adoption because oncology is thought to require complex and expensive software systems [9] which are not affordable in LMICs, especially considering the lack of prioritization and funding in LMICs.

Open source software systems offer a potential solution to the prohibitive cost, in addition to fostering collaboration and enhancing the use of interoperability standards [10; 11]. Open source systems are arguably more secure since the source code is reviewed by many independent members of the open source community. OpenMRS (https://openmrs.org/) is one such open source EMR platform that is widely used in LMICs particularly in the management of HIV/AIDS, tuberculosis, malaria, and maternal and child health [12]. It is a robust, modular and scalable web-based platform built in Java. It uses MySQL databases and has an extensive data dictionary called CIEL (Columbia International eHealth Laboratory) which maps to ontologies such as ICD-10, SNOMED CT, RxNORM, and LOINC. OpenMRS also uses interoperability standards such as HL7 and FHIR. It is freely available for download and has a large community of active developers and implementers in over 40 countries.

In this paper, we describe work in progress to leverage the OpenMRS platform to develop a fully functional oncology EMR that meets the needs and requirements of cancer care in LMICs [13]. The initial work focused on developing a chemotherapy management module to facilitating efficient, standardized, and safe chemotherapy ordering, documentation, and tracking by doctors and nurses.

Methods

Stakeholder Engagement and Requirements Elicitation

Stakeholders were purposively identified to include general doctors, oncologists, nurses, and others working in cancer care, especially those in LMICs or those familiar with this context. Organizations represented included Partners in Health (PIH), Uganda Cancer Institute, Dana-Farber Cancer Center and UNC Project Malawi. We also involved software engineers from the OpenMRS community (mostly from PIH), the OpenMRS leadership team, and IBM Health Corps. These regularly engaged in a variety of meetings and communication interactions: via email, video conferences, OpenMRS Talk (http://talk.openmrs.org), OpenMRS design forums, and face-to-face meetings in Boston, MA, to elicit and prioritize requirements, discuss design considerations and review sketches and prototypes. The technical members of the team also visited and engaged with those on the ground at the PIH's cancer treatment facility in Mirebalais, Haiti to review the current workflows, paper forms, and treatment protocols, and to interact with target end-users.

Development Process

We followed the rapid application development approach. The software engineers and OpenMRS implementers were co-located in Boston, MA over approximately one month. We reviewed the existing code (freely available in GitHub), the OpenMRS data model and concept dictionary to determine what needed to be modified and what could be reused. Then we developed mock-ups and prototypes for the user interfaces implementing the chemotherapy protocols. These were iteratively reviewed by target end users and changes made immediately. Several modules that are already available in the OpenMRS platform were used e.g., the metadata module for adding new concepts, and the OpenMRS API, a REST web service used to implement the technical workflows.

Results

Requirements

Several requirements for comprehensive oncology support were elicited, including oncology-specific documentation (e.g., tumor description), exporting data to cancer registries, computerized clinical decision support in terms of diagnosis, reminders, etc.

Chemotherapy management was prioritized of all the requirements because it is a high-risk part of the oncology workflow – complex drug combinations, tightly controlled doses, severe toxicity and need for several safety checks [14]. Currently, chemotherapy ordering at the represented cancer centers is paper-based and relies on verbal instructions between care team members.

For the chemotherapy management module, requirements, include the following: (i) provide an oncology-specific patient overview with patient identification, cancer diagnosis, cancer journey summary (e.g., On CHOP cycle 3 of 6); (ii) show list of appropriate chemotherapy regimens and pre and post medication for the cancer diagnosis, (iii) automatically calculate body surface area (BSA) from height and weight, and (iv) calculate doses and generate a prescription when the doctor chooses a regimen (v) allow the prescriber to modify the dose by a given percentage but provide a reason for the modification (vi) track cumulative doses of certain drugs (e.g., Anthracyclines) and notify the prescriber when ceiling doses are reached.

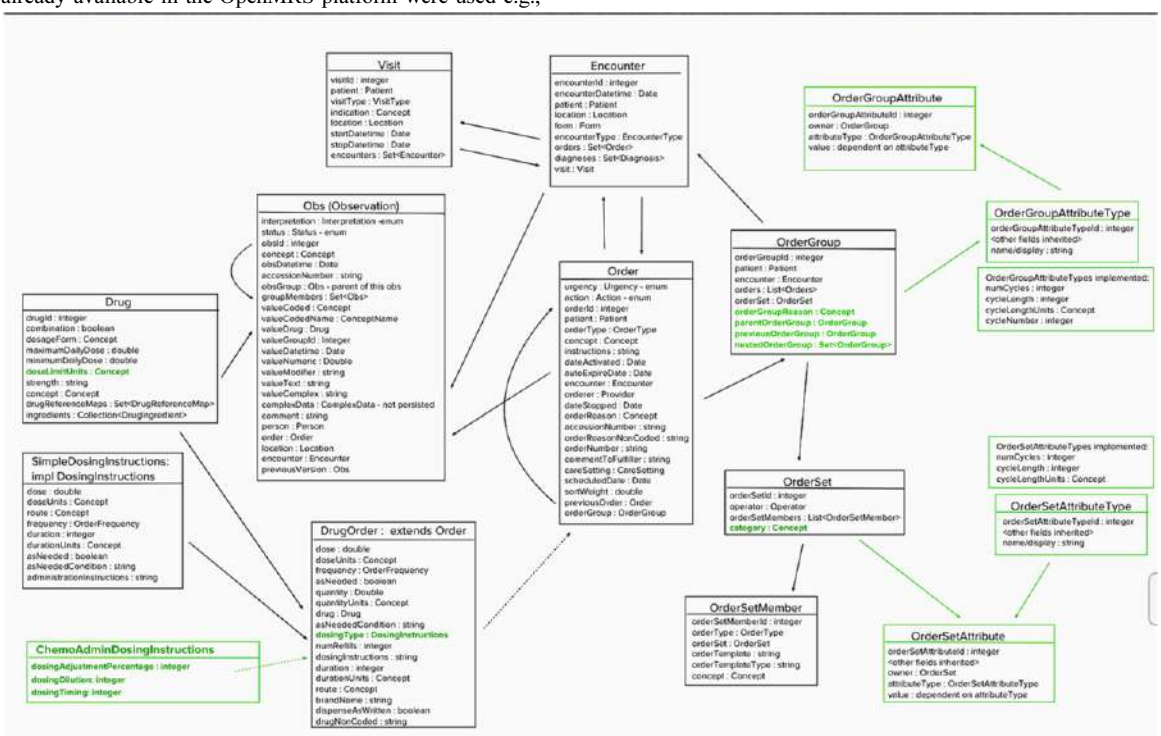

Figure 1 – Data model with chemotherapy related concepts added (in green).

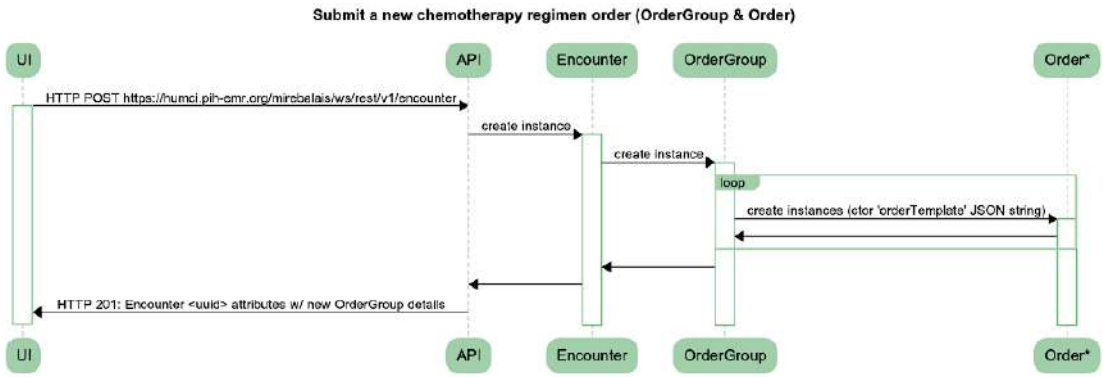

Figure 2 – OpenMRS API Invocation to create a chemotherapy order

Changes in OpenMRS

The oncology module required introduction of new concepts that are currently not available in the OpenMRS data model and concept dictionary. **Figure 1** shows the data model with chemotherapy-related concepts that were added during this project colored in green. These concepts are related to drug combinations and the cyclic nature of chemotherapy, as well as the requirement to track number of cycles in regimens, cycle numbers (e.g., 3 of 6), length of cycles, administration group (e.g., chemotherapy, pre medication, post medication), and maximum lifetime dose.

The *OrderGroup* (attribute of *Order*) and *Drug* objects that already exist in OpenMRS were modified to enable capture of information about chemotherapy regimen, such as *cycleNumber*, *cycleLength*, *cycleLengthUnits*, and *DoseLimitUnits*. *ChemoAdminDosingInstructions* was also added to The *DrugOrder* object (extension of *Order* object) to capture special instructions that are not captured by *SimpleDosingInstructions*. Classification into pre-medication, chemotherapy, and post-medication leverages the *OrderType* concept field in *Order*.

We also used the CIEL dictionary currently in PIH's version of OpenMRS, which contains oncology concepts, constrained to the workflow and context, e.g., mappings to ICD-O, the oncology subset of ICD. While each facility can add concepts to CIEL, a team of terminology experts at Open Concept Lab (https://openconceptlab.org/) coordinates and distributes CIEL, and encourages all local additions to be added centrally to ensure consistence.

After addition of the concepts, we hardcoded templates for twelve chemotherapy protocols currently used at Mirebalais for management of lymphomas, breast cancer and other solid tumors. The templates were made as metadata files in the YAML syntax, describing each chemotherapy regimen's medications and cycle details. YAML is data serialization language similar to XML but with a minimal syntax that focuses on data interchange rather than document mark-up. We chose to make the regimen templates in this format to facilitate ease of future addition of new chemotherapy treatments to the initial set, and to ease update of the delivered chemotherapy regimens by trained doctors, clinicians, and non-software programmers.

To allow changes to the chemotherapy regimen templates, or add new ones easily by different cancer centers, we developed the Yet Another Automated Regimen (YAAR) management tool, which can process the YAML files and manage the OpenMRS REST API back-end messaging. The tool was implemented in Python and is meant to be extended as requirements evolve. As a future goal, the tool should be extended to support additional treatment types (new schemas) beyond the chemotherapy regimens targeted in this project.

User Interface Design

We used the React UI framework (Material UI) to develop the front end. This first displays the oncology-specific patient summary as per the requirements above, with an option select "Prescribe chemotherapy". The prescriber is then taken to a screen that shows chemotherapy regimens and pre and post medication, their schedule, doses and information such as dose modifications or cumulative dose. With a few clicks the prescriber selects the appropriate regimen, schedule and doses, adds notes if necessary and submits the order.

Figure 2 shows a sample OpenMRS API invocation to create a new *OrderGroup* and *Orders* during chemotherapy ordering, and **Figure 3** shows some of the screens for the chemotherapy prescription interface. We also made a nurses' interface that allows the nurse to document the treatment after it has been administered as well as details such as patient reaction to medication or toxicity, track cycle numbers, etc.

All the code, documentation, workflow analysis and mock-ups, as well as links to other project resources are available in GitHub (https://github.com/openmrs/openmrs-module-oncology).

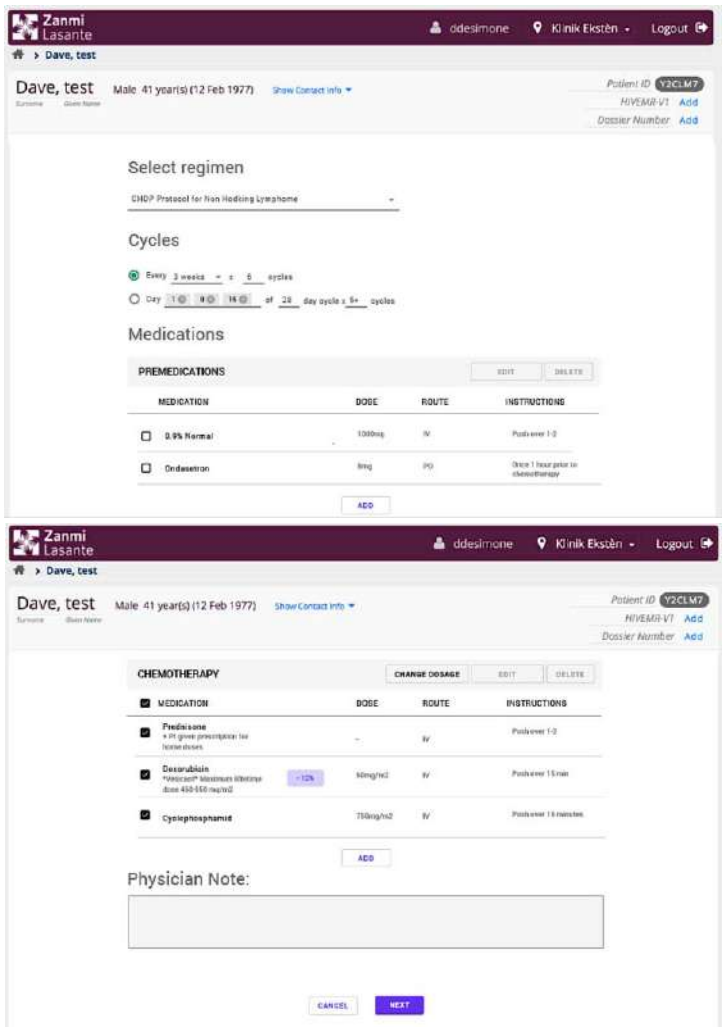

Figure 3 – Examples of user interface screens for chemotherapy prescription workflow

Discussion

In this paper, we describe collaborative efforts towards developing a fully functional oncology EMR for low resource settings based on the open source EMR OpenMRS. We began by focusing on chemotherapy management, and currently we have a functional prototype based on the workflow and clinical services at the PIH Mirebalais cancer center. We implemented twelve chemotherapy regimens and documentation requirements, but the product is scalable using the chemotherapy template authoring (YAAR) tool which allows new regimens to be added so that the system can be used in different contexts or at other cancer care centers. The prototype has been evaluated as part of the development process by oncologists and other cancer care providers from Uganda, Rwanda, Malawi, Haiti, and the US but the module is yet to be implemented at point of care. The twelve chemotherapy protocol templates that were configured were based on the care process at Mirebalais cancer center and that is where initial implementation is planned, but with minimal changes the module can be used elsewhere. Evaluations and further development for implementation in Uganda, Rwanda and Malawi are ongoing, and feedback from these clinical applications will inform future iterations of development.

This project also provides a basis for development of clinical decision support such as automatic body surface area calculation, automatic dose calculation, safety checks and alerts for dose (including lifetime cumulative doses) and schedules basing on protocols integrated in the system, as well as better clinical data capture and (re)use for forecasting and planning.

Future features will include the addition of pharmacist workflows to complete the chemotherapy administration workflow, as well as other forms for complete oncology documentation e.g., diagnosis, staging and treatment, follow up and interfacing with cancer registries.

Some challenges faced during the project included difficulty in gaining consensus on data model changes to support cancer specific concepts, and a complex code base that was hard for new developers to learn. Current challenges include dedicated software development teams and project management to advance the work quickly.

Conclusions

This project demonstrates the potential for collaborative development of affordable open source systems for addressing the cancer epidemic in LMICs. The system will facilitate a safe and standardized prescription of chemotherapy as well as proper documentation and monitoring. This is important because chemotherapy is very toxic, and cancer care is complex and prone to medical errors, which can be detrimental for the patient.

In this project, we also developed tools which can be used by other cancer care providers to implement their own protocols. Using the rapid application development approach allowed us to accomplish this project in a relatively short time. Constant interaction with the end users at all stages of the project was crucial for a proper understanding of the requirements and the oncology domain in general. Co-location of the technical team was advantageous since some members of the team were new to OpenMRS.

Abstract

Patient falls, a subcategory of patient safety events, cause further harm and anxiety to patients in healthcare systems. Patient fall reports are a valuable resource to identify safety issues that demand further attention. Still, the main challenge for patient fall reports is the lack of quality and detail in writing. A method of evaluating patient fall reports would help us better understand the root causes of falls and prevent their recurrence to improve patient safety. Employing the Agency for Healthcare and Quality rubric for assessing the quality of fall reports, we compared three different machine-learning models and identified the most effective method for scoring fall reports using AHRQ's rubric. The results of this study are intended to be applicable in healthcare facilities to score reports during reporting for reporters to improve report quality. The ultimate goal is to increase learning from fall reports for better prevention of patient falls.

Keywords:
Patient Safety; Falls; Machine Learning

Introduction

Measuring and analyzing incidents that could result in unintended harm towards patients, or patient safety events (PSE), are essential in forming strategies to improve patient safety. A PSE is gathered through a process called event reporting, which happens on a voluntary and limited basis [1]. However, the reports often vary in level of detail, bias, and ambiguity. Event reporting has proven to be successful in increasing safety in other hazard-prone industries, such as aviation [2]. Even with a plethora of technology and data, healthcare lags behind in collecting and applying PSE reports. In the 1999 report, *To Err Is Human*, the Institute of Medicine places incident reporting as one of the most urgent areas of healthcare to improve [3]. Clearly, managing an efficient PSE reporting system is crucial for clinicians and hospitals to learn from past events and form solutions to improve patient safety.

Patient falls, the most common type of PSE, are defined by the Agency for Healthcare Research and Quality (AHRQ) as "an unplanned descent to the floor with or without injury to the patient." There are between 700,000 and 1,000,000 patient falls each year in the United States [4]. A patient fall can have various consequences such as additional pain or injury. It may also lead to additional hospital stay, on average about 6.3 more days, costing the patient about $14,000 [5]. Even if there is no injury, the fall can cause anxiety or embarrassment to the patient. Insofar, the healthcare community has heavily emphasized report collection, but poor processing of safety reports remains a key challenge in PSE reporting [6]. Current reporting systems are suffering from low-quality reports, which has greatly damaged the learning value of previous events. Poor quality reports are not only unhelpful but also potentially dangerous, as missing information could cause hospitals to make incorrect decisions about the patient. High quality reports, on the other hand, provide hospitals with accurate and complete data to prevent future patient falls and increase safety. Quality improvement remains a problem because reporters have no way of receiving immediate feedback on their reports. Therefore, a tool of rapidly assessing reporting quality is necessary. If we could alert reporters of their report quality during the writing process, they could improve their description of the event and submit higher quality reports.

Although AHRQ has developed a rubric to identify if patient fall reports contain enough information for effective analysis [7], no real-time scoring system currently exists. In our previous study, we proposed a PSE similarity searching model that provides the reporter with suggestions on solutions and prevention, increasing the motivation of the reporter to include as many details as possible [8]. We also designed a user-centered, self-learning reporting system that assembles a large PSE knowledge database [9]. Therefore, a tool that scores reports would further upgrade our system by providing numeric scores to reporters and further increasing their motivation to improve the quality of their report. Scoring would also build a higher-quality database with more effective self-learning.

Instead of traditional human review, machine learning is a plausible alternative to score patient fall reports in terms of efficiency. Natural language processing (NLP) allows computers to understand human language and has been used to extract medication information from electronic health records (EHR), a similar data type to PSE [10]. Two classic machine learning methods, support vector machine (SVM) and random forest, have been successful in classifying hospital stay records for disease prediction [11]. Recurrent neural networks (RNN), a type of deep learning model, have recently been a popular approach for more complex text classification tasks [12]. In the healthcare field, RNN have displayed higher accuracy than other machine learning methods when learning diagnoses from EHR [13]. We hypothesize that machine learning, especially deep learning, will be highly effective in scoring patient fall reports. Different machine learning algorithms can have varying levels of success depending on the initial dataset and the classifier's ability to gain an effective generalization without overfitting [14]. Comparison of multiple algorithms is therefore necessary for finding the most accurate scoring method specific to the fall reports dataset.

This study compared the performance of three different machine learning models and identified the most promising for the classification and scoring of patient fall reports. We first processed the fall reports from a Patient Safety Organization (PSO) institute using NLP techniques and labeled them using

the AHRQ rubric. Then classifiers based on SVM, random forest, and RNN models were evaluated by measuring the model performance on AHRQ rubric labeling. We finally proposed a report quality scoring system and presented both high- and low-quality report examples. The results of this study could be used to give reporters immediate feedback and encourage improvement of reports before submission. Ultimately, better quality patient fall reports would help healthcare providers identify what causes falls and how to prevent them.

Methods

Construct a Database of Labeled Patient Fall Reports

Patient fall reports are commonly written as first-person narratives describing the event and any details that the reporter deems pertinent to the fall. The reporter is usually a nurse but can be a staff, volunteer, or any type of person witnessing the event. Therefore, fall reports can vary between reporters of different professions or backgrounds. The AHRQ toolkit for preventing falls in hospitals [7] includes a specialized rubric for assessing patient fall report quality, which has the potential to measure the fall reports from 13 perspectives (Table 1).

Table 1 – 13 Perspectives Measuring Patient Fall Reports

Labels
1. Witnessed/Not witnessed
2. Outcome of investigations recorded
3. Type of injury
4. Buzzer/bell available within reach before fall
5. Fall from Bed
6. Whether bedrails were in use
7. Floor wet/dry/talcum powder
8. Footwear
9. Walking aid in use/in reach
10. Mental state
11. First fall this admission or repeat fall
12. Days since admission
13. Medication affecting risk of falls

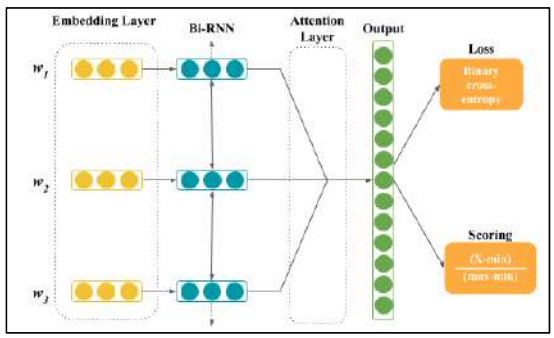
We used 2,046 de-identified fall reports from a PSO institute to extract and classify the unstructured portions of the reports using the categories shown in Table 1. We scored each report based on if each category was included ("1") or not included ("0") in the report. Two reviewers labeled the reports. First, the reviewers labeled the same 100 reports and resolved any disagreements in scoring through group discussion. Since the divergence rate was minimal at 0.15%, the reviewers then labeled the remaining reports separately.

Construct Machine Learning Models

The three models were constructed to perform multi-label, multi-class classification, where multiple labels could be assigned to one report. The labels were then used to calculate a final score reflecting the report quality. SVM and random forest classifiers are both suited for multi-label, multi-class classification and were constructed using the labeled patient fall reports. Each report was transformed into vectors and weighted using term frequency-inverse document frequency (TF-IDF). The SVM utilized the one-versus-rest strategy to achieve multi-class capabilities.

The tokenization of RNN model was conducted by using the Keras preprocessing module to transform report into a sequence of numbers corresponding to the frequency of each word. To simplify the input for the model, the sequences were padded to the length of the longest report (N=436). The model contained an embedding layer, hidden layers, an attention layer, and an output layer. Figure 1 shows the structure of the RNN.

Figure 1– Flowchart Representation of RNN



The first layer of the model was the word embedding layer, where each tokenized word was expanded into a 100-dimensional vector from the GloVe pre-trained library [15]. The GloVe library is trained on six billion tokens from public domains, helping the model become more generalized even if training data is limited. The word embeddings were set as trainable to fit the patient safety scenarios. After the embedding layer, the model contained a bi-directional long short-term memory (Bi-LSTM) layer with a hidden size of 128. An attention layer was placed on the top of Bi-LSTM layer to assign and merge weights of word. To prevent overfitting, we applied dropout with a dropout rate of 0.5 within the Bi-LSTM layer. The output layer used the sigmoid activation function and produced a list of 13 labels. The RNN was compiled on the Keras API with TensorFlow backend. Hyperparameters were tuned on the patient fall data to optimize performance.

Train and Test the Model

Due to the limited size and imbalance of our dataset, the structures of the models were first tested on single-label Yelp reviews from the Yelp Dataset Challenge in 2018 [16]. The Yelp Dataset Challenge is a public dataset of business reviews released by Yelp for academic and educational purposes and is especially useful to test RNN models [17]. A subset of 3,500 positive and 3,500 negative labeled reviews was chosen to be larger and more balanced than the patient fall dataset. After testing on the Yelp dataset, the models were optimized on the patient fall dataset. Both datasets were shuffled and split into training (70%), validation (10%) and testing (20%) sets. All three models were evaluated using the performance metrics accuracy and F_1 score.

Scoring the Reports

For each report, the probability estimates for the 13 categories were taken from the highest performing model among the three and summed. The quality score of report i was calculated using the scaling function:

$$Score_i = \frac{(E_i - E_{min})}{(E_{max} - E_{min})}$$

where E_i was the sum of probability estimates of report i, and E_{min} and E_{max} were the minimum and maximum sums among all the reports.

Results

Distribution of Labels

We labeled 2,046 reports based on the 13 categories from the AHRQ rubric on patient fall reports. There was high variation between frequencies of positive labels in the reports. The most frequent label was "Type of injury," seen in 1,290 reports. The least frequent label was "Days since admission," seen in only five reports. The average number of positive labels each report contained was 2.189 labels out of 13, with a standard deviation of 1.386.

Model Performance

The three models were first tested on the Yelp dataset, then the patient fall dataset. Table 2 shows the average accuracy and F_1 score for each model on the two datasets. The RNN model showed the highest performance on the patient fall dataset, but the SVM showed the highest performance on the Yelp dataset.

Table 2 – Yelp Performance

Method	Yelp Dataset		Patient Fall Dataset	
	Accuracy	F_1	*Accuracy*	F_1
SVM	87.1%	0.870	89.9%	0.648
Random forest	73.4%	0.714	87.6%	0.279
RNN	90.0%	0.889	86.3%	0.397

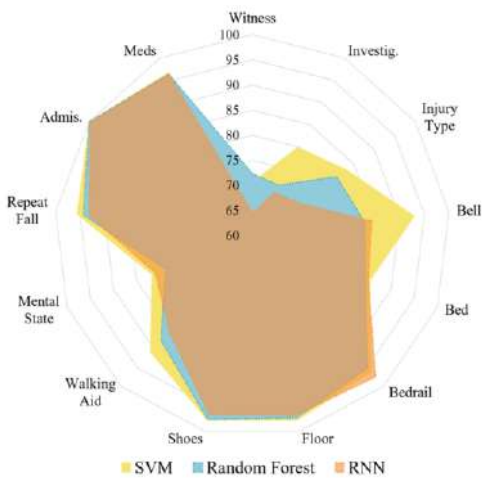


Figure 2 – Accuracy for Patient Fall Reports

Figure 2 shows the accuracy scores for each rubric category. For all rubric categories, SVM showed equal or better accuracy scores compared to random forest or RNN. Figure 3 shows the F_1 scores for each rubric category. For Figure 3, some rubric categories have no F_1 score if the model never assigned positive labels for that category. The SVM model showed much larger F_1 scores for all rubric categories for the patient fall dataset.

In contrast to the Yelp dataset, the SVM model was the highest performer in both accuracy and F_1 score for the patient fall dataset. SVM was also most successful in giving positive labels for minority classes during testing. The *r*andom forest and RNN models gave no positive labels for multiple rubric categories (i.e., Admission, Footwear, Bedrails, Medication, Floor, Repeat Fall). The SVM model gave no positive labels for only one rubric category (Admission).

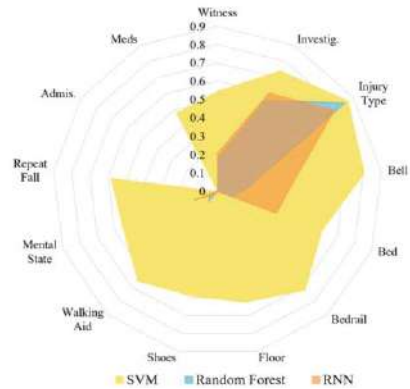

Figure 3 – F_1 Score for Patient Fall Reports

High and Low Quality Report Examples

To display the effectiveness of the SVM model, a high quality and low quality report from the database are presented in Table 3. The SVM model's scoring reflects the difference in the level of detail between the two reports.

Table 3 – High- and Low-Quality Report Examples

Report 1	**Label:** 1, 2, 3, 10, 13	**Score:** 0.843
"Patient received meds at 2100, including Ambien 5 mg for rest/sleep. Patient found on floor at 2120, confused with slurred speech. Staff assisted patient to stand, was able to bear full weight without difficulty or pain. No contusions or lacerations seen upon visual exam. Able to walk without pain or difficulty. Vs 99.8 100 22 B/P was 130/50. No change in LOC. Asleep in bed at 2200."		
Report 2	**Label**: 4	**Score**: 0.100
"Patient was up in chair; upon entering room found patient sitting upright on floor directly in front of chair with legs extended reading the TV guide. When patient questioned if she fell states no I slid out of chair. When questioned patient why she was trying to get up states I was going to throw some trash away. Call light was beside patient at time of incident."		

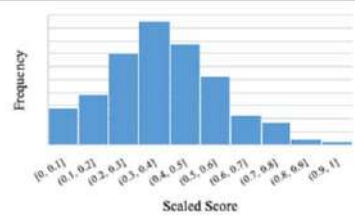

Figure 4 – Distribution of Scaled Scores

Scoring Distribution

Figure 4 shows the distribution of scaled scores made by the SVM model.

Discussion

Implement a Scoring System for Fall Reports

Patient fall reports are an important resource to understand the causes and prevention of patient fall events. Unfortunately, event reporting systems suffer from a lack of high-quality reports. Without high-quality reports, learning from past fall events becomes speculative and inefficient. This study identifies the most promising machine learning method to score patient fall reports. Providing immediate scores to reporters would increase the quality of patient fall reports and ultimately advance the learning and prevention of patient fall events.

Importance of Scoring Patient Fall Reports

Regardless of specific model, this study shows that machine learning is effective towards scoring patient fall reports. This discovery has implications for the healthcare environment because it addresses the need for higher-quality patient fall reports and provides a first step towards improvement. The majority of reports scored between 0.3 and 0.4, implicating that most patient fall reports are lacking in detail and quality. However, it is crucial that reports contain such information that could aid in post-fall patient care or discussions on prevention strategies. The two reports shown in the results section (Table 3) display how level of detail affects how patient falls can be studied. The high score report gives information on medication, where certain medications can lessen the patient's spatial awareness, induce dizziness, and therefore cause fall events. Healthcare providers could learn from this report and assess if that medication is dangerous for patients. The lower score report contains some details, like the patient's motivation for getting up, but not the specific ones included in the rubric that would be helpful for analyzing the cause of the fall. The two reports were of the same approximate length but of very different quality, signifying that a high-quality report does not have to take longer than a low-quality report to write. In the case of the low-quality report, real-time scoring would have helped the reporter become aware of missing information and improve the report quality before submission. Any future analysis of the report would become more meaningful and actually aid in patient fall prevention, whereas the original low-quality report would have been less usable.

Challenges of Scoring Patient Fall Reports

While machine learning has been utilized for similar data types like EHR, its application for patient fall reports presents several challenges. The effectiveness of machine learning depends heavily on the quality of the training dataset. If the training dataset lacks key data, the model's performance will be severely limited. For patient fall reports, both the size and quality of the current dataset need improvement for machine learning to reach its full capabilities. Specifically, deep learning requires a larger dataset of information to learn, since its neural structure is more complex than classic machine learning models. The current patient fall dataset has an imbalanced representation of the 13 rubric categories, with minority classes marked positive in under 100 reports. Machine learning models have difficulty classifying minority classes because the model rarely sees positive labels during training. The model will be applied to classify reports negatively for minority classes not based on learning, but on probability.

As a result, we used both accuracy and F_1 scores as performance metrics. Since the dataset contained more negative labels than positive labels, a model could increase its accuracy by selecting the negative label without learning anything. Therefore, accuracy cannot be the defining metric, but rather, the F_1 score better represents performance based on false positives and negatives. We also applied scaling to the model's scoring function to account for minority classes. With the average report having only two positive labels out of 13, many scores would be around or under 0.2 without scaling. Scaling allows reporters to understand the relative differences between high and low quality reports, whereas unscaled scores would have been too small to differentiate. The scaled scores will change dynamically as the database size increases, especially when higher quality reports are added. This makes the scoring system not just a tool for measuring report quality, but also for helping reporters improve quality relative to other reports.

Evaluate Models

We tested all three models on Yelp reviews before patient fall reports, since the Yelp dataset was larger and balanced. The Yelp dataset represents an expected improvement of the patient fall dataset in size and quality, which is especially needed for deep learning models. By using both datasets, we were able to see which model performs best currently and which model has the greatest potential for the future of patient fall reporting. The SVM model was identified as the best method for the current patient fall database. The SVM model was also more successful in learning positive labels for minority classes. Due to a lack of positive labels, Random forest and RNN labeled the entire testing dataset negative for multiple categories. Those categories correlated with a lower frequency of positive labels. SVM had this problem with only one category, "Days since admission", which had only five positive labels out of 2,046 reports.

However, for the Yelp dataset, the RNN model displayed the highest performance among the three models. This suggests that if the collection and quality of patient fall reports increases in the future, the RNN could become a better method than the SVM. Two specific features of the RNN support this statement. Firstly, the RNN might be better equipped for multi-label, multi-class classification. Deep learning has been shown to be better at capturing label dependencies for multi-label, multi-class classification on large-scale data [18]. Secondly, the RNN model used pre-trained word embeddings, while the SVM used TF-IDF vectors. TF-IDF weights use only the words in the training data, while pre-trained word embeddings represents all words from a larger vocabulary. If new words appear in the testing data, pre-trained word embeddings would be better at handling those words than TF-IDF vectors.

Limitations

The voluntary reports are usually submitted by frontline staff rather than patient safety experts. Therefore, it is inevitable that reports contain incomplete or biased information about patient fall events due to differences in background and training of reporters. Another limitation is the quantity and balance of the dataset used to train the models. All three models will improve with a larger and more balanced training dataset, especially the RNN. An improvement in the balance of the dataset starts with circulating knowledge on the AHRQ rubric and confirming that reporters understand the rubric when writing. It is important to focus on this aspect of event reporting in addition to the collection of reports. Our scoring system could aid in this process, since reporters would need to understand the AHRQ rubric so they could include the details necessary to improve their score.

Future Work

Any of the three models will be embedded to our reporting systems [9] and could be consolidated into existing computerized reporting systems in hospitals and other healthcare facilities. This would allow staff in hospitals to fill out reports per regular protocol and receive a score based on the quality of their reports before submission. Because of the model's scoring function, healthcare providers would see an increase in report detail and could better address what causes falls in their facility. In the future, an interface could be added to inform the reporter why the report received a certain score and specific areas of the rubric to improve upon. This would also teach the reporter the standards for patient fall reports and cause reporters to submit better reports in the future. More generally, while we focused on patient fall events in this study, there is still the challenge of improving the quality of other PSE reports. The models proposed in this study could act as a starting point for applying machine learning to other PSEs and improving the PSE reporting system in general.

Conclusions

We proposed a machine learning approach for classifying and scoring patient fall reports based on the AHRQ rubric. We identified the most promising machine learning method for both the current dataset and for the future of patient fall reporting. This study addresses the need for better-quality patient fall reports by creating a way that reporters can get immediate feedback on the quality of their reports. The improvement of patient fall reports would help us better understand causes the falls and develop strategies of fall prevention.

Abstract

This paper describes work to assess the feasibility of using a decision support tool to help patients with chronic conditions, specifically stroke, manage their condition in collaboration with their carers and the health care professionals who are looking after them. The system contains several novel elements: the integration of data from commercial wellness sensors, electronic health records and clinical guidelines; the use of computational argumentation to track the source of data and to resolve conflicts and make recommendations; and argumentation-based dialogue to support interaction with patients. The proposed approach is implemented as an application that can run on smart devices (e.g. tablets). The users have personalised dashboards where they can visualise their health data and interact with a conversational chatbot that provides further explanations about their overall well-being.

Keywords:

Decision Support Systems, Clinical; Artificial Intelligence; User-Computer Interface

Introduction

The aim of the CONSULT (Collaborative mObile decisioN Support for managing mULtiple morbidiTies) project is to explore the feasibility of employing a collaborative decision-support tool to help patients suffering from chronic diseases to self-manage their treatment plans. By 'collaborative,' we mean that the patient, carers, and medical professionals work as a team to decide on the best treatment plan for the patient. To establish feasibility, we are developing a system, called CONSULT, which connects a patient to wireless sensors that are gathering data about them, provides real-time updates of data from their electronic health record (EHR), and provides recommendations and explanations based on clinical guidelines. Separately, CONSULT provides a connection for a patient's general practitioner (GP) to have access to information being gathered about the patient. Feasibility is being assessed both at a technical level, in terms of whether it is possible to construct a working system that connects these disparate elements together, and at a usability level, in terms of whether all the parties find the system to be helpful. We are not, at this stage, assessing clinical benefit.

The CONSULT system exhibits the following novel features: (1) integration of data from commercial wellness sensors, patient's EHR, inputs from health care professionals (HCPs), and treatment guidelines to produce an adaptive care plan customised to the patient's current circumstances; (2) application of *computational argumentation* to structure and track the data from these disparate sources and identify reinforcing and conflicting information; and (3) interaction with patients via *argumentation-based dialogue* to ensure understanding of the information gathered in (1) and to address, and potentially resolve any conflicts found in (2). The users have personalised dashboards where they can visualise their health data and interact with the system.

Methods

Motivation

The CONSULT project was motivated by evidence that engaging patients in the self-management of chronic conditions can be beneficial to their well-being [1-3]. Clinical colleagues suggested that a suitable target population for a study in self-management would be stroke survivors, with the aim of the study being secondary stroke prevention. This suggestion was supported by an initial focus group with patients/carers and HCPs. In this focus group, stroke survivors reported a desire to receive additional support, beyond what can be provided by HCPs. In addition, HCPs at the focus group were keen to leverage new technology to help monitor patients.

The CONSULT System Overview

An overview of the CONSULT system architecture is shown in Figure 1. There are seven primary building blocks that make up the system: (a) patient input sources, including biometric data gathered by commercial wellness sensors and a patient's EHR; (b) user interfaces, including an interface for patients, as well as an interface for HCPs and a third interface for system administrators (orange blocks); (c) web-facing servers for gathering input data and supporting user interfaces (red blocks); (d) internal databases for storing raw data (blue blocks); (e) data mining processes, aggregating raw data and extracting natural language from arguments (yellow blocks); (f) aggregated data, including the output of the data mining and argumentation processes (pink blocks), and (g) a computational argumentation engine and associated sub-components, including inputs of computational guidelines, and drug interactions (green blocks). In the following sections, we describe the multiple information sources shown in Figure 1 in more detail, before detailing how these information sources are combined for the purpose of decision support. We then describe how a user can engage with the system.

Step (1.b) information provided by NICE guideline CG127:
"*Offer step 1 antihypertensive treatment with a CCB to people aged over 55 years and to black people of African or Caribbean family origin of any age.*
If a CCB is not suitable, for example because of oedema or intolerance, or if there is evidence of heart failure or a high risk of heart failure, offer a thiazide-like diuretic."

Formal Representation in the Argumentation Engine:
$(age \geq 55) \vee black\text{-}african \vee black\text{-}caribbean \rightarrow offer(C, S_1, d)$
$\neg tolerated(C) \rightarrow \neg offer(C, S_1, d) \wedge offer(D, S_1, d)$
$oedema \vee heart\text{-}failure \vee highrisk\text{-}heart\text{-}failure \rightarrow offer(D, S_1, d)$

Figure 2 - Example Representation of Step 1 of NICE Guideline CG127

Information Sources

Clinical Guidelines

Clinical guidelines are documents that help HCPs and patients to decide on appropriate treatments. However, guidelines are mostly expressed in natural language. Clinical guidelines should be represented in a structured way in order to automate the reasoning process in decision support systems. We represent domain-specific knowledge (e.g. the hypertension domain) using a logical language. We also use existing semantic representations of guideline information (e.g. drug interactions [4]) in the reasoning process.

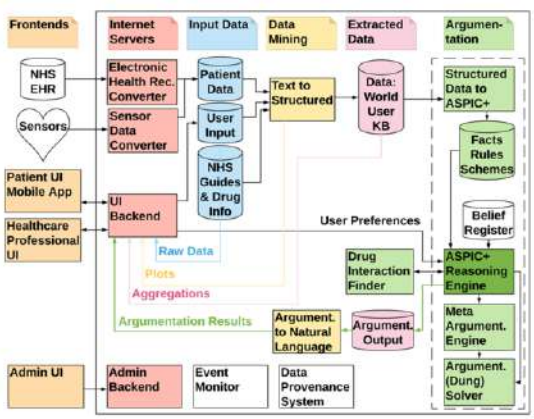

Figure 1 - Abstract CONSULT System Architecture

Domain-Specific Representation: In order for CONSULT to reason about treatment plans, we represent knowledge in the hypertension domain using first order logic [5]. For example, in Figure 2, we represent part of the hypertension treatment guideline CG127 published by NICE [6]. The information provided for this particular step is represented in terms of logical rules. Patient characteristics, such as ethnicity or experienced side effects, could change the treatment plan. Hence, we take a similar approach to represent the relations between possible treatment plans and side-effects formally.

Use of External Ontologies: Patients typically deal with multiple comorbidities, which makes the reasoning process difficult, as conflicts among recommendations may arise. This requires the representation of: (1) recommendations that can be made for each condition (as described previously) and (2) potential interactions among such recommendations. Zamborlini et al [4] introduce a semantic approach to detect interactions among recommendations by combining multiple guidelines. For CONSULT, we packaged Zamborlini's work as a web service, allowing us to create additional computational forms of guidelines in the semantic format required for the identification of interactions. This information is then used as an additional data source—*Drug Interaction Finder* in Figure 1—for the argumentation engine. Specifically, new guidelines are authored as *quad triples*, added to a triplestore, and then processed by a logic-based reasoner in order to identify interactions of interest to the argumentation engine. The web service allows the argumentation engine to interrogate various stages of the interaction identification reasoning process, such as which recommended drugs have been identified as being in conflict.

Electronic Health Records

CONSULT's next information source is a patient's EHR specifically their demographic information, blood pressure history, medication history and details of long term conditions. To integrate with a given patient's EHR, we rely on an endpoint provided by the vendor responsible for storing that patient's record. Typically, this endpoint is a local application programming interface (API) provided by each individual installation of the vendor's EHR software within a GP clinic. Therefore, CONSULT leverages the *data node connector* approach proposed in the TRANSFoRm project [7], by installing software within each GP practice that is designed to access this local API and transmit extracted EHR data to the rest of the CONSULT system for reasoning. Other models of EHR data access leveraged include direct collection of data on multiple patients from an external server provided by the vendor and simulated local API access using the N3/HSCN network. In any route to access the data, issues of governance are handled directly with the GP practice and the patient.

As each EHR vendor uses different formats to structure and code their data, once EHR data has been collected for a given patient, it needs to be standardized in order to enable the rest of the CONSULT system to be agnostic to the vendors from which the EHR data is derived. We choose Fast Healthcare Interoperability Resources (FHIR) standard as this format [8], and structurally transform each EHR to FHIR using a semi-automated matching and mapping process, while relying on services such as METMAPS [9] for code transformations, specifically to SNOMED which is used as part of the FHIR standard. Once transformed, data is inserted into a FHIR server, enabling the CONSULT system to operate as an *application* under the SMART-ON-FHIR paradigm [10].

Wireless Sensors

Our final data source is a patient's biometric health measures, extracted from a range of wearable devices. We primarily aim to acquire data on a patient's current blood pressure, pulse rate, activity and heart rate, since these are the most important measures for stroke patients. However, we do not ignore additional data that is also sent by the devices alongside this primary data (e.g. sleep quality). We employ a range of devices for this purpose, ranging from devices that are readily accessible to consumers (e.g. wrist worn devices) to more specialist medical devices (e.g. dedicated heart rate

monitoring devices), where the former is advantageous as it increases the accessibility of the system, and the latter potentially offers greater accuracy and frequency of readings. A separate study involving some of the authors evaluates the quality of sensor data produced by consumer medical devices.

In general, we aim to make the remainder of the CONSULT system as agnostic as possible to the hardware from which the readings originate. To do this, we build integration components for each wearable vendor's API—typically a remote REST endpoint, or a simpler data store—and then, upon the receipt of new sensor readings, convert this data from its vendor specific format to FHIR, which is also designed to represent and store patient health measures. This information can then be accessed by the rest of the system in the same manner as the EHR data via our FHIR server.

Integrating Data for Decision Support

The different patient data sources available to CONSULT (Figure 1) are exploited and combined to present an up-to-date view of the patient's situation and to support any reasoning in support of recommendations made. The data is merged and transformed to monitor how the patient's latest readings compare to the patient's baseline. In cases where there is deviation, relevant alerts notify GP and patient accordingly.

The argumentation engine in CONSULT is the component where recommendations are made. This engine generates possible arguments and conflicts between them (e.g. conflicts in treatment guidelines that arise in the management of multiple morbidities). It also computes treatment options to follow by providing further explanations for each option. We use argument schemes [11] and critical questions to automatically construct arguments and identify conflicts between them. Argument schemes are semi-formal representations of the structures of common types of arguments. They explain the construction a particular argument. The argumentation reasoning engine, based on ASPIC+ [12], uses the received data to instantiate argument schemes and attack schemes in a metalevel argumentation framework [13; 14], and it constructs arguments and attacks to support any self management or treatment query related to the patient [5]. Such queries are submitted through the personalised dashboards of CONSULT, where argumentation results are shared in a human-understandable way, and stakeholders can interact with CONSULT to understand the decisions made by the argumentation engine.

User Interface and Interaction Scenarios

The interface for the CONSULT system has two main components: (1) a dashboard component that visualises longitudinal personal health data, presents tailored health recommendations to patients for disease self-management, and communicates the effect of different treatment and preventive interventions on their health risk (e.g. the risk of experiencing another stroke); (2) a conversational agent (chatbot) component the role of which is to provide patients with alerts and explanations about their health state (e.g. an increase in systolic blood pressure beyond the ideal reference range), to present treatment recommendations for self-managing their condition (e.g. which over-the-counter painkiller is the most indicated for reducing their backache given their current blood pressure levels, treatment plan and clinical guidelines), or to allow users to perform, in an interactive environment, simple health information-seeking tasks (e.g. in the form of acquiring links to authoritative health literature and websites about a specific medication, measurement, or condition).

In the remainder of the paper, we refer to the following example of Martin, a 60-year-old male who has suffered a stroke, and who is using the CONSULT system and a variety of wellness sensors to monitor his own health. Martin and his GP interact through the CONSULT system.

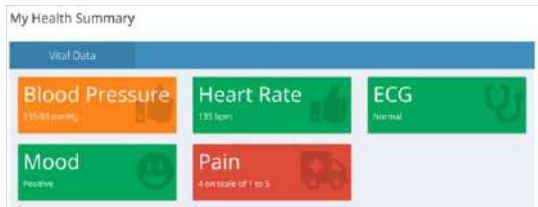

Figure 3 - The Dashboard (Overview) for an Android Tablet

Data Summary

The dashboard component of CONSULT contains an overview and a preview interface personalised for patients/carers and HCPs [15]. The overview interface, depicted in Figure 3, displays a summary of the most recent measurements for all types of personal health data collected from the patient (e.g. blood pressure, heart rate, sleep activity, pain, stress, mood). For the representation of this information in the dashboard, we use a tile-based design where each tile provides information about each health data type. Moreover, we use colour-coding to make clear immediately to the user when a specific measurement is outside the normal range [16]. For example, for blood pressure, the colour green was used to indicate that the latest measurement was within the specified normal range, the colour orange indicated pre-hypertension levels —as depicted in Figure 3— while red required attention. By selecting a tile from the overview interface, the user can access longitudinal health data about the specific measurement in the preview interface. A typical preview interface provides users the opportunity to view their data at specific time intervals (e.g. hourly, daily, weekly, monthly or yearly), as averages or all raw measurements (using line graphs for averages, and scatter plots for raw measurements). Also, for each time interval, the user is provided with additional descriptive information, such as the average, minimum and maximum value. In addition to personal health data, the dashboard provides users with the opportunity to use a risk calculator and to visualise (using *cates* plots) the effect of specific treatment and life-style interventions on their current risk of experiencing another stroke [17].

To improve the legibility and readability of content, these features were used: clean typeface (Arial), large default font size (12<), high contrast between characters and background (plain background and use of balanced colour saturation and luminance for text and graphs), writing that corresponds to a US sixth-grade reading level (equal to year 7 for England). In terms of accessibility, to improve access for colourblind users, both colour and symbols/labels were used to show that a value is within or outside normal range, or the selection of few well-contrasting colours instead of multiple colours.

Treatment Recommender

If Martin's blood pressure is not under control, then as part of the consultation with his GP, there needs to be a decision as to how to modify his treatment. The CONSULT system can support this by presenting the GP with relevant, summarised and up-to-date patient data, along with recommendations for possible treatments that consider these data, the patient's EHR, their preferences, and clinical guidelines. The treatment recommendations are generated through the argumentation

reasoning engine. A more in-depth description of the approach CONSULT takes when reasoning with the different possible and at time conflicting treatment options is described in [5].

Interacting with the CONSULT ChatBot

The conversational component of the CONSULT system serves two main purposes. The first purpose is to provide a patient the opportunity to seek evidence-based advice about a health problem. For example, Martin may be suffering from back pain and CONSULT, using a chatbot, can advise him on what he can do, as depicted in Figure 4. The chatbot is aware of the patient's latest wellness sensor readings, the data in their her – so will not recommend a treatment that caused side effects, for example – and clinical recommendations. These interactions are supported by argumentation-based dialogue [18; 19]. Additionally, the patient may have questions regarding their current treatment plan (e.g. why a particular medication has been prescribed). All the explanations are generated by the argumentation engine and displayed on the personalised dashboard. The second purpose of the conversational component is to alert the patient to an irregularity in one or more of their recent measurements and initiate a conversation, the purpose of which is to find a possible solution—suggesting the patient to review her blood pressure readings—or to advise the patient to contact a HCP.

Figure 4 - The interaction between Martin and the Chatbot

Results

We are currently in the process of evaluating the CONSULT system. Our intention was to design an application broad enough to accommodate the needs of people suffering from different chronic conditions, we have been focused on the context of stroke patients [1]. Based on our previous experience with this group of patients and the strong links to the South London Stroke Register (SLSR), we identified patients with different characteristics in terms of risk factors, comorbidity or demographic groups. The focus groups also involved co-design activities, following a design thinking approach [20], that resulted in user-generated versions of how information should be displayed. We will conduct additional user studies to evaluate the usability of the proposed system to answer the following questions: (1) do the stakeholders of the CONSULT system (patients and HCPs) use the system? (2) do they think that it is useful to assist them in making decisions? and (3) do they like interacting with the system through the chatbot? Our initial focus groups have already allowed us to explore the answers to some of these questions [1].

Additionally, in [5], we have shown that argumentation is promising in explaining decisions to help HCPs and patients choose a treatment plan together. The use of argument and attack schemes specialised for the medical domain will be a next step to consider to generate better explanations [14]. The CONSULT system collects data from multiple information sources; as such, it is important to represent the interactions between these sources. One way of doing this is the use of commitments, which help the system to automatically decide what information source to trust and reason accordingly [21].

Discussion

Several works combine patient and clinical data collected from a variety of sources for the purposes of decision support, however many do not consider the number and variety of sources that are integrated by the CONSULT system. Systems that use a subset of the sources found in CONSULT include those that rely predominantly on sensor data, such as the system proposed by Groat et al. [22], which integrates data collected from glucose and exercise monitors to determine if patients are adhering to self-reported self-management behaviours. Others rely predominantly on a patient's medical history, such as the system proposed by Evans et al. [23], which aims to identify COPD in patients through a range of offline sources, including EHR data and echocardiograms, and the system proposed by Mosa et al. [24], which aims to identify patients at risk of CINV by mining EHR data.

With respect to reasoning with data sources, various works focus on developing argumentation-based systems for clinical decision support. Atkinson et al propose the DRAMA agent to reason about patient treatment [25]. This is similar to our setting as it deals with treatment recommendations and makes use of argument schemes to construct arguments; however, each argument is associated with a value and the argumentation results change according to the prioritisation of such values. In *arguEIRA* [26], the authors make use of argumentation to detect and label anomalies in patient's reactions to treatments in the intensive care unit. In *Carrel+* [27], the goal is to develop an argumentation based tool where agents conduct a deliberation dialogue to decide on the organ transplant viability. In contrast to these works, we consider data coming from multiple information sources rather than a centralised database. CONSULT also goes further than previous work in the degree to which it allows stakeholders to interact with the system to understand the argumentation reasoning better. CONSULT also provides dashboards to help patients self-manage their conditions and so provides a health monitoring facility that goes beyond the previous work cited.

Conclusions

CONSULT is one of the few systems to take a collaborative approach to the management of chronic disease. It is also the first decision support system to make recommendations by combining multiple information sources, data science techniques, agreement technologies and an interactive chatbot. We implement our proposed approach as a mobile application for Android tablets to help stroke patients and HCPs make decisions during the treatment process.

Future work focuses on the full evaluation of the system as a feasibility study for the deployment of this kind of technology. The main questions that need to be resolved are the technical feasibility of successfully operating a system that connects patient, sensors, EHR and GP together in real-time, and the

feasibility of having patients, carers and medical professionals use the system without finding it burdensome. We believe that the principles behind CONSULT can be adapted to help with a number of chronic diseases, and we hope to explore this hypothesis in future work.

Abstract

Usability of health information technology (HIT) remains a predominant concern — one often exacerbated by clinicians' need to access information created by many different professionals in different settings, often using very dissimilar EHRs or even different configurations of the same EHR. Because of these variations, we argue that we must no longer think of usability as anchored in one setting, one EHR, one data standard, or one type of clinician. Rather, usability must be understood as a collective and constantly evolving process. This paper seeks to address that reality by 1) substantially expanding our previously-developed conceptual matrix of the wide range of settings and interfaces comprising modern HIT and 2) presenting actual examples of EHR usability issues with similar data but very different displays or processes.

Keywords:

Ergonomics, patient safety, evaluation studies

Introduction

Healthcare information technology (HIT) usability issues remain a predominant source of medical errors and other undesirable outcomes [1; 2]. While research has identified usability issues in a single system or setting, the challenge of usability across a range of systems remains problematic and far less rigorously examined. Patient care increasingly occurs across multiple providers, settings, and HIT systems. Thus, usability must be considered not just for one system, but across several systems and users. Functions or features in HIT (e.g. data retrieval or display) are seldom consistent across systems, which often leads to errors [3]. Clinicians may have to use several different systems, meaning they will encounter variability in how one logs in and out or enters and searches for data. They will also have to reconcile a wide assortment of fonts and displays. Ash, Berg and Coiera describe how unintended consequences from HIT usage – especially entering and retrieving information – can lead to 'silent errors' that remain prominent today [4; 5].

We cannot uncouple HIT usability considerations in one system from the broader context of how healthcare delivery occurs. The reality of modern healthcare delivery is that providers may have to use multiple systems and will encounter numerous ways of displaying data and of searching for and retreving information [6; 7]. While it may be infeasible to implement a standardized HIT across the many different settings where healthcare delivery occurs, there is a need to understand usability variations to proactively manage unintended consequences. While there is a wide body of research that has looked at ways to improve the usability of individual HIT systems (e.g. [8]), there is a paucity of studies that have looked at cross-system usability to better understand the issues clinicians encounter when they have to use multiple systems.

In previous work, we developed a matrix of eleven usability dimensions and contextual differences to stimulate discussion about usability issues across providers and settings [9]. This paper extends that work by expanding the usability dimensions to fifteen and also by identifying specific usability issues for each dimension. We assembled these examples from our decades of observations, from the human-computer interaction literature, and from lists of problems reported to the IT departments at several hospital systems (e.g. [3; 10-12]). We then provide a set of case examples to illustrate how our matrix helps to better contextualize multi-system usability issues.

Results

Expanded Matrix of Usability Dimensions and Contextual Differences

Table 1 shows our expanded matrix of usability dimensions and contextual differences. The matrix identifies three usability categories or dimensions: 1) Displays, Navigation, and Screen Rules; 2) Implementation, Staffing, and Cost; and 3) Authentication, Staff Access Rules, and Logins/Logouts. We believe these three overarching groups to be significant for cross-system usage. Each group encompasses a set of usability challenges within the dimension and specific factors that account for these challenges. For example, for the first usability dimension (Displays, Navigation, Screen Rules), the first usability issue is differences across electronic health record (EHR) systems and versions. Usability testing needs to account for contextual differences that will exist due to different EHR vendors and versions.

Following the expanded matrix we provide a set of case examples that help to visualize and understand how the specific usability issues described in the matrix vary across different clinical systems. We then illustrate our expanded matrix's utility with examples of multi-system usability issues. Each example refers to specific usability dimensions and issues from Table 1.

Table 1 – Expanded Matrix of Usability Dimensions and Contextual Differences

Usability Category	Usability Challenge	Specific Usability Factors
Displays, Navigation, Screen Rules	**1.** Different EHR systems & versions present data in very different ways. (Often, it is the cost or fear of chaos that inhibits shifting and upgrading.)	EHR vendor & version
	2. Inconsistent and confusing data displays. Fonts, colors, metrics, interfaces and more vary dramatically across systems. Providers become comfortable viewing data in a specific context and may be confused when the display changes. (Figure 1)	Usability displays (font, size, metrics, color schemes, color intensity)
	3. Finding patients and data – there is a high degree of inconsistency in navigation and search functions for patient location data and clinical data (e.g. lab or medication data). Problems locating patients or medical data cause inefficiency and, at worst, can be lethal. **a.** Patient-finding method: by last name, first name, MRN, MDs, unit, room #, team name, etc. **b.** Finding labs, meds, problem lists, etc. (Many different lab and test names for same item; listings can be sorted chronologically, in reverse chronological order, by requester name, by lab facility or lab tech name, alphabetically, by organ system, etc. [Figure 2])	
	4. Rules on the number of screens and patient charts that can be open at one time vary. Each new chart or screen increases the probability of entering an order into the wrong patient chart or reading data from the wrong patient chart. (Figure 3) **a.** ID safety, patient name and photo on each screen: name on every screen, photo on page, photo size, display clarity, position on screen **b.** Number of screens and patient charts open at one time	
Implementation, Staffing, Cost	**5.** The literature reflects myriad conflicts between medical staff and corporate leadership or consultants selected by management. **a.** EHR implementation authority: in-house, system-wide (enterprise) **b.** Role of implementation consultant(s): consultants largely determine configuration, consultants mostly advisory, consultants absent or not in authority	
	6. There may be a false belief that implementation of new EHRs will reduce the need for, size of, and proximity of IT teams.	IT team location (on site, not on site) & size (expanded, stay same size)
	7. Practice size, type and combinations thereof are major factors determining EHR cost, design and configuration.	Clinician type (e.g. MD, RN, NP), practice size (if outpatient), practice type (inpatient vs. outpatient)
Authentication, Staff Access Rules, Logins/Logouts	**8.** Need for repeated logins and complex authentication requirements cause frustration and errors via workarounds and interruptions. Circumvention of access rules creates opportunities for wrong patient errors and unauthorized access. **a.** Authentication (login rules): username, password, card, biometric, two-factor authentication, combination of multiple methods **b.** Number of logins: by type (e.g. for each patient, to give drugs, to order tests), total number per day or hour	
	9. Automatic logout times cause interruptions and prompt workarounds, such as the use of Styrofoam cups to defeat proximity sensors	Automatic logout times (too quick leads to thought & work interruptions, too long leads to security risks)
	10. Access rules that are inconsistent with clinical need and workflow are a major frustration and lead clinicians to share passwords and ID cards. More directly, they may create wrong patient errors by causing confusion about patients and associated data.	Access rules (by role [e.g. MD, RN], status [e.g. admin, clinical], patient, unit)
	11. Often governments or agencies (the FDA, for example) set rules for data formats and drug use. There are also often data formatting requirements from participating labs, drug naming or drug categorizing companies, and other linked facilities. (Figure 4)	Data interoperability requirements (formats can be set by health information exchange policies, cooperating labs or suppliers, governments or other agencies)

Displays, Navigation and Screen Rules

Example of Issue 2 – Inconsistent Displays and Confusing Screens

Figure 1 shows an EHR screen for ordering vitamin K to counteract excess anticoagulation medications causing unwanted bleeding in a patient. The interface presents several problems that make the simple task of selecting a delivery method for vitamin K difficult. The clinician is presented with a screen that offers little guidance or organization, yet offers many choices and options for this critical substance. An alternative presentation of the options, perhaps with decision trees and visually comprehensible categories of conditions, would make the process safer and more efficient.

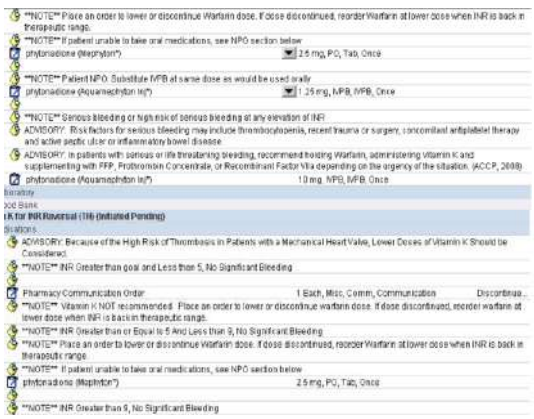

Figure 1 – This EHR screen is for selecting vitamin K to stop bleeding. Chaotic and confusing, it hinders a critical decision.

Example of Issue 3b – Finding Medication Data

Medication ordering errors are the most common form of medical error. There are roughly 4,500 medications in the average hospital formulary, with many more available through pharmacies. Variations in presentation of brand name vs. generic name, doses, routes, schedules, and the like add complexity and danger. Figure 2 provides examples of two different systems. The system in Figure 2A lists the drug name, dose and route in a single field, while the system in Figure 2B shows the generic name, drug name, route and dose in four separate fields. The different displays also have different methods by which drugs can be searched. In the system in Figure 2A, drugs can only be searched and selected alphabetically because there is only one field with all the details. The system in Figure 2B allows drugs to be searched or ordered by any of the fields (e.g. by drug or generic name).

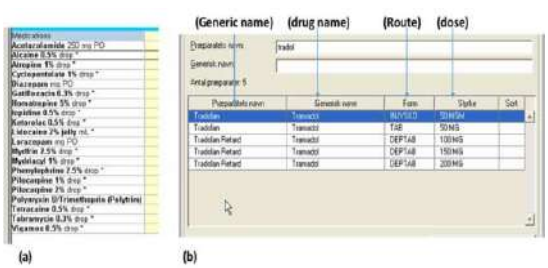

Figure 2 – Medication listings from two different systems

Other EHR systems have yet different configurations of the fields, and some have additional fields such as manufacturer or Anatomical Therapeutic Chemical (ATC) codes [13]. The different order, number of fields, and ordering and display capabilities puts the burden on individual providers to develop heuristics or other strategies to retrieve and interpret necessary information. This can present usability challenges that lead to medical errors and other unintended consequences.

Example of Issue 4b – Number of Screens Open at One Time

Figure 3 highlights the difference between viewing data on a single screen or via multiple screens. By separating the combined chart (Figure 3A) into two screens (Figures 3B and 3C) on the EHR, the pediatrician may be prevented from observing the relationship between the two variables. In this case, the dip ("dent") in weight that is not present in height may indicate gastrointestinal problems, abuse, malnutrition, or other maladies that would be missed due to the isolated charts. (The "dent" in the weight graph is exaggerated to illustrate the data in the small-format illustration; in actual practice, the chart takes up the full screen or page.)

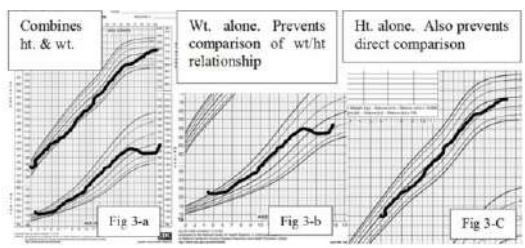

Figure 3 – Standard weight/height chart used by pediatricians for over 100 years (A); display of separate weight chart (B) and height chart (C) in some EHRs

Implementation, Staffing, Cost

Example of Issue 7 – Practice Size, Type and Combinations

Practice configurations can vary significantly depending on context. Usability challenges may be less pronounced in an independent primary care clinic where providers use a single system. Hospitals, however, can present specific usability challenges, as providers often have to access different systems depending on the context of care delivery. Specialty areas such as the operating room often have their own HIT systems.

A recent study of an implementation of a perioperative system provides an example of this issue [14]. Because the system in the study was a real-time system for perioperative data only, other data, such as lab or historical patient data, were not part of the perioperative system; therefore, clinicians needed to access this data in other systems. For example, a patient's pre-op data (e.g. diagnosis, surgical and anesthesia history) and their lab and radiology data were only viewable in the hospital EHR system. This led to two issues. First of all, the EHR system was not routinely used by surgical staff prior to implementing the perioperative system, meaning users had to learn how to use a whole new system. Secondly, and more significantly, the dual systems created a chasm between data from the EHR and data from the perioperative system. Users often needed information from both systems simultaneously. For example, on the day of surgery, a patient's historical data is in the EHR, while the active charting on the patient's case is occuring in the perioperative system. As a result, clinicians

have to look at records in two different systems, which creates visualization problems as they need to toggle between two different interfaces. Clinicians commented that they preferred to view the data side by side; thus, they were required to devise innovative ways to acess data across the two systems, such as using an iPad to access the perioperative system and the hospital terminal to access the EHR system.

Authentication, Staff Access Rules, Logins/Logouts

Issue 8a – Authentication and Login Rules

A common challenge to providers moving across settings is the need to log in and out of multiple HIT systems. This issue highights common authentication problems; namely, that many types can be used, including passwords, fingerprints, ID cards, or retinal scans. If providers must use multiple systems with different login systems, usability issues emerge.

Fingerpint readers, for instance, may become bacterial reservoirs, and they cannot be used by clinicians wearing gloves. Many clinicians are reluctant to place their eyes on iris readers, or their eyes may appear to change in response to diabetic retinopathy or cataracts. Clinicians who forget ID cards can be prohibited from accessing their EHR for an entire day.

Issue 9 – Automatic Logout Times Cause Interruptions

Automatic logout is designed as a security feature, but it can also lead to usability problems. In the aforementioned perioperative case study, the system had an automatic logout as a security feature. However, the usability impact of the logout feature was dependant on which perioperative area the clinician worked in. In high-traffic areas, such as surgical day care centers, nurses quickly moved from patient to patient, with only a few fields of data entry for each patient. In this case, the automatic logout was not a problem. However, in the operating room, the anesthesiologist would have the perioperative system open for the duration of the patient's surgery. Some anesthesiologists commented that there would be blocks of time during the surgery when they would not be entering data for a long enough period that the system would log them out. They would then have to log back in and find the patient record yet again. Worse, sometimes an anesthesiologist would pre-configure some of the upcoming data entry and would then lose that configuration when the automatic logout occurred.

Issue 10 – Access Rules

Patients with contagious infections are placed in isolation rooms. To enter those rooms, clinicians wear special gowns and gloves. Those clinicians also cannot roll the mobile computer workstations into those rooms with them. Therefore, they often rely on a colleague in another room or the hallway to access that patient's chart for them. However, the only way they can enter orders and data is by giving their password to the non-isolated clinician colleague or by leaving their computer ID card with the cooperating colleague before entering the room. This violates computer access rules and makes tracking the authors of orders impossible.

Example of Issue 11 – Governments or Other Agencies Often Set Rules for Data Formats and Drug Use

Figure 4 describes an issue at a major hospital with a home-built EHR system. There was insufficient funding to update the vaccine list for pediatricians, so vaccines that were no longer approved and no longer available remained on the EHR menus. If a pediatrician were aware of the change, they could simply prescribe a different vaccine. If the pediatrician were not aware of the change, however, they would prescribe it but the pharmacy would be unable to administer it. Worse, the pediatrician would assume the child was protected when they were not.

Vaccine	Vaccine Schedule and Status
~~ABCD~~	Found ineffective. Use XYZ drug instead
EFGH	Administer at 6 mos. and at 18 mos.
~~IJKL~~	Don't administer. Replaced by UVWX.
MNOP	Administer at 3 mos.
~~QRST~~	Prohibited. Do not use

Figure 4 – Discontinued vaccines remain on drug menus

Discussion

It has been said that consistency is one of the most important design principles for achieving usability [15]. However, the range of existing settings, care delivery models and HIT systems renders it improbable that we will have consistent HIT design guidelines any time soon. Rather, we must develop approaches to best manage the diversity of HIT systems that exist. This paper expands our previous multi-setting, multi-system, and multi-user matrix of usability dimensions [9]. In our ongoing work, we seek to encourage a more panoptic design of HIT software by incorporating the need to focus on usability across several facilities and many software vendors' products, addressing many clinicians' multifaceted needs when they confront substantial interface and functional differences. Frameworks for multi-dimensional usability are needed in settings where there are multiple systems for the same task, such as e-prescribing [16]. An expansion of usability considerations is also needed as we move toward greater collaborative care delivery and must train users in the use of HIT features across multiple settings and systems.

In this paper, we used examples to illuminate how this new and expanded matrix may be operationalized, illustrating how information retrieval methods for clinical data in one system may be inefficient or even impossible in another, and different usability issues users will encounter across different systems. We also highlight usability differences that can occur in the same settings because of different system uses and users across units or departments. Our work seeks to demonstrate how information retrieval differences can lead to serious usability and medical errors. It also emphasizes the need for ongoing user training and education in HIT, as expertise on one HIT system does not assure competence on other systems. Further, the factors differentiating how HIT systems are actually used will encompass not only the vendor's designs, but also the work of local IT teams, local implementation teams, implementation consultants, local regulations, corporate rules, and more. In addition, more modifications will be required due to changing patient and clinician populations, new medications, new mobile applications, patient-provided data, and new procedures.

The usability dimensions and issues we identified focus on our prior studies, which is a limitation of this paper. Other usability dimensions and issues will no doubt exist in other contexts and settings. Our next steps will be to conduct field studies to test our usability matrix across different providers, settings, HIT systems, and care delivery models.

Conclusions

The distributed nature of HIT systems and functions ensure they will always be emergent, interactive and multifaceted. Our approaches to studying usability and HIT must be equally emergent and multifaceted. The old model of a clinician learning and using one system is already superannuated by modern medical practice. As systems struggle to achieve interoperability and effective sharing of data, the need for cross-system commonalities across HIT systems will only increase. When one gets into a car, one assumes the gas pedal is on the right and the brake is on the left; such basic assumptions do not apply to EHRs. In some EHR systems, information access may require a patient's hospital room number; in another system the clinician may need to know the patient's medical record number. In some EHR systems, lab reports are found via the name of the test; in others, via the name of the laboratory or the requesting physician.

Given these variations, we assert that usability must encompass analyses and evaluations of many EHR interfaces as used by many different clincians in a range of settings with diverse implementations. Usability must be conceptualized on both an individual system level and as a collective reality.

Abstract

The development of electronic services for healthcare presents challenges related to the effective cooperation of systems and stakeholders in a highly regulated environment. Assessing the interoperability maturity of the provided services helps to identify interoperability issues in public administration. This paper presents a typical healthcare digital service: the inpatient admission in a public hospital in Greece. The Interoperability Maturity Model (IMM) is applied to assess its maturity, identify improvement priorities, and compare it with digital services of the healthcare sector. An analysis is also performed to compare a group of fourteen healthcare digital public services with sixty-seven public services of other sectors in the country. The IMM is a useful tool to facilitate awareness raising and priority setting concerning interoperability in public administration. What is discovered, through this preliminary assessment, is that healthcare digital services seem to have higher overall interoperability maturity than those of other sectors in Greece.

Keywords:

Health Information Interoperability, Health Information Systems, Public Health Administration

Introduction

Electronic Health or eHealth is a term incorporating different concepts, including health, technology, and business. Several definitions published include these concepts with varying degrees of emphasis. Health, as used in these definitions, usually refers explicitly to healthcare as a process, rather than to health as an outcome [1]. In eHealth, technology is portrayed as a means to expand, to assist, or to enhance human activities, rather than as a substitute for them. As such, eHealth can not only benefit citizens, patients and healthcare professionals, but also health organizations, businesses and public authorities [2]. Despite the opportunities and benefits, major barriers hamper the wider uptake of eHealth. One of the major ones is the lack of interoperability between eHealth solutions, which is far more than just data exchange. Interoperability in eHealth is about the delivery of contextually relevant understandings efficiently and securely to facilitate care coordination, irrespective of application, vendor or device [3,4]. It is about improving healthcare.

The healthcare sector has many digital services and tools that are interrelated with the Electronic Health Record (EHR) of the citizen, and several public services such as ones related to identification and authentication, health insurance validation, coordinated care and others. Interoperability in eHealth is challenging for various reasons, including the fact that different products and solutions in the market do not follow well-known standards and interoperability guidelines [4-6]. It is important to create the necessary conditions and frameworks to guide the market towards interoperability solutions that follow specifications that facilitate interaction with existing healthcare services and necessary public services, integrated care pathways and shared workflows [7]. Healthcare digital services must interact not only with many other digital services offered by administrative bodies within the sector, but also across different sectors. In addition, the need arises for cross-border sharing and utilization of services, data, and business processes [8].

Although shared and reusable data are gradually being introduced to the healthcare domain through increasingly interoperable systems, measurement of the interoperability maturity of those services has not been common. Interoperability assessment methods involve the use of maturity models as a framework to describe the way a service is carried out within the same or across domains [9].

The Interoperability Solutions for Public Administrations, Businesses and Citizens programme (ISA²) (https://ec.europa.eu/isa2/isa2_en) in the European Union (EU) supports the development of digital solutions that enable public administrations, businesses and citizens to benefit from interoperable cross-border and cross-sector public services. In recognition of the importance of creating and promoting interoperable public digital services, IMM [10] was developed, as part of the ISA² programme in order to assess the interoperability readiness of the digital public services and raise awareness of the need for interoperable solutions. The IMM helps public service owners to evaluate, improve and consider all key interoperability aspects of the public service. As an evaluation tool, the IMM can be useful for national and cross-border services. The interoperability maturity of public services has been assessed for 17 Trans European systems and the Swedish and Cyprus public administrations to evaluate a number of public services provided at national and local levels [11]. Interoperability assessment models have been used also in the United States and Australia [12,13].

This paper introduces the IMM and applies it to a specific, typical healthcare scenario found in a Greek hospital, to assess its interoperability readiness as a digital service for shared activities. This scenario is subsequently compared to interoperability readiness of other digital healthcare services. In addition, further analysis identifies the maturity levels of healthcare digital services compared to other digital public services in Greece. Healthcare in Greece is provided by the National Health System (NHS). As a public service, it does not

exist in isolation but as part of the wider national public administration. The paper concludes with discussion of the key findings and ideas for future research.

Methods

Methods used for this work were based on the IMM. The IMM was used to evaluate the inpatient admission service delivered through applications developed by the Foundation of Research and Technology – Hellas (FORTH) at the NHS of Greece. In addition, an analysis was performed to aggregate the interoperability maturity of 14 healthcare services in total. The inpatient admission service results were compared to the results of the other (13) healthcare services. Finally, all healthcare services results were compared to the maturity evaluation of 67 digital public services of other sectors in Greece. The methodology is described in detail in the next paragraphs.

Interoperability Maturity Model

IMM has been designed to help public service owners at different government levels (i.e. local, regional, national, and cross-border) to evaluate the current interoperability maturity level of a public service and gain insight into the improvement priorities that are needed to reach the next level of interoperability maturity. A public service is a service that addresses the public interest and is delivered by a public administration to citizens (A2C), to business organizations (A2B) and/or to other public administrations (A2A). A *process trigger* initiates the public service that consists of several process steps. IMM measures the level of interaction of a public service with services of other organizations towards the realization of mutually beneficial and agreed common goals through the exchange of information and reuse of services [10]. Interoperability is distinguished in three domains: *service delivery* which refers to the way the public service delivers its outcome to the end-user, *service consumption* which looks at the services or data that are being reused from other public administrations and businesses where the assessed public service has the role of the consumer, and *service management* which refers to the coordination of all interactions with the internal and external environment. Each domain can receive a score from 1 to 5. Explanations of the scores are provided in table 1.

Table 1– Domain Scores for Interoperability Maturity

Score	Interoperability Maturity
1	*ad hoc: poor interoperability* - referred to a service that cannot be considered interoperable
2	*opportunistic: fair interoperability* - the digital public service implements some elements of interoperability best practices
3	*essential: essential interoperability* - the digital public service implements the essential best practices for interoperability
4	*sustainable: good interoperability* - all relevant interoperability best practices are implemented by the digital public service
5	*seamless: seamless interoperability* - the digital public service is a leading interoperability practice example for others

The healthcare digital service that is analyzed and presented in this paper refers to the admission of a patient in the clinic of a public hospital in Greece. The scenario is presented and its maturity model is assessed. The IMM questionnaire was filled out to assess the interoperability readiness of the service for the three domains of interoperability: *service delivery*, *service consumption* and *service management*. The IMM was used vs the more lite version called Interoperability Maturity Assessment of a Public Service (IMAPS) which is a compact self-assessment online survey [11]. IMM was selected because it provides a comprehensive toolset for a detailed and in-depth analysis of the service landscaping. Based on the assessment a tailor-made set of recommendations is provided to the service owner. IMAPS has been introduced by ISA^2 at a later stage to support a faster self-assessment with easy to understand recommendations.

Assessment and Analysis

The IMM assessment took place as part of the work performed for the course *interoperability evaluation of digital public services* that was delivered by the National Centre for Public Administration and Local Government in Greece. The course introduced the IMM to public employees who were asked to apply it to a digital service and assess its maturity. The course was delivered 15 times through the years 2016-2018 and had overall 425 participants working in small teams. As part of the coursework, 81 different digital public services have been assessed. The quantitative analysis was performed on 81 public services, which were separated into two groups. One group had the digital services that were related to healthcare (14), and the other group had the rest of the public services (67). For the healthcare services, a comparison was made between the inpatient admission services and the rest (13). A descriptive analysis compared the services for the three domains of interoperability: *service delivery*, *service consumption* and *service management*.

Limitations of the Study

The study is considered as a preliminary assessment of healthcare services as the sample size is quite small. The interpretations of the analysis cannot be widely generalized but provide an indication of the interoperability maturity of the digital services of the public sector in the country. In addition, the IMM has an inherent limitation in that the assessment that occurs relies widely on self-reporting and interpretation of the questions. It is important to take into account that the results are based on qualitative critical evaluation. This limitation has been partly minimized with the intervention of experienced trainers during the assessment exercise of small groups of experts.

Results

Digital Healthcare Service in a Greek Public Hospital

The Patient Administration family of applications (ICS–A), is part of the FORTH Integrated Care Solutions (ICS) suite (https://www.ics.forth.gr/ceha/index_main.php?l=e&c=664). The ICS family of applications supports, among others, all patient management processes for both inpatients and outpatients in a healthcare unit, including all medical, nursing and administrative processes in the hospital. ICS applications support patient admission, transfer and discharge, hospitalization data logging, scheduling of appointments and surgeries, waiting lists, ordering and recording of medical acts, billing, payment collection, and electronic reimbursement [14]. ICS applications interact with digital services within and across the healthcare enterprise using interoperability services. They contribute to the improvement of organizational performance and cost savings by applying the *data entered-once* and *used-anywhere* key concepts.

The Inpatient Admission Service

The inpatient admission office application supports all the business processes related to inpatient admissions. It follows the movement of the patient during hospitalization, from admission to discharge. The *service process trigger* occurs when a patient or caregiver arrives at the patient admissions office for admission. The administrative staff searches for a patient record in the local hospital database and then in the regional central patient registry. If the patient record is not found, the administrative staff registers a new patient record. The patient demographic data, the patient insurance data and the insurance coverage validity are acquired online from the National Electronic Confirmation Service (ATLAS) [15], using the National Social Security Number (AMKA) as an identifier. The administrative staff fills out additional patient information and creates the patient record. If the patient record already exists in the Hospital Information System (HIS), the administrative staff checks for the validity of patient insurance coverage by retrieving data from ATLAS. Then the patient admission to the hospital is registered and the HIS sends a notification to the service of the National Organization for Health Care Services (EOPYY) [16]. Then, the ward management system at the clinic where the patient is admitted receives the corresponding patient admission notification and relevant data. The inpatient admissions office application also communicates directly or indirectly with third party systems including laboratory and radiology, pharmacy, enterprise resource planning, and business intelligence systems.

The family of applications described are based upon an open, scalable and evolvable architecture that integrates distributed information and knowledge in a flexible manner, focusing on the timely and effective delivery of the appropriate information to all authorized users. Being the outcome of applied research, it encompasses both state of the art trends and real-world requirements for effective use [14,17].

Interoperability Maturity Assessment

The assessment of the inpatient admission service scored 2.80 for the dimension s*ervice delivery*, 4.30 for s*ervice consumption*, and 4.45 for s*ervice management*. The overall interoperability maturity score was 3.98. The results are presented in table 2.

Table 2– IMM Assessment of Inpatient Admission Service

Maturity Dimension	Score	Interoperability
Service Delivery	2.80	*essential*
Service Consumption	4.30	*sustainable*
Service Management	4.45	*sustainable*
Overall Maturity	3.98	*sustainable*

The inpatient admission service consumes the digital electronic confirmation services of ATLAS for demographics and insurance coverage, and the inpatient admission announcement service provided by EOPYY. The ATLAS service has been implemented as a base registry for AMKA and insurance coverage. The inpatient admission announcement has been implemented as a service for cost control within the NHS. Both services are consumed, when needed, by digital services of the public sector. The inpatient admission service maturity level for *service consumption* is considered *sustainable* as it consumes all available digital services that exist.

Interoperability Maturity of Healthcare Public Services

The evaluated services in the healthcare sector are provided by various health administration authorities and other organizations such as hospitals and pharmacies. The list in table 3 contains services that are related to the healthcare and social welfare of citizens as evaluated during the course work.

Table 3– List of Assessed Healthcare Services

#	Service Description
1	Hematological examinations
2	Hospital patient admission ticket issue for outpatients
3	Hospital admission ticket submission to the Business Intelligence System of the Ministry of Health
4	Health insurance record
5	Registration of dependent family members for insurance eligibility assignment
6	Electronic submission of hospitalizations to EOPYY
7	Inpatient admission service
8	Issue of a European Health Insurance Card (EHIC)
9	Disability Certification
10	Registration of new members for the acquisition of AMKA
11	Electronic decision to grant Medicare benefit
12	Digital signatures for citizens
13	Updating of contact information for an insured citizen
14	Registration and information retrieval on insurance eligibility

Focusing on the assessment of evaluated healthcare services, the value of the overall interoperability maturity of healthcare services is 3.32 as shown in table 4, and is characterized in terms of IMM as interoperability level 3: *essential*.

Table 4– IMM Assessment of Healthcare Services

Maturity Dimension	Score	Interoperability
Service Delivery	2.69	*essential*
Service Consumption	3.55	*sustainable*
Service Management	3.49	*sustainable*
Overall Maturity	3.32	*essential*

The interoperability maturity level for the *service delivery* dimension was 2.69, for *service consumption* dimension was 3.55, and *service management* dimension was 3.49. Looking more closely at the internal dimensions of health services maturity level, it is noted that in healthcare, the highest level (3.55) is in *service consumption* versus the lowest in *service delivery* (2.69). The low score for *service delivery* can be attributed to the fact that healthcare digital public services are mostly delivered from administrative personnel on behalf of citizens. These services are usually applications within healthcare organizations. There are no multichannel options for the delivery of the services. In addition, the services are not part of a service catalogue. As a result, the score for *service delivery* in healthcare remains low. On the other hand, *service consumption* is high as there are specific digital services such as base registries and services for financial management that have to be consumed by the majority of healthcare services.

Interoperability Maturity of the Inpatient Admission Service vs Other Healthcare Services

The overall maturity level of the inpatient admission service is 3.98, which is *sustainable*. Analysis of the rest of the 13

healthcare services showed an overall interoperability maturity of 3.27 which is characterized as *essential* (figure 1).

It is seen from the interoperability assessment that the described scenario scores higher than other healthcare services examined.

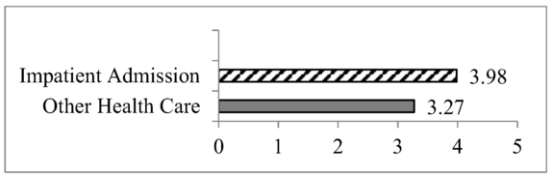

Figure 1 – Interoperability Maturity of Inpatient Admission vs Other Healthcare Services

Interoperability in Healthcare Services vs Public Services of Other Sectors

The average value of the interoperability maturity level of healthcare services is 3.32, which is not significantly higher than the interoperability maturity score of all other public services whose maturity is 3.29, as shown in Figure 2.

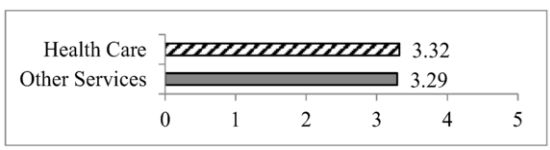

Figure 2 – Interoperability Maturity of Healthcare vs Public Services of Other Sectors

The healthcare services and public services of other sectors have, in terms of IMM, the same interoperability maturity at *essential* level. Looking more closely at the internal dimensions of healthcare services maturity versus those of all other services, as shown in Figure 3, it is noted that the *service delivery* dimension scores slight lower in healthcare than in other public services. This could be attributed to the fact that public services of other sectors could be used directly by citizens and are part of service catalogues.

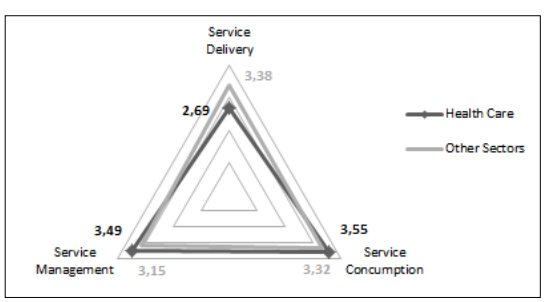

Figure 3 – Interoperability Maturity Dimensions of Healthcare Services vs Public Services of Other Sectors

Discussion

Based on the analysis of the real data generated during the conducted coursework, it has been shown that healthcare services score slightly higher in overall interoperability maturity to that of public services of other sectors. In the healthcare sector, several digital services have been implemented in the past years for the entire public sector. These implementations were reinforced through the economic crisis and the need for better control of costs within the NHS. Base registries for the healthcare sector, such as the electronic confirmation service ATLAS, are supporting instruments for public administrations.

The EU, through the ISA^2 programme, encourages cross-border public administrations to develop integrated digital services for national administrations in support of the vision for the European single digital market. To work towards this direction a number of instruments need to be in place to support this work. Development, implementation and use of these instruments in the European public sectors can help administrations reach the next level of maturity in the digital services they provide. Some of these instruments are presented in the following paragraphs.

Health Interoperability Framework: The framework gives specific guidance on how to set up interoperable digital public services. A framework can integrate the fundamentals and set the standards of healthcare services. The new European Interoperability Framework (new EIF) in combination with the healthcare specific interoperability framework provide an appropriate guide for establishing a national interoperability framework for healthcare [7].

European eHealth Governance: The eHealth Network is the main decision body on eHealth at a European level. It gathers representatives of the Member States at a high level, on a voluntary basis, to define a common vision and strategy for eHealth across Europe [18]. The eHealth network was established by article 14 of Directive 2011/24/EU on patients' rights in cross-border healthcare. The eHealth Network identifies areas for cooperation and meets two times a year to agree on common priorities.

Health Quality Assessment: Certification of healthcare processes will allow continuous monitoring in healthcare organizations. As far as interoperability and conformance testing are concerned, it is very important that a compliance strategy is in place as well as a roadmap for the development and maintenance of national specifications and interoperability principles, standards-related rather than self-defined. The creation of a mechanism for compliance control and certification of relevant software is considered critical.

Service Catalogues: The general service catalogue for public administration services can also help the healthcare sector by considering all possible extensions.

Healthcare Process Modeling: It is important to incorporate process modeling in healthcare service delivery using international standards, such as the graphical representation for business process model and notation (BPMN), and templates of descriptions of high level use cases and realization scenarios [7]. Standardized process modeling will facilitate the unified description of digital services for easier consumption and sharing.

Healthcare Service Vocabulary: The process of providing cross-border healthcare services across EU Member States is complex, due to the heterogeneity of the actors, information and services of the different Member States. The complexity of exchanging data may lead to semantic interoperability conflicts. The core public service vocabularies can be extended and used, in healthcare as in all other areas, to reduce these semantic conflicts (https://joinup.ec.europa.eu/solution/core-public-service-vocabulary).

Healthcare Learning Programs: Education and training about interoperability, interoperability assessment, and sector specialized interoperability challenges for end users, policy makers and public employees, are essential. These learning

courses providing the basic and advance understanding of interoperability challenges, needs and issues in the public sector.

Conclusions

Assessment of interoperability maturity and specific measures for interoperability enhancement can contribute to cost reduction and greater integration through reuse of available services. Orchestration of services is an effective manner to maximize service outcomes and benefits for citizens and public administrations. IMM is a way to investigate deeply how a service performs and relates to other digital public services. It helps service owners to gain a better understanding of the interoperability maturity of a digital public service. An evaluation strategy needs to be closely linked with specific policies to support the continuation of the assessment, governance and implementation of digital public services nationally.

The maturity of healthcare digital public services show a higher maturity in service consumption and service management, as well as to the overall interoperability maturity, compared to other public services. This indicates that the healthcare sector has made improvements towards harmonizing with relevant EU directives for integrated public services. Future work will involve the application of IMM in a wider range of public services as well as the tracking of interoperability maturity of public services across time.

There is significant space for improvements towards the development and implementation of seamless interoperable services for citizens, administrations and businesses in the public sector across Europe. Further work is necessary to validate the results amongst a larger number of services. In addition, further research can be conducted to evaluate similar public services across countries in Europe.

Acknowledgements

This work has been funded, in part, from the European Union's Horizon 2020 research and innovation programme under grant agreement No 688095 (SlideWiki) (https://slidewiki.eu/), and by the Center for eHealth Applications and Services (https://www.ics.forth.gr/ceha) of the Institute of Computer Science, of FORTH. The authors would like to acknowledge Fokion Logothetidis, Ioannis Petrakis, and Nikolaos Stathiakis for their contribution in the definition and assessment of the hospital scenario presented.

Enterprise Architecture in Hospitals: Resolving Incongruence Issues

Anne Kristin Ajera, Eli Hustada, Polyxeni Vassilakopouloua

[a] *Department of Information Systems, University of Agder, Kristiansand, Norway*

Abstract

Enterprise Architecture allows addressing technologies and processes in a holistic way and mirrors choices related to process standardization and data integration. It has the potential to address long-standing problems in health information systems related to fragmented IT portfolios, immature IT infrastructures, and silo-structured organizing. Nevertheless, uptake of Enterprise Architecture in hospitals has been slow. To understand the issues related to this slow uptake we have undertaken an interview study with architects and managers. The issues identified reveal a level of incongruence between healthcare as a domain and the practice of EA. Specifically, by analyzing the experiences of architects and managers we identified four different areas of such incongruence that create the need to reconcile a) Bottom-up vs. Top-down Planning b) Clinical vs. Systems´ Knowledge, c) Local vs. Global Arrangements and d) Patient Safety vs. Patient Privacy. Building on prior related research we propose ways for resolving the incongruence issues identified.

Keywords:

Architecture; Health Information Systems; Qualitative Research

Introduction

An organization's Enterprise Architecture (EA) describes in a hierarchical way its processes, the data and applications that support these processes, and all related information and communication technology (ICT) arrangements [3]. Practitioners and researchers have advocated EA as a systematic approach for designing, planning, and implementing process and technology changes [5; 21]. The EA approach addresses technologies and processes in a holistic way and mirrors choices related to standardization and integration [17]. During the last two decades, hospitals started EA initiatives aiming to address long-standing problems in health information systems related to fragmented IT portfolios, immature IT infrastructures, and silo-structured organizing.

Norway has formally adopted EA as a strategic tool for hospital information systems and processes [14]. Nearly all hospitals in the country are public and organized as health trusts that can include several local hospitals. The trusts are allocated to four independent regional health authorities under the jurisdiction of the Ministry of Health and Care Services. The strategic coordination, prioritization, and consolidation of key ICT issues across the regions are performed by a separate organizational entity dedicated to healthcare ICT called the National ICT (NICT). Four regional health authorities is jointly owned by NICT. The Norwegian government has issued several white papers that describe how ICT shall be used to achieve health policy objectives and deliver more effective and efficient services, with emphasis on quality and patient security [9]. Two of the most important white papers that guide the development of eHealth services are "The Healthcare Coordination Reform" (2009) and "One Citizen – One Record" (2012). The first one addresses issues related to collaboration, while the second one, sets the targets for the evolution of healthcare services [2; 8].

Norwegian hospitals are supported by complex information infrastructures that evolved over many years. The earliest use of electronic documentation of patient information in health services dates back to the 1970s while the first implementations of applications for entire hospital coverage started in the 1980s [7; 16]. With the adoption of EA, structured, comprehensive and aligned blueprints for current and future states of hospital systems and processes can be developed. Furthermore, EA can provide guidance for implementing processes and technology changes to operationalize strategies. Nevertheless, despite the potential benefits and the state mandate for introducing EA, there have been significant delays and challenges.

To gain insights about EA introduction in Norwegian hospitals, we performed interviews with key actors at the local, regional and national level across the hospital sector. Prior research has shown that the introduction of EA is far from straightforward and pointed to the importance of a favourable organizational culture [1; 15; 23]. Intrigued by this previous research finding, we specifically investigated the following research question: *are there inherent issues related to incongruence between healthcare as a domain and the practice of EA?*

The rest of the paper is structured as follows. First, we describe the empirical setting and explain our research method. Second, we provide the results. Third, we discuss the results and drawing from prior related research we propose ways for resolving the incongruence issues identified. We conclude the paper by pointing to the contributions and limitations of our research.

Methods

Data collection

Semi-structured interviews were conducted with Enterprise Architects and Managers involved in the introduction of EA in Norwegian hospitals at the local, regional, and national level. In total 17 interviews were performed between November 2016

and August 2017 (Table 1). All the informants interviewed had at least two years of experience in their current position. At the national level, most of the interviewees had been working since NICT started (2.5 years ago) while all were experienced before joining NICT. At the regional level, the enterprise architects had been employed for an average of about 5 years, and the managers for about 7 years. At the local level, the enterprise architects had been employed for an average of 10 years and the managers for 8 years on average. Interview questions explored the experiences of participants. The interviews included topics on how EA was used, the role of enterprise architects, and issues about national coordination and collaboration in eHealth. All interviews were audio recorded and transcribed.

Table 1– Interviews Performed

Level	Informants	# interviews
National	5 Enterprise Architects	5
Regional	4 Enterprise Architects and 2 Managers	7
Local	2 Enterprise Architects and 3 Managers	5

In Figure 1 we present the overall structure of the hospital sector in Norway (as described in the introduction) marking the specific units where interviews have been performed.

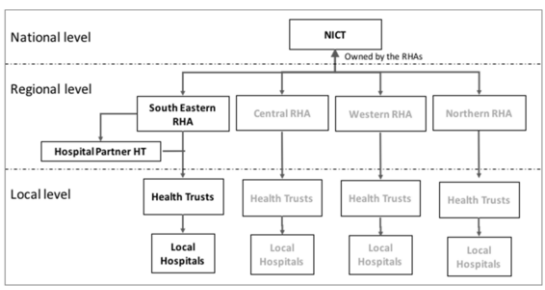

Figure 1–Overview of the Norwegian Hospital Sector (units covered by interviews are marked in bold)

Analysis

An iterative approach was followed for the data analysis. The coding followed the principles of first- and second-cycle coding [13]. The first cycle was done in NVivo where all anonymized transcripts were entered. The transcripts were further analysed and grouped into Excel forms. In the second cycle, the data were discussed, organized, and compared in an iterative process to identify emerging patterns. This initial analysis yielded a wide range of challenges, some related to the technological landscape, the financing mechanisms in place, the different logics of actors involved and the governance arrangements. Furthermore, we also encountered issues related to inherent healthcare characteristics that complexify the introduction of EA. Drawing from these initial findings, and building on previous research that points to the significance of idiosyncratic characteristics (such as culture) for the introduction of EA, we focused our analysis on issues related to incongruence between healthcare as a domain and the EA practice.

Results

We identified four key themes related to healthcare characteristics that create friction in the introduction of EA. In the paragraphs that follow we present the findings from the interviews organized according to these key themes.

Clinical vs Systems Knowledge

Several informants expressed concerns related to the instances where core hospital processes need to be redefined. In such instances, systems´ knowledge encounters medical knowledge. One of the architects wondered about the role of systems experts since they "*do not treat patients*". Another architect said, "*administrative tasks can be standardized, but for clinical ones we cannot suggest the best way*". One of the managers pointed to the singularity of healthcare domain related to the key role of the medical staff for setting the norms for patient care irrespectively of hierarchical positioning: "*the tax director does not understand that the health director cannot decide*". Another architect pointed to issues of distributed control in the domain "*you have so many strong doctors … you have strong departmental directors…there are many little kings*". Overall, hospitals unlike other large-scale organizations such as banks or public administrative services where EA has been successfully introduced, are characterized by strong professional practices that have a decisive role in process and systems optimization.

Local vs Global Arrangements

One of the architects lucidly expressed a key challenge with EA work: "*they want their local systems, not regional ICT services*". The health trusts want autonomy to meet local needs and there is a power struggle with the regional authorities. The regional authorities do own the health trusts, but they do not treat patients directly, so they do not experience day-to-day operational challenges. A manager explained that health trusts are similar to individual companies; they do not really have a "*mother-daughter*" relationship within the overall healthcare structure. One of the enterprise architects said, "*a model that ensures both standardization and taking care of local wishes may be beneficial*". Another architect pointed to concrete differences between two major hospitals: "*hospital A is much more IT mature than B, doctors and many nurses are involved in the IT department, they are much closer to the users*". A manager explained that although the needs may be similar in different regions there are different cultures across hospitals and these cultural differences matter.

Bottom-up vs Top-down Planning

EA is a plan-driven approach, however, holistic planning of ICT within healthcare can be especially challenging as explained by one of the architects interviewed "*the biggest challenge is to maintain local understanding…it should be taken from patients to clinicians and upwards not top-down*". Another architect explained that it is important to follow a bottom-up approach because clinicians often have good solutions to their own problems. Nevertheless, one of the managers pointed to the importance of top-down approaches that allow better coordination, the manager pointed to the need for a stronger central role "*everybody wants new systems,*

nobody wants to change". Balancing bottom-up with top-down planning has proven to be challenging for the EA initiatives.

Patient Safety vs Patient Privacy

An architect pointed to the need to consider data flows not only in terms of security and privacy but also in terms of patient safety. The standard regulations and procedures for systems analysis and risk containment are addressing issues related to data security and patient privacy but not issues of patient safety. Architects are not experts in issues related to patient safety. Another architect explained how important it is to make available patient data when patients move from region to region, but this is not straightforward to implement. A manager pointed also to the need for data exchanges between primary care and hospitals. Overall, the visions for data integration are bringing up unresolved issues related to balancing patient safety and privacy.

Table 2 provides an overview of the results, mapping the four key themes identified to key EA features that are challenged by the singularities of the healthcare domain. Specifically, the practice of EA is plan-driven and oriented towards process standardisation, and data integration and these characteristics relate to friction experienced when introducing EA in healthcare.

Table 2– Incongruence Themes Identified

EA characteristics	Healthcare characteristics	Incongruence themes identified
Plan-driven	National strategies but also pivotal bottom-up initiatives	Bottom-up vs Top-down Planning
Process standardisation	Processes inscribe clinical knowledge Local variation	Clinical vs Systems´ Knowledge Local vs Global Arrangements
Data integration	Sensitive but also mission-critical data	Patient Safety vs Patient Privacy

Discussion

The issues identified reveal a level of incongruence between healthcare as a domain and the practice of EA. The friction themes identified, can be related to prior research findings in Health Informatics. Healthcare is "work regarded as unusually complex, uncertain, and of great social importance." To ensure the best possible outcomes under these difficult circumstances, "the strategy pursued is to couple capability with discretion in one responsible actor and place him or her as close as possible to the problem situation … legitimate control over the nature and quality of professional practice is vested in the professional staff, not in the administration" [18]. Prior research [20] has identified that in healthcare universality is always "local universality" in the sense that it "always rests on real-time work and emerges from localized processes of negotiations and pre-existing institutional, infrastructural, and material relations". Furthermore, along the same line of thought, researchers [4] have conceptualized the distinction between conjoint and context-dependent design negotiations showing how in successful standardization processes stakeholders define and agree on boundary factors (elements that are meaningful across borders) while creating possibilities for local reconfigurations.

Prior research has also pointed to the fact that frequently, advancements in healthcare come out of practice-driven initiatives without a predetermined strategy and without the initial support of management; a novelty in healthcare usually entails extensive work over lengthy periods of time by different participants [10; 11; 19]. An approach that balances between bottom-up and top-down approaches for the evolution of Health IT Systems has been proposed in the literature [6]. The approach is labelled "middle-out" and is described as a situation where governments provide incentives and support that encourage clinical providers to acquire systems that are technically or functionally compliant, and to pursue innovations that keep their systems compliant over time. Such an approach entails specifying commonly agreed compliance requirements.

Ensuring data security and privacy while catering for patient safety is one of the big challenges when it comes to streamlining data flow and pursuing data integration in healthcare. A possible way to address this challenge is by enabling a more active role for the patients. A patient-centric logic not only spans the whole spectrum of patients' needs from preventive healthcare, to treatments and long-term care but also presumes a more active role for the patients themselves. Patients can contribute through information sharing, self-service, and assisting healthcare staff acting as resource integrators [12]. To do this, they need to be able to access, manipulate and contribute data. Moreover, they need to stay informed about who is accessing their data and be able to manage access. Enabling patients to control data flows entails ensuring the clarity, user-friendliness, and transparency of patient-oriented data handling solutions.

Overall, healthcare is a safety-critical domain that requires everyday coping with uncertainty. Patients can have unique combinations of conditions and this explains the acknowledged need for medical discretion. Reliability in healthcare is not only the outcome of protocols and formal procedures but also, of an acquired capacity to perform even though working conditions fluctuate and are not always known in advance. This capacity frequently found in high-reliability settings is a mix of risk anticipation and containment encapsulated in the term "mindfulness" [22]. Mindfulness is analysed to: a) preoccupation with failure; healthcare practitioners are concerned with success as much as with failure – Hippocrates' Oath "do no harm", b) reluctance to simplify; simplifications are avoided, c) sensitivity to operations; attention is given to process dependability under diverse circumstances, d) commitment to resilience; healthcare professionals need to be able to recover from mishaps and cope with surprises pursuing alternative means to goals, and paying attention both to error prevention and containment, and e) deference to expertise; the need for a wide array of specialisms is acknowledged and respected. EA initiatives need to retain and possibly further enhance mindfulness in the domain.

Implications for Practice

The findings suggest that in order to advance with EA in hospitals, it is important to resolve key issues related to the characteristics of EA and the singularities of the domain. There is limited prior research on the domain-specific characteristics

that hinder the introduction of EA in healthcare. This is work that we have begun to undertake. The table that follows (Table 3) is building upon prior related research to propose a set of resolutions for the incongruence themes identified. These proposed resolutions can guide practitioners involved in the introduction of EA in hospital settings.

Table 3– Resolutions for Incongruence Themes Identified Directions for Mindful EA Initiatives

Incongruence Themes	Proposed Resolutions	Brief Description
Bottom-up vs Top-down Planning	Middle-out	Incentivize clinicians to acquire compliant systems (based on common requirements).
Clinical vs Systems´ Knowledge Local vs Global Arrangements	Configurable solutions catering for both standardisation and local needs	Technology accommodating clinical discretion and local variation.
Patient Safety vs Patient Privacy	Stronger patient role – patient data access management	Patients can contribute acting as resource integrators.

Limitations and Strengths

The study has been conducted within Scandinavian healthcare so we cannot judge to what extent the findings reflect friction and tension with the introduction of EA in hospitals in different countries that have different institutional characteristics. However, the issues identified relate to the characteristics of healthcare as a practice in general and are also found in prior research conducted in different countries. A strength of our study is that it links to prior related research to propose concrete resolutions. Furthermore, it provides detailed qualitative data on the experiences of architects and managers involved in the implementation of EA at different levels (local, regional, national) and can provide insights for those that seek to contribute to such initiatives.

Conclusions

This study suggests that there are inherent issues in the introduction of EA in hospitals that relate to some level of incongruence between EA and the key characteristics of the healthcare domain. Specifically, by analyzing the experiences of architects and managers we identified four different areas of such incongruence that create the need to reconcile a) Bottom-up vs. Top-down Planning b) Clinical vs. Systems´ Knowledge, c) Local vs. Global Arrangements and d) Patient Safety vs. Patient Privacy. Our study can be used as a basis for further research towards the development of a measurement instrument to assess trade-offs in the four incongruence areas identified. As these areas relate to the nature of healthcare delivery, prior research has brought insights related to potential resolutions. Although the introduction of EA in hospitals is far from straightforward, working towards resolutions for the specific incongruence themes identified can be a basis for mindful EA initiatives. Mindful EA can be a healthcare-specific EA approach for systematically designing, planning, and implementing process and technology changes.

Abstract

This article describes development of the multi-professional discharge checklist and its implementation into the nursing documentation system (NDS) as part of the patient's overall care plan. The aim was to harmonize patient's admission and care period documentation and to improve the quality of electronic nursing discharge summaries. The ultimate goal was to ensure continuity of care. The multidisciplinary discharge checklist was developed in two phases to support the discharge of elderly patients (over 65 years). First, the information content of the checklist was defined, and second, it was integrated into the NDS. Focus groups of social and healthcare professionals (n = 82) in specialist health care, primary health care and social services defined the information content and participated in the feedback and checking rounds. The development work should continue. Particular attention should be given to the technical performance of discharge checklists in the NDS.

Keywords:
Continuity of Patient Care, Checklist, Patient Discharge

Introduction

Continuity of patient care is not always realized when the patient moves from hospital to home or primary health care; as a result, up-to-date information is not available to the professionals [1]. Poor communication and lack of documented guidelines or checklists have increased the incidence of handoff errors [2] and adverse events, with adverse events associated with information and medication being the most common [3]. The lack of standardization of information availability forces professionals to search for information in multiple places and pages of documents, which is not an efficient use of professionals' time and adds to their cognitive load [4]. Standardization of these procedures is thus a Joint Commission requirement for accredited hospitals [5].

In Finland, nursing documents are produced, stored and presented using the Nursing Documentation System (NDS) which is part of the Electronic Health Record (EHR). The Finnish nursing model applied is based on the nursing process, a nationally defined nursing core data set and the Finnish Care Classification (FinCC). The FinCC consists of the Finnish classification of nursing diagnoses (FiCND), the Finnish classification of nursing interventions (FiCNI) and the Finnish classification of nursing outcomes (FiCNO) [6,7]. An important objective of the implementation of the nursing model has been to enable multi-professional collaboration and exchange of information between health professionals [8].

An electronic nursing discharge summary (ENDS), which is part of the Finnish nursing model, is recorded at the end of the care period or as a mid-term review in long-term care [6,7]. It is stored in the Patient Data Repository and available for professionals and patients [9]. The aim of the ENDS is to ensure the continuity of patient care when the care responsibility passes from one organization to another, and to gather the key information of the service event into a readable and comprehensible form [6]. According to a recent study, nurses working in primary health care valued the ENDS's efforts to improve information flow and cooperation, but the data content was estimated to be poor [1].

Safe discharge from the hospital is an important way of supporting home living and safe rehabilitation after hospitalization. A recently published systematic review stated that inadequate or delayed information transfer between hospital and primary health care professionals was common [10]. To facilitate the interface between specialized health care and primary health care, so-called discharge checklists are recommended [11-16]. The checklist is a tool for systematic work. It seeks to prevent memory lapses and to avoid human error [17,18]. They include important issues related to the patient's discharge [17,19], such as things that describe the patient's functional performance ability [20,21].

Discharge checklists have made it possible to ensure that all relevant issues related to the discharge have been taken into account [12]. Acute medicine discharge checklist has helped to add structure to the complex interprofessional communication which is essential to safe discharge transitions [22]. In a systematic review, they have been found to improve the quality of medical case summaries [16]. Patient's own checklist that engages the patient can make discharge safer by targeting gaps in patient education and correcting potential adverse events [23].

Checklists remain paper-based [23] and their functionality is limited [15,17]. Recently, the integration of the electronic discharge checking lists, especially in medical processes, has been shown to be beneficial [15,18]. Technologies must be highly usable to ensure high-quality and safe delivery of care without unnecessary increases in workload [24]. Nurses have had to integrate data and information for summaries from EHRs and devices by hand, typically by remembering data [25]. Technical implementation of checklists in the EHR system has

proved to be challenging. Extra difficulties have been caused by the fact that they have had to be added separately "by hand" to each patient's patient record [15]. Besides causing extra work, transferring and duplicating patient data in the patient information system manually is prone to changes in information [26] and thus a threat to patient safety [3]. Structured documentation has improved the quality of documentation, i.e., recording of nursing activities and results, supported the exchange of information, and contributed to the continuity and coordination of care and the reuse of information [27].

According to a systematic review, mere transfer of the discharge checklist into electronic format may not ensure its successful implementation. In order for it to be successful, it is essential to integrate it into existing work processes [18]. Hospitals should develop documented guidelines, promote cooperation and clarify work processes [2] so that the information content of the discharge checklists can be immediately updated and shared among the various occupational groups involved in the care of the patient [15].

According to our knowledge, a multidisciplinary discharge checklist has not previously been implemented in the day-to-day Nursing Documentation System. The purpose of this article is to describe the development of the information content of the multiprofessional discharge checklist into a NDS to harmonize patient's admission and care period documenting and to improve the quality of electronic nursing discharge summaries. The ultimate goal is to ensure continuity of care.

Material and Methods

Setting

In Finland, municipalities are responsible for organizing social welfare and primary health care. Hospital districts (n = 21) organize specialized health care [28]. This development project was carried out in the Satakunta Hospital District (SHD) in 2014–2016 as part of a project funded by the Ministry of Social Affairs and Health for the discharge and rehabilitation processes of older people. In 2018, SHD provides specialized health care services to approximately 223,000 residents in co-operation with primary health care and social services [29]. The NDS has been in use in SHD since 2015.

The multidisciplinary discharge checklist was developed within the project in two phases to support safe discharge of elderly patients (over 65 years). In the first phase, the information content of the discharge checklist was defined, and in the second, it was integrated into the NDS.

Phase I. Definition of the Data Content of the Multi-Professional Discharge Checklist

The development of the information content of the discharge checklist was preceded by a comprehensive literature review on the continuity of care [1]. In addition, we acquired some examples of paper checklists used elsewhere in Finland. The data content of the discharge checklist was developed using focus group interviews in workshops related to a development project in elderly care. This method can be used at the beginning of development projects, whereby focus groups can highlight, for example, the wishes or needs concerning the information content of the system or the user interface solution[30].

Focus groups of social and healthcare professionals (n = 82) in specialist health care, primary health care and social services defined the information content of the discharge checklist and participated in the feedback and checking rounds. Participants in the working groups were found and selected on the basis of volunteering and interest expressed. The sizes and configurations of the focus groups at the meetings varied (Table 1).

*Table 1 – Composition of the Multidisciplinary Team (n = 82) by Profession**

Professional title	n
Nurse	35
Doctor	11
Physiotherapist	6
Rehabilitation counselor	6
Social worker	6
Practical nurse	5
Home care supervisor	2
Senior manager of the elderly	2
Project worker	2
In addition, one representative of each: occupational therapist, fitness instructor, senior care supervisor, service counselor, psychologist, nurse and elderly care professional	7

* The number of professional groups is indicative

The aim of the workshops was to find out key information for the patient's discharge to ensure continuity of care from the perspective of different professionals and organizations. The workshops were designed in a multi-professional team. There were always two team leaders, one asking questions and the other taking notes. In the workshops, small group work based on patient cases and free-form ideas was used.

The material consisted of examples of paper checklists used elsewhere, written output from workgroups, and notes from team leaders. The material was analyzed and categorized thematically. The results made up the thematic areas of the discharge checklist.

The paper discharge checklist was piloted between July 1, 2015 and May 16, 2016 in several units in specialist health care and primary health care at SHD. The checklist was updated three times. The functionality of the paper checklist was evaluated using the so-called principles of continuous evaluation (oral, written, Webropol®).

Phase II. Integrating the Multidisciplinary Discharge Checklist into Nursing Documentation System (NDS)

The fourth version of the checklist was implemented into special health care NDS as a template for the electronic form. The use of a template is recommended to improve the usability of NDSs, multi-professional co-operation and the utilization of information [8,31,32]. The template content was constructed from the FinCC classification [6,7]. The template contains the default parts. It can also be edited for individual patients [33].

An electronic discharge checklist was tested between May 16, 2016 and September 30, 2016 in specialist health care in elderly psychiatry, rehabilitation, pulmonary diseases, neurology and internal disease ward patients over 65 years of age because it was a project of older people. The use of the checklist was evaluated face-to-face in discussions and feedback sessions (n = 4). Additionally, five random samples were taken from each of the units participating in the pilot (n = 5) to assess whether the checklist was filled or used and whether the information was transferred to the electronic nursing discharge summary.

Results

Information Content of the Multi-Professional Discharge Checklist

After continuous dialogue with feedback and three check rounds, the content of the paper-based multi-professional discharge checklist consisted of the following content areas: (1) housing, home care and follow-up care, (2) functional ability at discharge, (3) medication, (4) social benefits and (5) patient involvement.

Multi-Professional Discharge Checklist as Part of NDS

The contents of the paper-based discharge checklist were transferred in structured form, as a so-called template, into the NDS (Figure 1). The categories corresponding as closely as possible to the data content were selected from the FinCC classification. The template serves as a plan for co-ordination of care and follow-up care as well as a daily documenting base.

At the beginning of the discharge checklist, a space is reserved for the planned discharge date. It is recommended that the discharge date is recorded immediately at the beginning of the care period to ensure a safe and systematic discharge.

The planned care activities in the structured discharge checklist are shown in bold in Figure 1. They are in accordance with the Finnish classification of nursing interventions (FiCNI version 3.0): (1) involvement in planning and implementation of care, (2) supporting patient coping, (3) supporting patient self-help, (4) providing aids for day-to-day activities, (5) orientation tracking, (6) mental state monitoring, (7) pharmacotherapy and (8) planning for continuity of care. After the end of the project, nutrition-related guidance was added to the discharge checklist.

The planned care activities, such as orientation tracking, are specified by keywords (oriented/forgetful). The contents of the discharge checklist can be modified in accordance with each patient's personal care needs and a particular care activity can be included in the NDS as an exclamation mark (for example: blood glucose drops easily <3.0 mmol/L). (Figure 1.)

CARE PLANS

COORDINATION OF CARE AND CONTINUITY OF CARE, NEED FOR FURTHER CARE

30.10.2018-

Objective of care: planned discharge date:

Planned care activities

Involvement in planning and implementation of care: Patient/relative/sender

Supporting patient coping: Type of accomodation/home life/services/social situation/family carer

Supporting patient self-help: Movement/toilet functions/personal hygiene/dressing/eating

Providing aids for day-to-day activities: Aids/care accessories

Orientation tracking: Oriented/forgetful

Mental state monitoring: Normal/depressed/anguished

Discussion

In this paper, we described how the information content of a multi-professional discharge checklist was developed into NDS to harmonize documenting patient's admission status and hospital period and to improve the quality of electronic nursing summaries. The ultimate goal was to ensure continuity of care. The starting point for this development project was that *"cannot cope at home"* is not a sufficient description of admission to hospital. Instead, the preparation of the patient's discharge should be started as early as possible so that the patient and his/her family or friend can stay at home as well as possible after acute care. For example, the patient's ability to function or any need for aids or care accessories should be clarified as early as possible.

Improving effectiveness of communication among caregivers and the safety of medication use have been included as items for hospital accreditation [5]. The use of structured documentation has improved the quality of the documentation [27], and the use of discharge checklists can reduce the potential for preventable adverse events associated with transfer of data [2]. Standardized checklists have previously shown benefits in patient care, especially in medicine. They have helped to standardize and harmonize good practices in the organization of continuity of care [13,16,23].

Previously, professionals had to search numerous pages of documentation for information that might not be there [4]. Matters that are relevant for the discharge are often only in the hands of professionals. This introduces patient safety concerns of increased risk for errors [3]. According to our knowledge, an electronic multi-professional discharge checklist is not available elsewhere in NDS. In this project, it was desired that the content of the discharge checklist in NDS was constructed from the patient's point of view and that it would be generic to the social and healthcare professionals involved in the patient care regardless of profession. The aim was to avoid situations where no single document contains all the information needed for the patient's discharge.

The discharge checklist was implemented as a template on the NDS, based on the recommendation of an IT vendor. The categories describing the data content of professionals were found quite well from the FinCC classification [6,7]. On the other hand, there were problems with the compilation of the data content into electronic format. We knew that lack of written guidelines has led to errors in patient transfer situations [2]. That is why we provided end users with technical and substantive written guidelines in support of the discharge checklist. The guidelines for using and filling in the discharge

list were not detailed because different units care for patients with various disorders and the patients have different personal care needs.

In our project, the technical implementation of the discharge checklist into the NDS was challenging. Past experience has shown that usability problems with these records can have unintended consequences that harm patients and cause additional workload for nurses and other clinicians [24]. In our project, professionals made many suggestions for improvement which were passed on to the IT system supplier. Based on initial user experience, they suggested, for example, that the discharge checklist should open automatically for all patients over the age of 65. Furthermore, it was recommended that the position of the discharge checklist that has been added to the NDS should be interchangeable. The information contained in the checklist should be automatically transferred to the electronic nursing discharge summary. End users also hoped that the content of the discharge checklist could be "hidden" and opened as a drop-down menu as display space is limited [compare 15].

A systematic review by Kattel et al. [10] has suggested dynamic documentation development and implementation of electronic discharge software that can automatically populate sections of discharge summariers. These recommendations are noteworthy. Patient data transfer within the information system is a risk for patient safety [26]. Unless technology supports the work processes [18], commitment to the discharge checklist can be challenging and the desired benefits will be missed.

Strengths and Limitations

The representativeness of the material was good. The workshops had a wide representation of different professional groups in specialist health care, primary health care and social work. It is noteworthy that in this project, customers and patients (families) did not participate in defining the data content of the discharge checklist although the original aim was to build a content-enhancing patient perspective.

Recommendations for Future Work

Patient discharge cannot be designed solely for professionals. In the future, patients and families should be engaged and included in the development work. It would also be desirable to link patients' self-generated entries to the discharge checklist. The contents of the checklist and its introduction should also be looked at in relation to other retrieval situations than discharge from the special health care ward (e.g. from nursing institution to hospital).

Conclusions

In this article, we described how the key issues from the hospital were standardized through an electronic multidisciplinary discharge checklist in NDS to ensure continuity of care. We found that based on preliminary user experience, the electronic multidisciplinary discharge checklist was perceived as a useful tool. More research is needed, however. We suggest that development work should continue. Technological developers should be aware of the different functional needs that must be taken into account when data contents are configured in the EHR system. In the future, particular attention should be focused on the technical performance of discharge checklists in the NDS.

Abstract

Continuity of patient care (COC) is considered an essential feature of good quality care, but the ambiguity of the concept has given rise to methodological challenges in scientific studies. This study has a strong link to the functional definitions of electronic health records (EHR). In order to evaluate how COC is achieved, through a discharge summary, for example, the contents of COC should be defined. Conceptual consensus on COC as a multidimensional concept has increased. This study was conducted to provide an overview of the dimensions and descriptions of informational and management continuity of care. A scoping review was conducted. We found that informational continuity of care refers to data tool, data content, data structures or information quality related processes. Management continuity of care refers to information flow, co-operation, co-ordination, multiprofessionality or management processes. We identified the need to define next the contents of relational and cross-border continuities.

Keywords:

Continuity of Patient Care, Electronic Health Records, Patient Discharge Summaries (MeSH)

Introduction

Continuity of patient care (COC) is considered an essential feature of good quality care, but the ambiguity of the concept has given rise to methodological challenges in scientific studies. COC is more often default than defined. [1] This study has a strong link to the functional definitions of electronic health records (EHR). Unless COC is clearly defined, it can not be measured [1; 2], achieved [3], or continuity-promoting methods [4] such as shared and synchronized EHRs can not be developed [5].

Continuity of care is a global priority for reorienting health services to the needs of people [5]. Through COC, the reduction in the risk of re-hospitalization is significant both for individual patients and in terms of the effectiveness of the service system [6; 7]. COC is associated with information flow, collaboration [2], patient safety issues [8], improved care results [9] and reduced costs [10].

Surprisingly, COC is a broad concept that has been loosely defined and used without a stable or clear aim [2]. This, in turn, leads to challenges when it comes to identification of effective methods for improving COC [4]. Originally identified in Canada [1], the classification into relational (also called inter-personal), informational and management continuity of care has been quoted a great deal [e.g. 2; 5; 11; 12; 13; 14; 15]. Conceptual consensus on COC as a multidimensional concept has increased, but only single standardized measures exist [13]. Different measures are needed to measure different dimensions of COC [2]. The vagueness of the methods of measuring COC makes it difficult to compare studies [9].

Electronic nursing discharge summary (ENDS) is a data tool that is supposed to comprise shared use of information to help maintain patient continuity and safety, collaboration between professionals, and thus provide good care results [15]. In order to evaluate how COC is achieved when using ENDS, the concept of COC needs to be defined. It is obvious that there is a need to determine explicitly what informational and management continuity of care mean. The purpose of this paper is to provide an overview of the dimensions and descriptions of informational and management continuity of care based on previous studies. The research questions are: (1) What are the dimensions and the descriptions of informational continuity and (2) What are the dimensions and descriptions of management continuity. The aim is to present the contents of informational and management continuity of care.

Methods

A scoping review, which is a systematic approach for synthesizing research evidence, was conducted in 2016 (Figure 1). Searches were updated in 2017–2018. The scoping review was used to investigate the scope, nature and gaps in the COC research and literature and to identify and present relationships between concepts [16].

Regional information system[20, 29]	Patient summary[34, 35]		
National patient records archive[30, 31]			

Systematic searches were made in relevant databases (PubMed, Cochrane, Science Direct and CINAHL Complete) and search services (Google and Google Scholar) without search restrictions and with 2018 as start time limit. The data search was supplemented by a manual search to ensure comprehensive retrieval of information. The search terms were used alone and in combination (Figure 1). The abstracts of retrieved references were studied. The scoping review was not limited to particular countries, but only included literature published in Finnish or English.

When it was found that conceptual clarity of COC had been sought in multidimensional models, in particular the continuity of care trilogy [1; 5; 11; 13], searches were targeted at literature on the informational and management dimensions of COC. The aim was to refine the contents of COC and continue with the definition of the concepts. The literature was tabulated by author, publication year, country, purpose, material acquisition method, target group, time and key results. Detailed tables are available online at http://epublications.uef.fi/pub/urn_isbn_978-952-61-2707-1/ [15].

Inclusion criteria were articles about dimensions and descriptions of informational and management continuity of care during the patient transfer process. Peer-reviewed studies as well as expert articles and reports were included to ensure a meaningful and comprehensive review of the literature. The exclusion criteria were unpublished manuscripts (abstracts) and articles on the relational continuity of care, because this study focuses on the professional perspective.

The material was analyzed thematically [17]. After compilation and encoding, the material was compared and the dimensions of informational and management COC (e.g. data tool) and their descriptions (e.g., paper or emails) were searched and synthesized.

Results

What are dimensions and descriptions of informational continuity of care?

Table 1 shows the *dimensions and descriptions of informational continuity* of care based on the choices made by the researcher in the literature. The dimensions are data tool, data content, data structures and data quality.

There are many types of data tools. Information is forwarded on paper [e.g. 18; 19], by phone [e.g. 18], mail, e-mail or fax [6; 20]. Information is generated by dictation [20] and using video [21]. Electronic summaries are used for information sharing between organizations [20; 22] and the automatic composition of the data stored in EHR is sought [23; 24]. Summaries can be conveyed by the patient [20] or e.g. by means of telecommunication [25]. The common infrastructure between hospital and primary health care is sought from the e-message system [26], regional eHealth network [27; 28], regional information system [20; 29] and national patient records archive [30; 31].

Data content of the discharge summaries consisted of administrative, demographic and clinical data [32] and was found to be inadequate in medication [13; 20; 24; 26], basic patient knowledge, identification of the provider [19; 20] and investigation results [6; 20]. Information was insufficient regarding care needs, goals, nursing interventions and outcomes [33]. The discharge summaries written by doctors and nurses were professional-specific and partly overlapping [15]. One solution could be a patient summary [34; 35]

Structuring of information requires standards-compliant interoperability [32] and was studied from the perspective of its need [20; 36], benefits [20; 37], challenges [15] and deficiencies [33].

Description of the quality of the information refers to spelling and grammar, sufficiency [16], correctness of information [28] and patient-oriented approach [16; 30].

What are the dimensions and descriptions of management continuity of care?

Table 2 presents the *dimensions and descriptions of management continuity* of care based on the choices made by the researcher in literature. The dimensions are information flow, co-operation, co-ordination, multiprofessionality and management.

Table 2. The Dimensions and Descriptions of Management Continuity of Care

Information flow	Co-operation	Co-ordination	Multiprofessionality	Management
Health IT[14]	Partnership[13]	Coordinator role[13, 14]	Multiprofessional documenting[38]	Resourcing and organization[39]
Timeliness[8, 20, 22]	Networks[14]	Care plan[11, 13, 38]	Multiprofessional discharge planning[41]	Encouragement and support[37]
Information gap[13]	Inadequate cooperation[30]	Follow-up care plan[6, 20, 33]	Multiprofessional cooperation[42]	Politics and decision-making[43]
Reliability [10, 28, 30, 38]	Work practices[27]	Care, service and patient management plan[11]	Multiprofessional information exchange[42]	Knowledge management[44]
	Confidence[39]	Advance care plan[40]	Role clarity[13]	Financial aspects[14]
	Communication[12]	Discharge summary[14, 38]	Confidence in team[13]	
	Understanding other's work[38, 39]	Nursing discharge summary[14, 15, 29]		
		Multiprofessional summary[24, 36]		

The information flow was studied in terms of health IT [14] timeliness [8; 20; 22], information gap [13] and reliability. Reliability was analyzed with regard to access to patient information [38], the confidentiality and security of electronic data [10], sensitive data [28] and privacy risks [30].

Co-operation was looked at in terms of partnership [13], networks [14], inadequate cooperation [30], work practices [27], confidence [13; 39], communication [12] and understanding other's work [38; 39].

Co-ordination descriptions are coordinator role [13; 14] and different care plans, such as care plan [11; 13; 38], follow-up care plan [6; 20; 33], care, service and patient management plan [11] and advance care plan [40]. Different summaries include discharge summary [14; 38], nursing discharge summary [14; 15; 29] and multiprofessional summary [24; 36].

Multiprofessionality was described in the field of documenting [38], but also in terms of multiprofessional discharge planning [41], cooperation, information exchange [42], role clarity and confidence in team [13].

Management in relation to continuity of care was studied resourcing and organizing [39], encouragement and support [37], policy and decision-making [43], knowledge management [44] and financial aspects [14].

Discussion

The purpose of this study was to provide an overview of the dimensions and descriptions of informational and management continuity of care. This study was carried out because we think that the previously published and much cited continuity typology, i.e. information, management and relational continuity [1; 11; 13; 14], do not give a sufficient picture of the dimensions and descriptions of informational and management continuity. The pressure on data interoperability [30; 31; 32] and care integration has increased [3] since the publication of the continuity typology. This study thus supplements the continuity trilogy [1; 11; 13; 14] in terms of the contents of informational and management continuity of care.

Informational continuity (Table 1) has previously been defined as follows: "*The use of information on past events and personal circumstances to make current care appropriate for each individual"* [11]. In nursing literature, information transfer has been the most prominent of the content areas of COC [1]. Technology and different data tools play an important role in enabling informational continuity, and data tools provide access to information. Electronic information exchange between organizations is hampered by lack of interoperability and the fact that patient information systems do not "talk to each other" [42]. Traditional data tools are still in use. Exchange of information from hospital to home care takes place using paper [18] or fax [6; 20; 26], which are not secure data tools. In addition, many referrals from primary health care to specialized healthcare are still paper-based [19].

Informational continuity has been considered to comprise how well patients' health information follows them over time between different places of care and service providers [5; 11]. For years, a common infrastructure for facilitating information exchange between the hospital and the community has been sought from the regional information system [20; 29], eHealth network [27; 28], electronic message system [26], and the national patient records archive [30; 31]. If professionals have to use a number of separate data tools that are not part of the professional workflow they may not be used [27].

The data content of medical case summaries has seen a lot of development. Still, their contents are inadequate [6; 20]. However, there exist standards as to which data should be included in discharge summaries [32]. For the time being, discharge summaries are professional group-based and partly overlapping [35]. The solution could be a patient summary [31; 32] generated automatically from EHR [23; 24]. Getting an automatic summary of the data recorded in the IT system requires standards-compliant interoperability [30; 31; 32].

Descriptions of data structures are seen especially in articles from the 2010s. They have been studied e.g. in patient transfer and discharge situations [37] and nurses' handoffs [35].

Informational continuity is largely a combination of shared, synchronized care records and their accuracy [11]. From the point of view of the quality of the information, especially important are language, sufficiency [18] and correctness [30] of information, as well as the patient-oriented approach [18, 33].

Management continuity (Table 2) has previously been defined as follows: "*A consistent and coherent approach to the management of a health condition that is responsive to a patient's changing needs"* [11]. We found that management continuity of care is related to organization structures and care planning. It is emphasized when the patient moves across organizational boundaries and focuses, for example, on patient management plans [38; 40] and summaries [15; 29]. In Scandinavia and the USA, researchers studied information flow from hospital to home care and found that accurate and in-time information was difficult to achieve [8].

Partnership [13] and networks [14] are an important part of co-operation. From the technology point of view, work practices

involve the need to learn how to work with new data tools [27]. Unless technology supports work processes, commitment to the new data tools (e.g. discharge checklists) can be challenging and the desired benefits will be missed.

Co-ordination requires a coordinator [13; 14] and includes different care plans [6; 11; 13; 20; 33; 38; 40], summaries [14; 15; 24; 29; 36; 38] and workflows. For example, ENDS has promoted information flow, cooperation and getting a complete picture of the client [15]. In Finland, the Patient Data Repository is in use [31]. Today, many patients in need of social and health services can have a number of services, care, rehabilitation or other plans (Table 2).

Multiprofessionality in documenting has long been discussed [36]. Despite this, it still does not work very well [15; 33]. One solution could be role clarity and confidence in team [13].

We found a few references on management support [34] from the point of COC [14; 37; 39; 43; 44].

Strengths and limitations

Scoping review is best suited for examining complex and heterogeneous topics like continuity of care [16]. The reliability of this review was increased by the use of pre-defined inclusion and exclusion criteria and the utilization of methodical literature [16; 17].

An information technician checked the searches made [17]. Data retrieval was continued until references repeatedly recalled the same articles. The analysis proved to be the greatest challenge [see 17] and the reliability of the review may be slightly weakened by the fact that one researcher (AK) made the selection of articles.

Recommendations for the future work

Our findings are a starting point to expand on and provide further insight into the construct. We identified the need to define the contents of relational continuity, i.e., the relationship between the professional and patient and cross-border continuity, i.e., situations where the patient's care responsibilities change.

Conclusions

We found that informational continuity of care refers to data tool, data content, data structures or information quality related processes. Management continuity of care refers to information flow, co-operation, co-ordination, multiprofessionality or management processes. Continuity of care is a concept that underlies many applications in eHealth and is thus one of the core constructs of biomedical and health informatics. Further work is still needed but the foundations are laid with this study.

Differences Between What Is Said During the Consultation and What Is Recorded in the Electronic Health Record

Abstract

Electronic Health Records (EHRs) can be used for research but this raises the problem of data quality.

Objective: To evaluate the quality of the information recorded in an EHR by a general practitioner (GP) during a regular office consultation.

Method: 191 dialogs between the GP and patient were recorded and translated into the International Classification of Primary Care Second edition (ICPC-2) codes. Written information of the corresponding EHR was extracted and coded for comparison.

Results: The primary reason for the consultation was recorded in the EHR in 41.2% of the cases and the diagnosis in 44.1% of the cases. Diagnoses noted in the EHR were less often communicated to the patients than the primary reasons ($p<0.0001$).

Conclusion: There is a loss of information between the dialog during a consultation and what is reported in the EHR. Consequences in terms of continuity and safety of care can be expected.

Keywords:
Electronic Health Records; Information Management; Self Report.

Introduction

Although the first traces of the medical record appeared in the 9th century with the creation of interesting case registers, the medical records attached to each patient did not appear until the end of the 18th century [1]. However, their contents were significantly limited and the medical record, as we understand it today, dates from the 19th century with the creation of the modern hospital.

In France, the medical record has assumed an important place since the 1970s, but was declared mandatory only in 1995 (deontology code and Public Health Code). Their computerization began in the 1980s and, according to a survey conducted in 2017, 96% of the general practitioners (GPs) reported having software for the management of their patients [2].

This computerization of data provides a rich source of data that can be leveraged to support research and public health [3-5], and large databases in primary care, such as Clinical Practice Research Datalink (CPRD) [6], were created in Europe. This model of data collection is being developed in France with the project PRIMEGE PACA (health data warehouse prepared from the EHRs of GPs in southeastern France using International Classification of Primary Care Second edition coding). However, secondary use of EHR raises the problem of data quality and especially in terms of missing data [7, 8]. While, in French hospitals, quality and safety of care indicators are clearly defined by the High Authority of Health [9] and ensure a certain quality level of the patient record, this is not the case in ambulatory care. Indeed, if the deontology code makes the possession of a patient record mandatory, it specifies that it not be subject to any formalization. In addition, neither the Remuneration about Objectives of Public Health (ROSP) nor the "forfait structure" (funding to facilitate the organization and computerization of the medical office) for GPs mention any element concerning the quality of the EHRs [10].

The objective of this study was to evaluate the quality, mainly in terms of completeness, of the information recorded in an EHR by a general practitioner (GP) during a regular office consultation.

Methods

Protocol of the Study

Nine GPs from the south east of France using the same software were recruited on a voluntary basis. For each doctor, consultations were recorded with a Dictaphone. A total of 191 consultations (one per patient) were recorded between June 2016 and June 2017. EHRs corresponding to these consultations were retrieved for data comparison. Once all the data were collected, they were anonymized.

On the day of the data collection, an information notice was displayed in the waiting room and the patients who agreed to participate had to sign a consent form at the beginning of the consultation.

Data Processing

Firstly, the recordings were analyzed to identify the reasons for the consultation and the diagnosis. These elements were noted in an information grid and were compared with the content of the corresponding EHRs to check whether all data had been recorded. Reasons for consultation and diagnoses present in the EHRs without having been located in the recordings were also noted. The reasons and the diagnoses were classified into three categories: "oral only", "oral and written", "written only" and all the data was recorded in an Excel® file.

To be properly exploited, the collected data had to be standardized. To this end, the International Classification of Primary Care 2nd version (ICPC-2), recognized as the reference classification in primary care by the World Organization of Family Doctors (Wonca) and the World Health Organization (WHO) was used. It has a biaxial structure and consists of 17 chapters [11], each divided into 7 components (comp.) that address symptoms and complaints (comp. 1), process codes (comp. 2), infections (comp. 3), neoplams (comp. 4), injuries (comp. 5), congenital anomalies (comp. 6) and other diagnoses (comp. 7). All the reasons and the diagnoses where coded in ICPC-2 using Prometheus, an encoding help engine [12]. All these stages were performed by a resident in general medicine.

Statistical analysis

Statistical analysis was performed using R version 3.4.3 software (the R Foundation for Statistical Computing). Chi² and Fisher tests were used, and multivariate analysis was conducted using logistic regression. The Alpha risk value was set to 0.05.

Results

Description of GPs and Patients

Nine general practitioners, including five men and four women, were recruited. Their average age was 53.56 years and five were trainer GPs. One GP declared that all consultation elements are noted in his EHR. For the others, the reasons for consultation were primarily noted (75% of GPs), followed by diagnoses (62%) and biometrics (37%).

Of the 191 patients involved in the consultations, 58% were women and 41% were men, and for 1% of patients' gender was not specified in the EHR. They were, on average 51.70 years old, with extreme values of 2 and 90 years old.

Reasons for Consultation

A total of 683 reasons for consultation were identified, which is an average of 3.6 reasons per consultation. Most of them corresponded to ICPC-2 chapter A (general / unspecified: 41.43%), chapter L (musculoskeletal: 11.57%) and chapter R (respiratory: 9.81%) (Fig 1). In more than half the cases, reasons for consultation expressed during the consultation were not recorded in the EHR (375 reasons compared to 638 oral reasons, 58.78%). Those recorded in the EHR had been orally expressed in the majority of the cases (263 of 308 written reasons, 85.39 %).

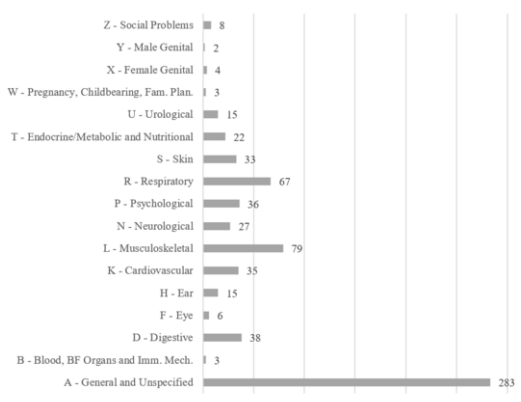

Figure 1: Reasons for Consultation by ICPC-2 Chapters

Diagnoses

A total of 159 diagnoses were identified, which is an average of 0.8 diagnoses per consultation. Most of them corresponded to ICPC-2 chapter A (general / unspecified: 22.01%), followed by chapter L (musculoskeletal: 18.24%) and chapter R (respiratory: 15.09%) (Fig 2). Most of the diagnoses noted in the EHR had not been orally expressed during the consultation (66 of 107 written diagnoses, 61.68%). Those specified during the consultation were recorded in the EHR in less than half of the cases (41 diagnoses compared to 93 oral diagnoses, 44.09%).

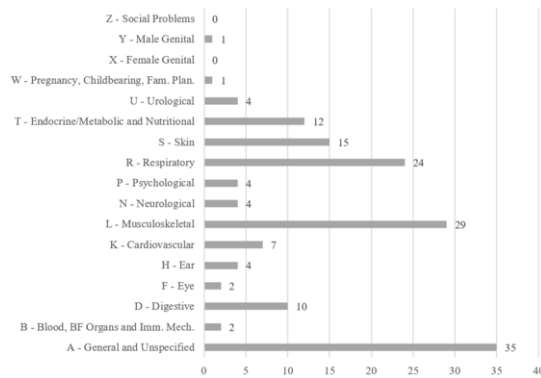

Figure 2: Diagnoses by ICPC-2 Chapters

Analysis

There was no significant difference between the transcription of the reasons for consultation and diagnoses ($p = 0.6527$), but diagnoses were present more often only in the EHR than the reasons ($p < 0.0001$).

Trainer GPs and older physicians had recorded the reasons in the EHR more often (OR = 1.864 [1.302 – 2.680] and OR = 1.052 [1.026 – 1.080]). The psychosocial reasons (chapters P and Z) were less often transcribed than the others (OR = 0.473 [0.217 - 0.965]). Regarding the ICPC-2 components, the reasons corresponding to symptoms and complaints (SPL) or process codes were transcribed more often than the others (OR = 1.834 [1.199 – 2.844]) (Table 1).

It was among new patients that we found the most reasons for consultation present only in the EHR (OR = 4.172 [1.567 – 10.614]). The ophthalmological (F), cardiovascular (K), metabolic / nutritional or endocrine (T), urological (U) or social (Z) reasons were found more often in the EHR without being addressed during the consultation than in other chapters of ICPC-2 (OR = 3.204 [1.387 - 7.122]). Concerning the ICPC-2 components, the reasons corresponding to the categories infections and other diagnoses were most often found only in the EHR (OR = 2.217 [0.981 – 4.781]) (Table 2).

With regard to diagnoses, those in the general / unspecified (A) category were less often recorded in the EHR than the others (OR = 0.263 [0.072-0.823]) (Table 3). We also observed that trainer GPs were less likely to note the diagnoses in the EHR without telling the patient during the consultation (OR = 0.379 [0.160-0.871]) (Table 4).

Discussion

Main findings

Reasons and diagnoses were recorded in the EHR in less than half the cases (41 % for reasons and 44% for diagnoses).

Incomplete medical records is a well-known problem. Long [13] compared the medical records of 17 patients with the care received when consulting for a sore throat, and he noticed that the items of the interview and the clinical examination were completed more often than they were noted in the medical record. While prescriptions are generally well recorded, that is not the case for lifestyle data [14,15], and several studies have also demonstrated that doctors have carried out more preventive action than was noted in the medical records [8,16].

Diagnoses were found more often in the EHR without being expressed to the patient than the reasons for consultation. This could be explained by still-hypothetical diagnoses for which the GP wishes to wait for confirmation before informing the patient, in order to not worry the patient unnecessarily.

The teaching activity of trainer GPs could explain their resolve to leave more information in their file and thus to transcribe more reasons for consultation. They also more often communicated their diagnosis to the patient. We can assume that they are more receptive of their obligation to inform the patient of the diagnosis and to the legal obligation to record it in their EHR.

Older physicians may be less concerned about profit and have longer consultations, which allows a more faithful transcription of the oral data. In addition, some may intend to prepare EHRs as complete as possible to facilitate the transition with their successor.

Differences between ICPC-2 chapters were found. Psychosocial reasons for consultation were less often noted in the EHR than in those related to other categories. This could be explained by the GPs favoring discussion and eye contact in this type of situation or by a desire not to record elements that may be stigmatizing for the patient. On the other hand, certain reasons may have been detected during the analysis of the recordings without having been perceived by the GP. Indeed, the difficulty to detect social problems has been described by Bentsen [17]. Conversely, reasons corresponding to the SPL or process codes components were more often transcribed, probably in a process of transparency and clarity for the record

to facilitate subsequent patient care. For diagnoses, those corresponding to ICPC-2 chapter A (general / unspecified) were less often transcribed. This could be related to the lack of specificity of this chapter, which may also correspond to a health concern, a request for information, a request for renewal, etc., that GPs do not consider noteworthy in their EHR.

The first consultation with a new patient is a moment of discovery during which many things are expressed. During this consultation, the GP probably employs a great deal of interpretation in his EHR to draw a clear patient profile, which could explain the presence of a greater number of reasons for consultation that have not been verbalized.

Limits

To prevent the patient from feeling intimidated and to keep the consultation as natural as possible, a Dictaphone was used instead of the researcher attending the consultation and transcribing it directly. However, we cannot rule out an observation effect (effect Hawthorne [18]). Indeed, if the physician is aware of being observed, it may influence the filling habits and behaviors during the consultation.

The recruitment of GPs and patients were made on a voluntary basis and we do not have information concerning the patients who refused registration. This is a measurement bias and we can presume that patients with "sensitive" reasons for consultation, such as risky behavior or psychological problem, for example, refused registration more often.

For the purpose of reproducibility and to limit the biases related to the use of multiple software, we selected GPs with the same software. However, the effect of the software's ergonomics in the filling of the EHR could not be studied.

This study compared only oral/written reasons for consultation and oral/written diagnoses, but we cannot assert that missing data was not recorded in an inappropriate field. For instance, a reason for consultation could have been recorded in the EHR as a diagnosis or a symptom.

Implications

A French Public Health Authority (ANAES) analyzed several studies and concluded that data contained in medical records are for internal use [19]. Doctors use them as a reminder and record only the information they consider necessary, without worrying about accurately recording their actions. However, in 1972, Weed said, "most doctors can remember three problems of a patient; the very good doctors retain five; but the average patient has eleven" [20]. This lack of completeness leads to several problems. Carsley et al. found that drug allergies are not recorded for a large proportion of patients [15]. If there is no information in the EHR, it is difficult to know if the patient does not have allergies, if the practitioner did not look for them or if forgot to record them. This situation raises safety issues. Continuity of care can also be affected. Indeed, Haggerty et al. argue that informational continuity of care represents one of three dimensions of care continuity and is defined as the use of information on past events and personal circumstances to make current care appropriate for each individual [21]. Furthermore, continuity of care has a positive impact on the care of chronically ill patients [22].

The prevalence of chronic diseases continues to grow, and GPs have to face a real "epidemiological transition" [23]. This increase of chronic diseases is associated with an increase in polypathology. A health survey conducted in France between 2002 and 2003 found that the number of reported diseases increased with age: four for 40-64 years old, five for 65-79 years old and six for those 80 years and older [24]. As a result of population ageing, GPs consultations become more intense and more complex. Given the consultation complexity, it seems unrealistic to expect GPs to record all the elements of the consultation. It will be challenging to find the right balance between a certain level of quality and EHR completeness to ensure safety and continuity of care without prolonged consultations.

However, the use of EHRs for evaluation and research will require a higher level of quality. According to Goldberg [25], limiting the risk of error and bias would be possible only under several conditions:

- Systematically record a minimum of information for each patient;
- Define a core of data to record;
- Record information using a recognized classification;
- Control real-time input and verify data (missing data, outliers);
- Check intra-observer and inter-observer variability.

Perspectives

Improving data quality in EHRs could serve two purposes:

- Obtain a minimum data quality to ensure safety and continuity of care;
- Collect data from general practitioners wishing to support research in primary care, and agree to follow a quality chart when recording data in their medical records.

To improve data quality, several options can be considered:

- Train GPs on ICPC-2 to encourage them to code their data and on the proper use of medical software;
- Involve patients so that they can complete their data [26];
- Develop algorithms to assign ICPC-2 codes to free text;
- Develop algorithms to restore some missing data (e.g., a diabetes diagnosis for patients receiving oral antidiabetic drugs).

Qualitative studies could be conducted to identify barriers and facilitators for recording consultation elements in the EHR. Individual feedback has already been identified as a low-cost tool to improve data quality [27,28]. Qualitative studies could also be used to define a quality chart in collaboration with GPs and to validate acceptable and achievable criteria.

Conclusions

There is a loss of information between the dialog during a consultation and what is reported in the EHR. Reasons and diagnoses were recorded in the EHR in less than half of the cases. This lack of completeness can be expected to affect safety and continuity of care.

Reachable and acceptable quality criteria must be defined with French GPs to improve the quality of their EHRs.

Abstract

Sepsis remains a significant global health problem. It is a life-threatening, but poorly defined and recognized condition. Early recognition and intervention are essential to optimize patient outcomes. Automated clinical decision support systems (CDS) may be particularly beneficial for early detection of sepsis. The aim of this study was to use retrospective data to develop and evaluate seven revised versions of an electronic sepsis alert rule to assess their performance in detecting sepsis cases and patient deterioration (in-hospital mortality or ICU admission). Four revised options had higher sensitivity but lower specificity than the original rule. After discussion with clinical experts, two revised options with the highest sensitivity were selected. Further analysis on the number of alerts and time intervals between alerts and patient outcomes was conducted to decide the option to be implemented. This study has provided a data-driven approach to improve the CDS on early detection of sepsis.

Keywords:

Sepsis, Clinical Decision Support Systems, Early Diagnosis

Introduction

Sepsis is a life-threatening condition that arises when the body's response to an infection injures its own tissues and organs [1; 2]. Despite advances in care, existing epidemiological studies suggest that sepsis remains a huge burden. A recent systematic review extrapolated data from high-income countries to suggest global estimates of 31.5 million sepsis and 19.4 million severe sepsis cases, with potentially 5.3 million deaths annually [3].

Sepsis is one of the most pervasive, but poorly defined and recognized conditions. It has been called "one of the oldest and most elusive syndromes in medicine" [4]. Early recognition and intervention are essential to optimize patient outcomes. To improve early sepsis detection, several automated sepsis alert systems using electronic medical record (eMR) data have been developed for use in hospital intensive care units (ICU) and in non-critical care settings [5]. The St. John Sepsis Surveillance Agent is one such system. It was developed by Cerner Corporation, an American supplier of health information technology solutions, services, devices and hardware. The St. John Sepsis Surveillance Agent has been implemented in more than 550 hospitals in the United States [6; 7].

An updated version, the Modified St. John Rule, was developed by the Clinical Excellence Commission (CEC) in New South Wales (NSW), Australia. It includes additional clinical criteria for activating sepsis alerts in addition to SIRS (systemic inflammatory response syndrome) alerts. There are three panels in the Modified St. John Rule as shown in Figure 1: i) CEC – a sepsis alert if any of two clinical criteria are satisfied; ii) SIRS – a SIRS alert if three or more modified SIRS criteria are met; iii) Organ dysfunction – a sepsis alert if two or more SIRS criteria and at least one organ dysfunction criteria are satisfied. An alert would be triggered if any clinical criterion is satisfied when all relevant measurement(s) within the specified lookback time period (Figure 1) is(are) available.

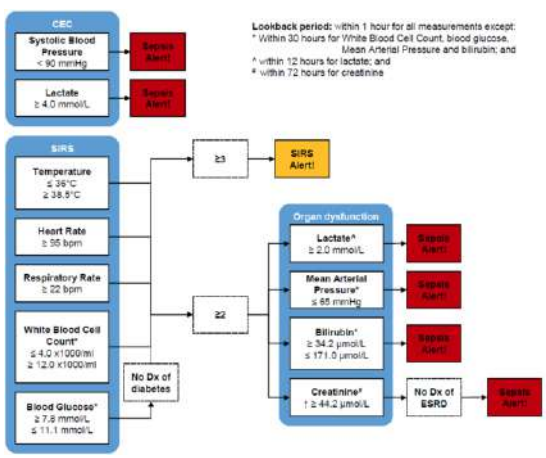

Figure 1 – Simplified Flow Diagram for the Modified St. John Rule. Note: ESRD=End-stage Renal Disease and Dx=Diagnoses.

The modified SIRS criteria used in the Modified St. John Rule were adapted from the original SIRS definition, which was introduced in the first two consensus sepsis definitions [8; 9]. The original SIRS criteria have been criticized for their poor specificity, with 90% of ICU patients and 50% of general ward patients meeting the criteria at some point during their hospitalization [2; 10]. These criticisms are consistent with our findings based on the evaluation of the Modified St John Rule [11], where more than half of the alerts were SIRS alerts. Of patients who experienced a SIRS alert, nearly half of them had two or more SIRS alerts during their hospital stay. The most recent sepsis definition (Sepsis-3) was developed in 2016 and has abandoned SIRS entirely. Sepsis-3 defines organ dysfunction as

an increase in total quick Sequential Organ Function Assessment (qSOFA) score of ≥ 2 [12; 13].

The Adult Sepsis Pathway is a paper-based tool developed for early detection of sepsis in adult patients and currently in practice in hospitals throughout NSW, the most populous state in Australia. The Adult Sepsis Pathway is part of the SEPSIS KILLS program [14; 15], aiming to reduce preventable harm to patients through improved recognition and management of severe infection and sepsis in NSW hospitals. This program has been associated with improved patient outcomes [16]. In this study, we proposed seven revised options of the Modified St John Rule by: i) removing the SIRS alerts and ii) incorporating clinical criteria and threshold values from the qSOFA criteria and the Adult Sepsis Pathway (details in the Methods section). For example, the clinical threshold for heart rate was "≥95 beats/minute" as per the Modified St. John Rule. In the revised options, we included the heart rate clinical thresholds as "≥ 95 beats/minute or ≤50 beats/minute", which was used in the Adult Sepsis Pathway. The aim of this study was to develop and evaluate a set of revised versions of the Modified St. John Rule in order to improve the early identification of patients with sepsis.

Methods

Study Design, Setting and Population

This retrospective observational cohort study included all adult patients (aged 18 years and over) admitted to an acute care teaching hospital in Sydney between December 2014 and June 2016. The hospital is a 570-bed tertiary urban hospital with 24,500 inpatient admissions annually. Sepsis cases were identified based on sepsis-related diagnosis codes based on the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, Australian Modification (ICD-10-AM) and assigned after discharge. The Classification of Hospital Acquired Diagnoses (CHADx) [17] was applied to patients' diagnoses to identify sepsis cases. Ethics approval was obtained from the Macquarie University Human Research Ethics Committee.

Revised Modified St. John Rules

Seven revised options were proposed to improve the performance of the Modified St. John Rule (Figure 2). The changes in these options were:

- Removing the SIRS alert (all seven options)
- Including at least one of five modified SIRS criteria satisfied plus at least one organ dysfunction as a trigger for a sepsis alert (options 2, 4, 5, and 7)
- Including base excess <-5.0 mEq/L as an immediate trigger for a sepsis alert (options 3, 4, 6 and 7)
- Including lactate ≥2 mmol/L as an immediate trigger for a sepsis alert (options 1, 5, 6 and 7)
- Adopting different clinical threshold values:
  - systolic blood pressure ≤100 mmHg (options 1, 5, 6, and 7)
  - heart rate≥ 95 beats/minute or ≤50 beats/minute (options 1, 5, 6 and 7)

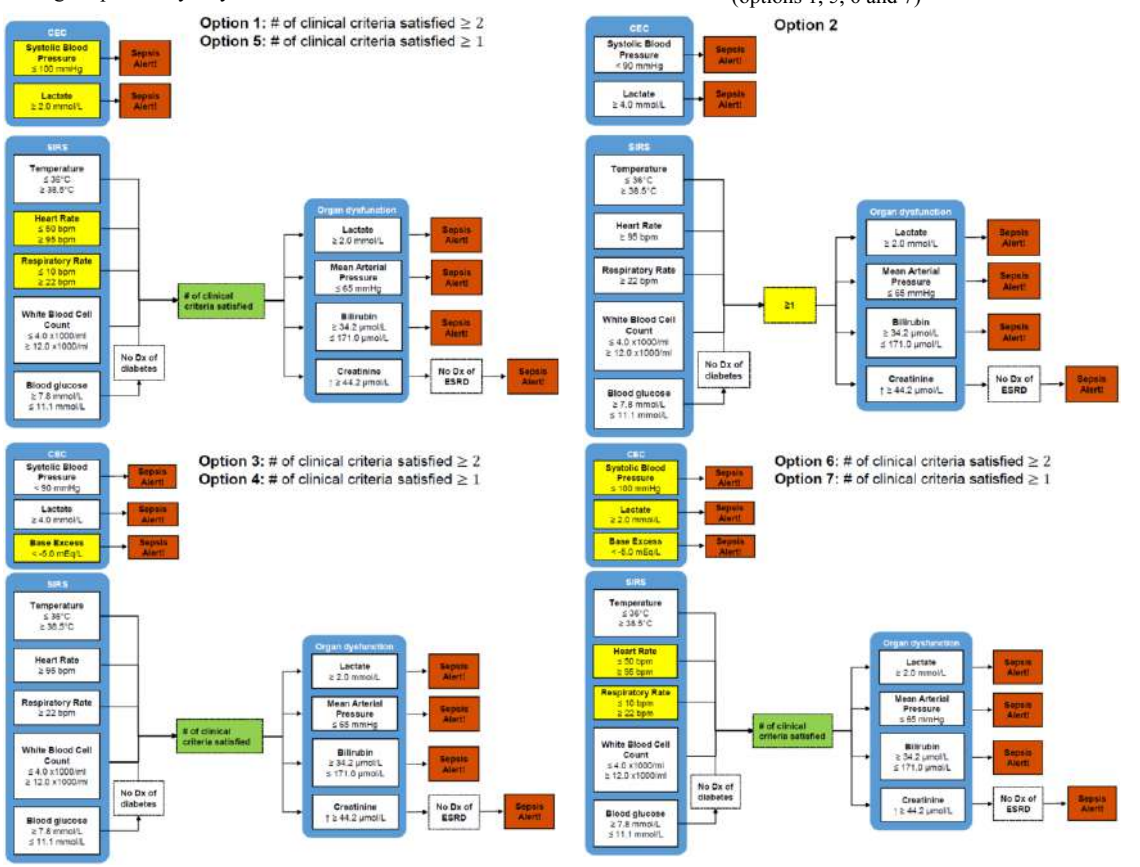

Figure 2 – Simplified Flow Diagrams of Seven Revised Versions of the Modified St. John Rule. Yellow and Green Highlights Indicate the Changes in Each Option. Note:#=Number, ESRD=End-stage Renal Disease and Dx=Diagnoses. See Figure 1 for the Lookback Periods.

- respiratory rate ≥ 22 breaths/minute or ≤10 breaths /minute (options 1, 5, 6 and 7)

Data Sources, Linkage and Management

Patient demographic data and admission related data, including vital signs, laboratory results and ICU admissions were extracted from different clinical information systems. Vital signs and laboratory tests were time-stamped. Data sets from different sources were linked using de-identified medical record numbers and related time stamps. ICD-10-AM diagnosis codes were used to identify patients with diabetes (E10 to E14) and end-stage renal disease (ESRD; N18.5).

Data Analysis

Two patient outcomes were used for assessing the performance of each revised option: i) ICD-10-AM coded sepsis and ii) In-hospital mortality or ICU admission. Performance metrics of seven options and the original Modified St John Rule were calculated, including sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and the area under the receiver-operating characteristic curve (AUROC). After discussion with clinical experts, two options with the highest sensitivity were chosen as best options for screening. Further analysis was conducted based on these two options to compare three different time intervals: i) time from admission to the first sepsis alert, ii) time from the first sepsis alert to the ICU admission, and iii) time from the first sepsis alert to death in hospital. Analyses were performed using R (version 3.5.0) and SAS (version 9.4).

Results

A total of 36,065 patient admissions for 28,957 unique patients were included in the study. Patients' median age was 55 years (inter-quartile range [IQR]: 38-71) and 41.3% (N=11,946) of these patients were male. Among these patient admissions, 3.9% (n=1,402) involved admissions to ICUs during their hospital stays and a total of 483 patients died in hospital during the study period. The median length of stay (LOS) was 1.9 days (IQR: 0.3-4.9). A total of 3.5% of admissions (N=1,279) involved an ICD-10-AM coded case of sepsis during their hospital stay.

Detection of ICD-10-AM Coded Sepsis Cases

ICD-10-AM coded sepsis cases were used to assess the performance of these revised options for detecting sepsis (Table 1). Options 2, 3 and 4 had an increased specificity and PPV compared to the original Modified St John Rule. Option 2 had the highest specificity (96.26%) among all options. Option 3 flagged 30 false positives (FP) for every ten true positives (TP, i.e., FP/TP=1,529/502), compared to 40 for the original rule (i.e., FP/TP=2,492/611).

Options 1, 5, 6 and 7 identified more sepsis cases, i.e., true positives than the original Modified St. John Rule. Option 7 had the highest sensitivity (64.97%) among all options, closely followed by Option 6 (64.43%). Options 6 and 7 would correctly identify at least six sepsis cases for every ten admissions with a sepsis alert, compared to less than five out of ten for the original rule (sensitivity 47.77%). Both options 6 and 7 had the highest NPVs (98.39% and 98.40%).

Although these options generated more false positives resulting in lower specificity (Option 6: 79.76% and Option 7: 79.31%) than the original rule (92.84%), fewer false negatives (FN) meant fewer sepsis cases would have been missed than the other options and the original rule. For every ten correctly identified sepsis cases, five cases might be missed (i.e., FN/TP=448/831) for Option 7. In contrast, Option 2 would miss 20 false negatives, i.e., sepsis cases, for every ten correctly identified sepsis case (i.e., FN/TP=865/414); the original rule would miss 10 sepsis cases (i.e., FN/TP=668/611).

Detection of Deteriorating Patients

Death in hospital or ICU admission was used to assess the performance of these seven revised options for detecting patients' deterioration (Table 1). Similar to results for detecting sepsis cases, Option 2 had the highest specificity (97.01%) and Option 3 had the highest PPV (43.57%). Options 1, 5, 6 and 7 had higher sensitivity and AUROC than the original Modified St. John Rule. Options 6 and 7 had much higher sensitivity (71.74% and 72.56%) than the original Modified St John Rule (50.99%). For patients who experienced a sepsis alert based on options 6 or 7 during their hospital stays, at least seven out of ten patients would have died or been admitted to an ICU compared to five out of ten patients if based on the original rule.

Table 1–Revised Modified St. John Rule Options for Detecting i) ICD-10-AM Coded Sepsis and ii) In-hospital Mortality or ICU Admission (N=36,065). Note: PPV=Positive Predictive Value; NPV=Negative Predictive Value; AUROC= Area Under the Receiver-Operating Characteristic Curve; CI=Confidence Interval; Original: the Assessment Based on the Modified St. John Rule (Figure 1)

Options	Sensitivity (%, 95% CI)	Specificity (%, 95% CI)	PPV (%, 95% CI)	NPV (%, 95% CI)	AUROC (%, 95% CI)
	i) ICD-10-AM coded sepsis				
Option 1	62.16 (59.44-64.82)	80.07 (79.65-80.49)	10.29 (9.86-10.74)	98.29 (98.17-98.41)	71.12 (70.74-71.49)
Option 2	32.37 (29.81-35.01)	96.26 (96.05-96.45)	24.13 (22.42-25.92)	97.48 (97.39-97.57)	64.32 (63.92-64.71)
Option 3	39.25 (36.56-41.99)	95.60 (95.38-95.82)	24.72 (23.19-26.31)	97.72 (97.62-97.81)	67.43 (67.04-67.81)
Option 4	42.92 (40.19-45.69)	94.18 (93.92-94.42)	21.32 (20.07-22.62)	97.82 (97.72-97.92)	68.55 (68.16-68.94)
Option 5	62.86 (60.15-65.52)	79.59 (79.16-80.01)	10.17 (9.75-10.61)	98.31 (98.19-98.43)	71.23 (70.85-71.60)
Option 6	64.43 (61.73-67.05)	79.76 (79.34-80.19)	10.48 (10.06-10.92)	98.39 (98.26-98.50)	72.10 (71.73-72.46)
Option 7	64.97 (62.29-67.59)	79.31 (78.88-79.73)	10.35 (9.94-10.78)	98.40 (98.28-98.52)	72.14 (71.77-72.51)
Original	47.77 (45.00-50.55)	92.84 (92.56-93.11)	19.69 (18.63-20.80)	97.97 (97.87-98.08)	70.31 (69.93-70.68)
	ii)In-hospital mortality or ICU admission				
Option 1	67.38 (65.11-69.60)	80.87 (80.45-81.29)	15.00 (14.50-15.51)	98.02 (97.88-98.15)	74.13 (73.77-74.48)
Option 2	40.06 (37.73-42.42)	97.01 (96.82-97.19)	40.15 (38.16-42.17)	97.00 (96.88-97.11)	68.54 (68.15-68.92)
Option 3	51.45 (49.06-53.84)	96.66 (96.47-96.85)	43.57 (41.79-45.38)	97.55 (97.43-97.66)	74.06 (73.70-74.41)
Option 4	59.30 (56.94-61.64)	95.47 (95.25-95.69)	39.61 (38.13-41.11)	97.91 (97.79-98.02)	77.39 (77.04-77.73)
Option 5	68.60 (66.35-70.79)	80.42 (80.00-80.84)	14.93 (14.45-15.42)	98.08 (97.95-98.21)	74.51 (74.15-74.87)
Option 6	71.74 (69.55-73.86)	80.70 (80.28-81.12)	15.69 (15.21-16.19)	98.28 (98.14-98.40)	76.22 (75.87-76.57)
Option 7	72.56 (70.38-74.66)	80.26 (79.83-80.68)	15.54 (15.08-16.02)	98.32 (98.18-98.44)	76.41 (76.06-76.76)
Original	50.99 (48.60-53.38)	93.52 (93.25-93.78)	28.26 (27.04-29.52)	97.44 (97.32-97.56)	72.26 (71.89-72.62)

Table 2–Comparison between Options 6 and 7 on the Number of Sepsis Alerts and the Timing of the First Sepsis Alert during the Admission. Note: IQR=Inter-quartile Range and CI= Confidence Interval

Characteristics	Option 6	Option 7
Total number of alerts	37,170	43,616
Total number of admissions with at least one alert	7,863	8,029
Number of alerts per 100 admissions, mean (95% CI)	103 (98-108)	121 (115-127)
Admission to the first alert (hours), Median (IQR)	23.9 (10.1-60.3)	24.1(10.2-60.3)
Time from the first alert to death (hours), Median (IQR)	149.4 (41.4-315.3)	149.2 (46.5-314.3)
Time from the first alert to the first ICU admission (hours), Median (IQR)	233.3 (111.0-428.6)	235.7 (113.6-425.8)
Time from the first alert to death or ICU admission (hours), Median (IQR)	221.8 (98.1-391.1)	223.0 (101.8-390.5)

Further Comparison of Two Options with the Highest Sensitivity

Across the two study outcomes, options 6 and 7 had the highest sensitivity and AUROC. The only difference between two options was the number of SIRS criteria required to trigger a sepsis alert: at least two for Options 6 and at least one for Option 7 (Figure 2). As a result, more alerts would be triggered for more patients using Option 7 than that for Option 6 (Table 2). Option 7 had 121 sepsis alerts per 100 admissions (95% CI: 115-127) compared to many fewer alerts from Option 6 (103 alerts/100 admission, 95% CI: 98-108). In addition, 8,029 admissions would have experienced a sepsis alert if Option 7 was implemented compared to 7,863 admissions if Option 6 was in place.

Both options had very similar alert timing patterns. The median hours from admission to the first alert was around 24 hours and the median hours from the first alert to death in hospital or an ICU admission was around 220 hours (~9.2 days).

Discussion

Automatic clinical decision support systems (CDS) have the potential to provide notifications to clinicians to facilitate real-time early detection of sepsis cases. Following our previous evaluation of one such system [11], i.e. the Modified St John Rule, we proposed seven revised options to improve early identification of patients with sepsis. Using retrospective data, two of the revised options were found to have much higher sensitivities and AUROC in identifying both sepsis cases and deteriorating patients than the original Modified St John Rule. These two options would correctly identify at least six sepsis cases for every ten admissions with a sepsis alert compared to less than five out of ten for the original rule. Similarly, for every ten admissions with a sepsis alert, at least seven patients would be correctly identified as either dying or having an ICU admission compared to five out of ten for the original rule.

The study results were presented to a panel of clinical experts to decide which options should be selected for further implementation in the clinical information system. Given there is a tradeoff between sensitivity and specificity, the high sensitivity options had relatively low specificity. However, a highly sensitive test also means that there are few false negative results, and thus fewer sepsis cases would be missed. Sepsis is a life-threatening complication and any delay in treatment with effective antibiotics increases the risk of organ failure and death. Choosing the options with high sensitivity would save lives. The recommended option, i.e. Option 6, has been adopted by the Clinical Excellence Commission in New South Wales for further implementation and evaluation.

One strength of this study is that we used the composite outcome of in-hospital mortality or ICU admission in addition to ICD coded sepsis cases given the known limitation of ICD coding [18]. A major United States study recently published in the Journal of the American Medical Association found that estimates of the sepsis incidence based on ICD coding ranged between half and twice the actual clinical rate [18].

In medical informatics, large data have been collected for different purposes, including clinical care, administration, and research. We developed algorithms to retrospectively evaluate the performance of seven revised options using data collected routinely from different clinical information systems. This data driven approach allowed us to test different scenarios without utilizing resources and time to develop and implement the CDS.

Previous studies have demonstrated that Big Data techniques, such as machine learning, can be incorporated into electronic health records to predict clinically relevant outcomes in patients with sepsis [19]. Although early identification of sepsis is still challenging, Big Data techniques make it possible to utilize these large volumes of heterogeneous data to provide deeper insights and better understanding of poorly defined and recognized conditions, such as sepsis.

Conclusions

Sepsis remains a significant global health problem. This study has provided a data-driven approach to improve the CDS for early detection of sepsis patients. CDS for early detection of sepsis can be improved and assessed using routinely collected data from different clinical information systems. This data-driven approach would save valuable resources in the health care system and potentially save lives.

It is essential to combine early recognition of sepsis patients with early intervention in order to optimize patient outcomes. The CDS may integrate the early warning systems with the availability of rapid response teams designed to achieve earlier intervention [20]. However, it is important to note that rigorous studies are lacking to evaluate the benefits of these CDS systems [21].

Acknowledgements

This study was commissioned by the Clinical Excellence Commission in NSW, Australia and was conducted as part of project to evaluate the risk identification tools for the early detection of sepsis. MG, MF and HL are employed at the Clinical Excellence Commission. They contributed to the study design and revisions of the manuscript but were not involved in the data assessment and interpretation. We acknowledge the contribution of eHealth NSW to this project.

Abstract

Falls are the leading cause of injuries among older adults, particularly in the more vulnerable home health care (HHC) population. Existing standardized fall risk assessments often require supplemental data collection and tend to have low specificity. We applied a random forest algorithm on readily available HHC data from the mandated Outcomes and Assessment Information Set (OASIS) with over 100 items from 59,006 HHC patients to identify factors that predict and quantify fall risks. Our ultimate goal is to build clinical decision support for fall prevention. Our model achieves higher precision and balanced accuracy than the commonly used multifactorial Missouri Alliance for Home Care fall risk assessment. This is the first known attempt to determine fall risk factors from the extensive OASIS data from a large sample. Our quantitative prediction of fall risks can aid clinical discussions of risk factors and prevention strategies for lowering fall incidence.

Keywords:

Falls, Health Risk Assessment, Machine Learning

Introduction

Falls are the leading cause of death due to injury in the home, especially for the elderly [1–3]. Falls are typically recurrent; those who fall once are two to three times more likely to fall again [4,5]. In 2015, direct costs related to fatal and non-fatal falls were $637.5 million and $31.3 billion respectively, making it one of the most costly patient safety problems among people aged 65 and older [6,7]. Identifying risk factors for falls is critical to the design of prevention protocols. Many research studies analyzed falls among hospitalized, long-term care, and community-dwelling older adults, yet few studies focus specifically on the frail, homebound population of older adults receiving home health care (HHC) services [8–10].

Medicare and agency policies direct clinicians to screen every HHC patient for fall risk, but only one HHC validated tool exists. The Missouri Alliance for Home Care assessment (MAHC-10) is a 10-item fall risk screening tool [11] with excellent sensitivity (97%), but with poor specificity (13%). In our study cohort, MAHC-10 identified over 93% of the cohort as having high fall risk, but only 5.14% actually had a fall (Figure 1). Therefore, using MAHC-10 as the default fall risk screening tool may increase the cost and burden of healthcare providers by triggering unnecessary provision of fall prevention strategies to almost every HHC patient. Moreover, MAHC-10 provides the clinician a score out of 10 instead of an actionable profile or fall risk as a probability per individual patient, making the design and implementation of personalized fall prevention difficult.

In this study, we devised a machine learning pipeline to explore the utility of existing HHC data containing rich patient information to predict fall risk. This is the first study to analyze large and comprehensive HHC datasets representing the characteristics of vulnerable older adults and the care they received in their homes to create models of effective fall risk prediction. With this larger dataset and additional input features from the electronic health record (EHR), we evaluated whether our models could achieve higher precision and accuracy than the existing risk scoring system.

Methods

Data Description

We leveraged patient information from the Centers for Medicare and Medicaid (CMS)-mandated Outcome and Assessment Information Set (OASIS) [12] data on an ethnically diverse population of nearly 60,000 patients from one large HHC agency in New York City. The OASIS is a mandatory detailed assessment with over 100 items evaluating a patient's clinical, behavioral, cognitive, and environmental conditions. The newer version (OASIS-C) was utilized for the patient population included in this study.

The HHC cohort was also assessed for fall risk using the 10-point Missouri Alliance for Home Care fall risk assessment (MAHC-10) [11]. A score greater than or equal to 4 is clinically regarded as at risk for falls. We took the intersection of patients who had both OASIS-C and MAHC-10 data and were over 65 years old, resulting in a final cohort of 59,028 unique patients. We supplemented the feature set with additional demographic information from the EHR, including language group and borough of residence (New York City).

Data Cleaning

We defined the binary outcome of fall incidence per patient from three sources: two OASIS-C items indicating whether the patient received emergent care or hospitalization due to falling (items M2310 and M2410), and whether a date of last fall was recorded in the EHR. Therefore, the outcome is True (presence of a fall) for a patient if the date of last fall is between the start and end of the HHC episode, or the answer is Yes for either M2310 or M2410. Using this definition, the fall incidence rate in our cohort is 5.14%. An episode of home care can be up to 60 days.

The OASIS-C start of care assessment contains 114 items, the majority being multiple-choice questions. Upon review from

clinical experts, we considered 46 items that are relevant to fall risk prediction. For the multiple-choice OASIS-C items, we categorized the items based on the type of answer choices and applied the data cleaning strategy per category as follows.

For OASIS-C items with ordinal answer choices (for example, a 0-5 scale where 0 denotes never and 5 denotes all the time), we represented these items as continuous features. For OASIS-C items and EHR items with nominal answer choices (for example, gender, language group, type of assistance), we used one-hot encoding to create a binary feature per answer choice. The same encoding scheme applied for OASIS-C items that allowed multiple answers ("select all that applies"). We discarded patients under 65 years old to focus on the older adult population receiving HHC and used age as a continuous feature. Since OASIS-C is a mandatory assessment at the start of HHC, missing data is minimal (< 0.005%). We considered the rare missing entries as a separate answer choice for the corresponding questions.

Two OASIS-C items require listing diagnosis codes and severity of each diagnosis on a 4-point scale. These items were combined to reflect the overall physical well-being of a patient. To incorporate these items meaningfully into our feature set, we constructed summary features of diagnoses including: total number, total severity, and average severity. After data cleaning and feature engineering, our feature space contained 169 features from the OASIS-C and EHR that described the demographics, clinical, behavioral, and environmental characteristics of each HHC patient.

Machine Learning Pipeline

We devised a two-step machine learning pipeline with a feature selection step followed by a falls classification step. We randomly split the data into training (50%) and testing (50%) sets. Given the high-dimensionality and potential multi-collinearity of our feature set, we employed the ReliefF feature selection algorithm [13,14] to rank the features by the ReliefF score, computed based on the discriminative ability of each on the outcome, conditional on its neighboring features in the feature space.

We trained and compared random forest classifiers using three feature sets. First, we considered the OASIS-C features with positive ReliefF scores. We trained a random forest model with 5-fold cross-validation, using 300 estimators and default parameters as specified in the python scikit-learn [15] module *(OASIS model)*. Second, we took the ten items from MAHC-10 scoring as binary features and trained a random forest model using the same parameters as the OASIS model *(MAHC model)*. Finally, we explored if the features from OASIS-C and MAHC-10 together would augment the prediction accuracy of the random forest model. We combined the OASIS-C feature set with the 10 features from MAHC-10 to train a random forest classifier with the same parameter settings and 5-fold cross-validation *(Combined model)*.

Model Assessment

We evaluated the accuracy and precision of predictions from the OASIS model, the MAHC model, and the Combined model against the baseline MAHC-10 total score (hereafter called baseline), where a score greater than or equal to 4 is clinically considered at risk of falls. Since our outcomes are heavily skewed with only about 5% experiencing a fall, we used balanced accuracy as the metric to assess model accuracy. Balanced accuracy is defined as the average accuracy calculated from the two outcome classes. To highlight the performance of each model in correctly predicting the positive outcome, we contrasted the precision-recall curves of our models to that of the baseline. To summarize the precision-recall curves, we computed the average precision (AP), defined as the arithmetic mean of precisions at different recall thresholds.

Furthermore, we computed the area under ROC curves (AUC) for the test data corresponding to each feature set and contrasted them to the AUC of the baseline. To assess for significant differences between ROC curves across models, we performed bootstrapping on the test data to generate a confidence interval for each ROC curve. For each test set, we resampled with replacement for 1,000 times the outcome states and predicted probabilities, then calculated the AUC for each bootstrapped ROC curve. The 95% confidence interval of a ROC curve is given by all curves with AUC between the 2.5 and 97.5 percentile of all bootstrapped AUC values.

To evaluate the clinical significance of the OASIS model, we ranked the input features by their importance scores generated from the random forest classifier. To quantify the contribution of each feature to the accuracy of the model, we computed the gain in balance accuracy per added feature by refitting a random forest classifier iteratively, adding one feature at a time from the ranked feature list. Finally, by performing a hierarchical clustering of pairwise correlations between top-ranked OASIS-C features and the MAHC-10 items, we revealed fall risk factors identified by the OASIS model that were not captured in the baseline MAHC-10 assessment.

Results

We compared the random forest classifiers for three feature sets: 137 out of 169 OASIS- and EHR-derived features with positive ReliefF scores (OASIS model), MAHC-10 items (MAHC model), and OASIS-C plus MAHC-10 items (Combined model), in contrast to the MAHC-10 scoring (baseline). Overall, the MAHC model had comparable performance as the baseline, while the OASIS model and the Combined model had almost identical metrics that outperform the MAHC model and the baseline.

Although the baseline and the MAHC model both had an AUC of 0.6, the balanced accuracy of the MAHC model at 0.58 was slightly higher than that of baseline scoring measured at only 0.51. The OASIS model and Combined model both attained a balanced accuracy of 0.62 and an AUC of 0.67. The 95% bootstrap confidence interval of the OASIS model ROC was (0.66, 0.68), which was completely above the MAHC model ROC 95% confidence interval at (0.59, 0.62).

The precision of all models and the baseline was low, due to the low proportion of cases in our dataset. The average precision (AP) of the baseline was 0.07, and the AP of the MAHC model was 0.08. The OASIS and Combined models had an improved precision at AP=0.10. Consistent with the AP trend, the precision-recall curve of the OASIS model (and that of the Combined model) was above the curve of the MAHC model at all sensible recall thresholds (Figure 2).

Given the above metrics and the rule of parsimony, the OASIS model was the best out of the three models and the baseline. To investigate clinical relevance of the OASIS model, we ranked the input of 137 OASIS-C features by feature importance scores estimated by the classifier. The most important feature was age, with an importance score of 0.05, followed by the average and total severity of home care diagnoses. Frequencies of therapy visit and pain also had high feature importance scores. Balanced accuracy of the random forest classifier increased as features were added to the model in the order of importance; the balanced accuracy converged at around 0.62 after the top 45 features were added. The remaining 92 features had small

contributions to the balanced accuracy of the random forest classifier.

To further evaluate the potential gain of using OASIS-C over MAHC-10 for fall risk prediction, we computed the pairwise correlation between each top-ranked OASIS-C feature among the MAHC-10 items, and performed a hierarchical clustering on the correlations. Four OASIS-C features had an analogous MAHC-10 item, including history of falls, visual impairment, cognitive impairment, and pain (Figure 3), as reflected by the strong positive correlations that were statistically significant (p-value $< 10^{-5}$). However, each of the four MAHC-10 items was also significantly correlated with a broad range of other OASIS-C items, indicating the heterogeneity among patients who scored the same on the MAHC-10 scale. In addition, some OASIS-C items were correlated in opposite directions to different MAHC-10 items, meaning that the effect of these features might be masked in the total MAHC-10 score. In particular, four top-ranked OASIS-C features were weakly correlated in opposite directions to MAHC-10 items but were not correlated to the total MAHC-10 score: frequency of ADL/IADL (activities of daily living/ instrumental activities of daily living) assistance, number of inpatient diagnoses, patient living alone, and patient living with others. These features provide new information on the patient's fall risk that was not available from the baseline scoring system.

Discussion

In patients receiving HHC services, falls rank as the top avoidable event that leads to disability, hospital admission and emergency department care [16,17]. Motivated by the low specificity of the existing fall risk assessment for HHC patients, we investigated the benefit of predicting fall risk using the Centers for Medicare and Medicaid Services (CMS) mandatory OASIS assessment for HHC coupled with supplemental EHR data. OASIS evaluates in detail the clinical, behavioral, cognitive, and environmental properties of a patient upon the start of a HHC episode. To analyze a large sample size of almost 60,000 and a high-dimensional input set comprising over 130 features with positive ReliefF score, we trained a random forest classifier on 50% of the sample and tested the accuracy and precision of the classifier on the remaining 50% of the data. Predictions leveraging this big data show improved accuracy and precision over a simplistic 10-point scoring system. We investigated if the ten items in the MAHC-10 would be more informative when used as features in a random forest model. We found a negligible change in precision and a slight improvement in balance accuracy in the MAHC model.

Furthermore, since all MAHC items are correlated to one or more OASIS items, complementing the OASIS features with the ten MAHC items did not result in detectable improvement over the OASIS-only model. This signals a potential to implement the OASIS model for clinical use, such that clinicians can obtain the per-patient fall risk from the model, once the mandatory OASIS assessment is completed. Clinicians burdened by required assessments and documentation may appreciate the efficiency gained.

Using our random forest classifiers, each patient in the test set gets an estimate of fall risk as a probability. This probability and the ranked list of important features are clinically relevant and potentially of great value when health care providers discuss fall risk with patients, allowing providers to customize and prioritize prevention strategies corresponding to actionable risk factors for each patient. Clinical decision support provided at the point of care may help clinicians target the most effective interventions and help patients recognize their risk and the impact of embracing preventive strategies to decrease their risk.

Limitations

This study used data from one large home care agency in New York City. The precision of the OASIS model is still lower than ideal for clinical use because the two outcome classes in our dataset are heavily imbalanced. Almost 95% of the patients in our cohort were not reported to have a fall. The low fall incidence from our structured data is consistent with the presumption that falls are often underreported. Recent reports in a national sample of older adults revealed 72% failed to report a fall when asked [18]. We hypothesize that a significant proportion of fall cases are recorded in the EHR narrative data instead of the structured data. Therefore, an immediate extension of our work is to use natural language processing techniques to identify additional fall instances from EHR narratives [19]. We also hope to extend the measurement period of falls beyond the home care episode. By having a more accurate estimate of fall incidence, we can fine-tune our classifiers and achieve higher precision.

Conclusions

This is the first known large-scale study to predict fall risk and characterize risk factors in the HHC community using the readily available OASIS assessment. By using machine learning models to analyze the rich feature set in a large cohort, we see promising improvement in the precision and accuracy of fall risk prediction over the MAHC-10 scoring system. Our results suggest that fall risk is a complex trait affected by a large number of risk factors of small effects. The machine learning approach also allows us to predict fall risk as a probability for each patient, and rank the importance of each risk factor. Our model confirms that a broad range of factors including age, clinical diagnoses, daily habits, living environment and hygiene, all contribute to a patient's fall risk. Further study incorporating an expanded feature set from the EHR will improve the estimate of fall incidence and fall risk prediction.

Figures and Graphs

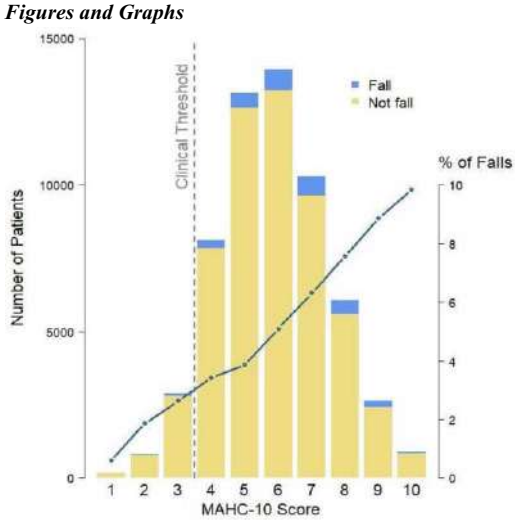

Figure 1. Number of patients per MAHC-10 score. Each bar shows the observed fall cases in blue and the non-cases in yellow. The black line shows the percentage of fall case per score. The clinical threshold of high fall risk is MAHC >=4 (Dashed vertical line).

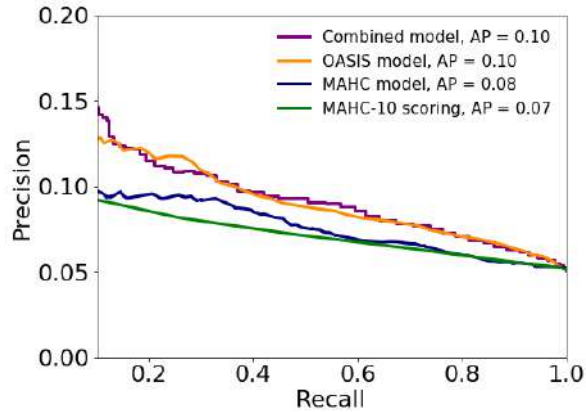

Figure 2. Precision-recall curves of the baseline scoring, MAHC model, OASIS model, and Combined model. For clarity, the panel only shows recall > 0.1 and precision < 0.2.

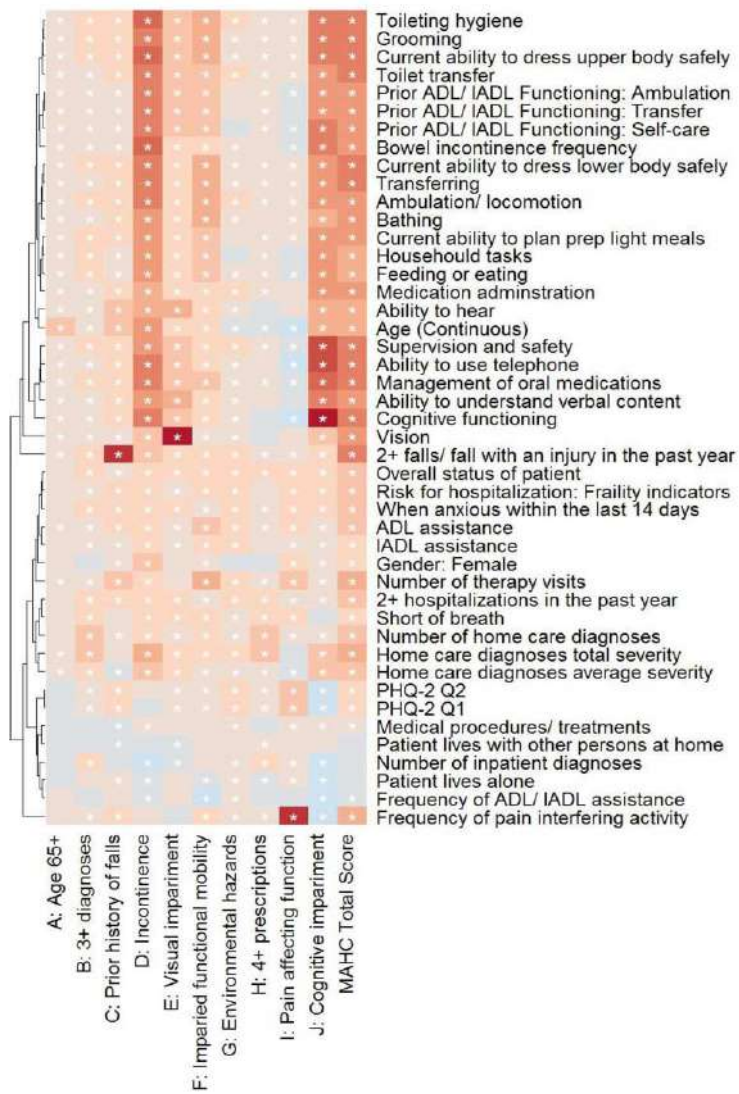

Figure 3. Hierarchical clustering of pairwise correlation (ρ) between top OASIS features (rows) and MAHC-10 items (columns). Blue represents negative correlation (-1 < ρ < 0) and red represents positive correlation (0 < ρ < 1). The asterisk (*) in a cell represents significant correlation after Bonferroni correction for multiple testing ($p < 10^{-5}$).

Abstract

Due to various etiologies and pathogenesis of kidney diseases, an invasive procedure called renal biopsy may be needed to determine the specific type of kidney disease, its severity, and the best treatment for it. This study aims to detmine if a text understanding technology based on admission records can recommend such an invasive procedure objectively. To understand clinical documents from nephrology, a semi-automatic learning-based lexicon construction method based on CRF and Word2vec was used. We constructed a dictionary of symptom terms for the nephrology department from clinical document, and then extracted patients' symptoms and detected their negation from admission notes. Combined with the preliminary diagnosis given by the doctor, an eigenvector was produced and fed to a machine learning classifier. When compared to the gold standard marked by physicians, the final recommendation achieved 83.5% accuracy, 80.6% precision, 76.6% recall, and 78.6% f1-measure respectively.

Natural Language Processing; Kidney Diseases; Decision Support Systems, Clinical

Introduction

Renal biopsy, also known as kidney biopsy, is a clinical procedure to diagnose multiple suspected renal diseases, especially those unable to be identified alternatively. It is the only definitive route to diagnosis and identify interstitial inflammation including lymphocytes, monocytes, and eosinophils [1].

As an invasive procedure, not all the patients with hematuria and albuminuria need to have a kidney biopsy. This requires comprehensive consideration of patients' conditions. Also, renal biopsy puts patients at risk for bleeding, pain, arteriovenous fistula, and other complications such as hematoma, infection, and hypertension [2]. Physicians should pay special attention to contraindications beforehand.

Artificial intelligence (AI) technologies, such as natural language processing (NLP) and machine learning algorithms, have significantly affected clinical practice and research. AI algorithms usually deal with (transformed) structured data [3]. However, for clinical applications, a large amount of information is concealed in unstructured documents, which is a traditional way for clinicians to record and communicate information.

This study used a corpus of hospital admission notes by the nephrology department. These notes include natural language decscriptions of basic patient information, including history, physical examination findings, reasons why the patient is being admitted for inpatient care, plan of care, etc. This information serves as the basis for further clinical treatments. Even so, different physicians will make different quality choices. The hypothesis of this study is text understanding technologies can evaluate the situation described in free-text documents and provide objective, homogenous decision support.

Methods

In order to solve the above problems, methods were developed acording to the following flow diagram (Figure 1). Traditional knowledge engineering tasks, such as ontology and semantic network for text understanding, are labor-intensive an do not have broad applicability. So, a semi-automatic construction of domain-specific semantic lexicon was designed. Then an NLP pipeline was constructed to extract comprehensive clinical information to feed different clinical decision support models.

CRF-based Semi-automatic Construction of Domain Lexicon

The lack of Chinese medical terminology resources and the complexity of expression in Chinese natural language have led to many difficulties in the automatic acquisition and utilization of information in China.

A previously reported method [4], which iteratively discovers new symptom terms from the clinical corpus using the conditional random field (CRF) algorithm, was used in this study. A general homegrown medical dictionary served as the seed dictionary. The training domain corpus was segmented using the Pangu segmentation tool [5] and reverse maximum matching (RMM) to label based on the seed dictionary. For each iteration, the CRF model output newly identified terms. These new terms update to the seed dictionary and work for the following iterations. After post-processing eliminated false positive terms, an XML file was generated for each test document. The similarity calculation was performed based on the XML file, and the result determined the number of iterations when no more new terms were identified.

The default feature template of the CRF toolkit was used. In the process of calling the CRFSharp API, files named CRFSharp.dll and CRFSharpWrapper.dll were added as references, which provided the core algorithm and low-level and high-level interfaces [6]. They were employed when training the CRF model from training corpus in the program, i.e., model encoding. In order to achieve better results, we modified some of the default parameters to ensure that the extracted symptom terms were more common (occurred at a higher frequency) and that the iterations were more thorough.

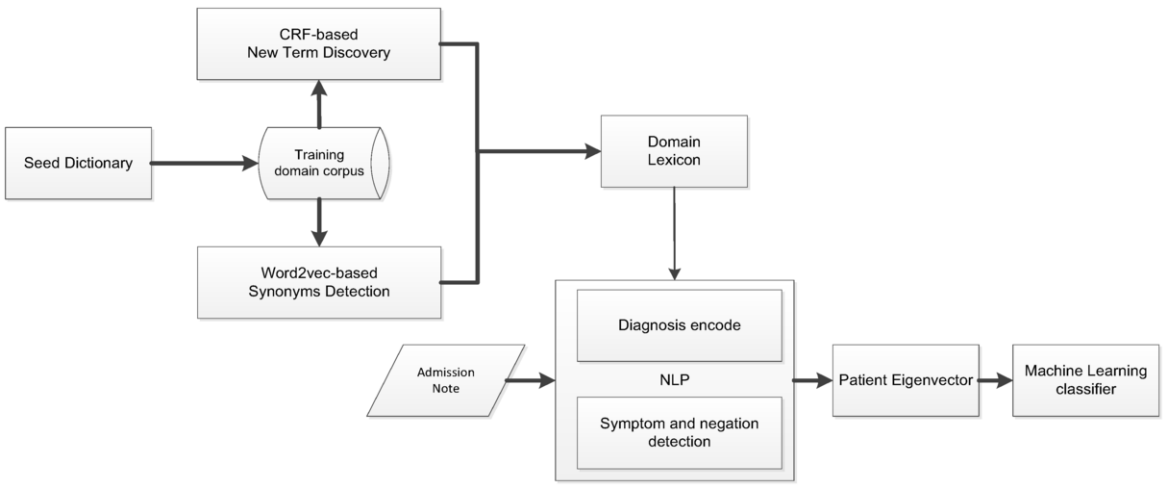

Figure 1–The Flow Diagram of Renal Biopsy Recommendation Based on Text Understanding

After manual review, the accurate new words were integrated with the initial seed dictionary, and we obtained a list of accurate symptom terms. Due to the vague definition of symptom terms, the results might include other signs and diagnoses according to the needs of doctors.

Symptom Synonyms Identification

Due to the different habits of recorders, the same symptoms might have different expressions. Thus, we needed to sort out synonyms to construct the eigenvector, since the integration of the seed dictionary and newoly identified terms might regard different expressions of the same symptom as different symptoms. In order to identify these cases as completely as possible, symptom synonyms detection was required.

Tokenization

Unlike English, Chinese does not separate words by a space or other punctuation [7]. In order to deal with Chinese corpora, we used the "Jieba" Chinese text segmentation, a python-based Chinese word segmentation module. In addition to its built-in dictionary, customized dictionaries were also introduced to improve the accuracy of tokenization, especially for texts in professional fields. After loading the domain specific dictionaries, the Jiaba segmentation generated a Trie tree, divided the text content into phrases, used DAG and dynamic programming to obtain the maximum probability path, and used HMM model and the Viterbi algorithm [8] for phrases not included in the dictionary (i.e., identification of new words). Finally, it built a word generator using Python's yield syntax, returning words one by one.

Word Embedding

Word embedding is actually a manner of word representation, to a form which is suitable for computer processing such as a vector or matrix. In NLP, the representation of words can be divided into two categories: one-hot representation and distributed representation. Since the use of one-hot representation often causes data sparsity [9], people prefer the latter. Word embedding is closely related to the neural language model (NLM) [10]. This process, based on distributed hypothesis, involves of mapping words into real vector spaces [11] and evaluating the similarity between the meaning of two words by their contexts.

Through the Word2vec algorithm, we could represent a word in a lower dimensional space and map the related concepts to similar feature vectors [12].

Synonym Identification

Word2vec comes with a data set called text8, which can train the tokenized texts to obtain a model. We used the generated model to find synonyms for symptom terms based on the similarity of word vectors. By calling the function provided in Word2vec, we were able to calculate the distances between word vectors of other words and the input word. Results were sorted according to their cosine similarity order. The closer the value was to 1, the more similar the position of the words were in the context, and we regarded them as synonyms or words that described different performances of the same symptom. Conversely, the closer the value was to 0, the lower the similarity was between words [13-15].

By manually screening the results, we obtained an accurate list of words covering the symptom terms that had appeared in the nephrology medical records and their synonyms (if any).

Eigenvector Construction

With the list of symptom terms obtained, we matched the text content to terms and then performed negation detection to determine if the patient had the mentioned symptoms or not. After further processing, an eigenvector could be generated for each patient. In the n-dimensional vector, the first column is the patient id, and the last column is reserved for the label, with the remaining columns having a value of 1 or 0, indicating that symptoms and diseases appear or do not occur, respectively. The disease here is the result of a preliminary diagnosis. Therefore, the number of columns of the feature vector is n +2, where n represents the sum of the numbers of the symptoms and diseases (synonyms are considered one symptom).

Reverse Maximum Matching

In the field of Chinese word segmentation, commonly used methods are segmentation algorithms based on a dictionary, understanding, and statistics, among which dictionary-based is the simplest and most practical method [16]. Due to the features of Chinese word formation, dictionary-based string matching often uses reverse maximum matching, which generally

possesses higher segmentation accuracy and encounters fewer ambiguities [17].

Input (Trigger)

Table 1– State-transition Table for FSA of NegDetector
R：Reset NegAff to positive
M：Modify NegAff to negative
†Words in light grey cells are NANegation and corresponding verbs.

The specific steps of the RMM algorithm are as follows: the large segment of text is divided into a plurality of sentences according to the punctuation marks. Each sentence is cyclically read, and the length is n Chinese characters (1 Chinese character is equivalent to 2 characters). Set a maximum length k, and take the last k words as the matching field each time. If the matching fails, remove the first word (k becomes k-1) and continue looping until the matching is successful and gets a word. Repeat the above steps until the remaining length n=0.

Negation Detection

The negation detection method here, an FSA-based algorithm called NegDetector, was derived from an article by Zheng Jia et al. [18]. A concept named NegAff was proposed, whose value was used to describe the affirmation or negation of terms in the electronic medical record (EMR). According to the appearance of sentence structure and negative signals, a state conversion table of FSA was established as Table 1.In the initial state, NegAff defaulted to affirmative, with its value modified according to the FSA state. If we were in state 2 and we saw a term or noun, then the NegAff of the word was modified to negative. If we were going to 0 (R), it meant we need to return to the start state and reset NegAff.

Through the above algorithm, the value of NegAff was defined to determine the contextual polarity of the symptom terms.

Dimension Reduction of Preliminary Diagnoses

The processing object in this section was the disease derived from the preliminary diagnosis of EMR, part of the columns of the eigenvector. The International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) [19] converts words representing diseases and diagnoses into alphanumeric codes, greatly facilitating the storage and retrieval of data. CCD is the Chinese version of Classification and Codes of Diseases (GB / T 14396-2001), expanded and refined on the basis of ICD-10, with the encoding changed from 4-char to 6-char [20].

When dealing with the initial diagnosis of EMR, the use of a detailed classification hierarchy would result in a large number of entries. To this end, in the multilevel disease categories, we had 805 distinct ICD six-char encoding diseases (single-level disease [21; 22], such as I45.102, “完全性右束支传导阻滞”, complete right bundle branch block) classified into subcategories, in which the first four characters were the same (e.g. I45.1, “其他和未明示右束支传导阻滞”, other and unspecified right bundle branch block). It was found that the number of entries could be reduced to 675. That is to say, by reducing the number of coded bits from 6 to 4, the number of distinct diseases could be reduced by 16.1%. Changes in categorization could effectively decrease the number of diseases and control them in a manageable number.

Machine Learning Classifier

The eigenvectors of the cohort were used to train logistic regression models. We randomly selected 70% of the total data as the training set and used the remaining 30% as a test set. Five-fold cross-validation was used on the training set.

Results

Data Description

A total of 3,149 admission notes from the nephrology department were used in this study. We used the recommendations given by physicians in first-day progress note as the gold standard for renal biopsy recommendation. We selected all statements in the document that represent "the patient needs a renal biopsy", such as "Renal puncture examination if necessary, to determine the pathological type" and "Renal puncture examination if necessary.” These were used as the gold standard for providing accurate judgments for subsequent training and test results.

The eigenvector was composed in order of patient ID, 675 4-char encoding diseases, 385 symptoms, and a label representing whether the patient was recommended for renal biopsy. The value 1 stood for “appeared” or “recommended”, and 0 represented the opposite.

Results of Renal Biopsy Recommendation

Results of New Terms Identification

Even if the parameters had been adjusted, there were still low-frequency terms that appeared after multiple iterations. Here we

did not use all newly identified symptoms, and we eliminated symptoms of extremely low frequency. We selected 800 new terms and conducted manual screenings to get 561 new accurate terms. The precision was 70.1%.

In addition, the terminologies identified using machine learning contained combined symptoms, such as "tenderness and rebound tenderness." Among them, "tenderness" and "rebound tenderness" were different symptoms, but might be recognized as a symptom because they were used adjacently in the medical record. In practical application, we regarded the words of the combined symptoms as multiple symptoms, and the degree of refinement of the data became higher so that the granularity became smaller.

Results of Symptom Synonyms Identification

By inputting a word and taking the top ten from the lists that Word2vec retrieved, we could obtain 10 words which appeared in the document that had the closest meaning to the certain word. We chose the symptom terms that had a synonym in the corpus and randomly extracted 10 symptoms and 15 symptoms. After manual proofreading, the calculated precisions were 57.0% and 54.0%, respectively.

Results of Renal Biopsy Recommendation

We performed word segmentation, reverse maximum matching and negation detection on all documents, labeled doctors' recommendations for renal biopsy according to the gold standard, and used scikit-learn to train logistic regression models for binary classification. We used the default parameters of the sklearn toolkit. We used five-fold cross-validation for the training set and calculate the average. The results are shown in Table 2. The ROC curve of the test set obtained by the method of this paper is shown in Figure 2.

Discussion

In this work, we used the accuracy, precision, recall, and F1-measure to evaluate the proposed method. It can be seen that this method works in the recommendation renal biopsy. In addition, a combination of the recommendation system and visualization techniques should be a promising research direction, since it can be used as a support tool. In practical applications, doctors can be assisted while drawing conclusions with a more intuitive view.

Although this method has achieved good results, there are still some inadequacies with it. First, the precision of the word segmentation results has room for improvement. Some terms that were not related to the seed dictionary were not recognized or excluded from screening. Secondly, Word2vec is based on the contextual environment to generate word vectors to judge the similarity of words, which has little to do with the meaning of the words themselves; and some words have few synonyms in the medical records, which lead to high coverage of some synonyms, but low precision. Medical staff input errors (typo and grammatical errors, etc.) can also result in reduced accuracy of term extraction. The above reasons may also lead to prediction failures.

Furthermore, feature selection is performed using the SelectFromModel feature selection method from the scikit-learn library. The features of higher significance and stronger correlation include recurrent and persistent haematuria, nephrotic syndrome, acute tubule-interstitial nephritis, isolated proteinuria, hypersensitivity angiitis, membranous nephropathy, obstructive and reflux uropathy, hyperplastic IgA nephropathy, nephrostomy, hyperplasia of prostate. Further analysis of these clinical meaning of clinical indicators with renal biopsy will help to concrete the expertise to a more explicit form.

We believe that the proposed approach represents an interesting strategy to deal with clinical text data and knowledge fusion for therapy recommendation besides renal biopsy, which may provide advantages in clinical decision supporting applications.

Conclusions

The present paper introduced a renal biopsy recommendation system based on text understanding. We utilized a semi-automatic domain lexicon constructed using CRF and Word2vec for preliminary text analysis, then extracted symptoms and diagnoses to construct an eigenvector with negation detection. Finally, with the help of the machine learning classifier, the system was able to draw a conclusion on whether the patient should perform a renal biopsy based on the given gold standard. To some extent, it provides credible clinical decision support for doctors. Future work could be built relating to method improving and practical application such as visualization. Although clinically it is still necessary to rely on the experience of doctors for kidney biopsy recommendations, this method can provide some help. It is believed that with the accumulation of data and the improvement of the database, the indicators of this method will gradually get better, and expand the application scenarios to assist doctors in various departments to make clinical decisions.

A Paradigm Shift: Sharing Patient Reported Outcome via a National Infrastructure

[a] *Danish Health Data Authority, Denmark*
[b] *MEDIQ – Medical Informatics and Quality Development, Denmark*

Abstract

Digital solutions transform the way clinical services can be provided and make it possible for patients to participate in decisions concerning their own treatment. With the aim to support a better and more efficient healthcare system in Denmark, it has been agreed among authorities and care providers to establish a national infrastructure for sharing data between hospitals, municipalities, general practitioners and patients and concurrently develop standardized national digital cross-sector questionnaires for the purpose. Sharing data via the national infrastructure enables proactive involvement through patient reported outcomes (PRO). The national infrastructure forms a paradigm shift 1) for collaboration by moving from a baton-passing workflow to sharing-based workflow and 2) for the development of digital cross-sector questionnaires. Cross-sector questionnaire definitions are stored in a national questionnaire repository, and are used in local PRO applications to capture the patients' responses.

Keywords:

Patient Reported Outcomes, Information Dissemination, Questionnaire Design, Questionnaires

Introduction

It is well known that history taking is the most important source of information in healthcare and patients are the best providers of information regarding their own health [1]. Usually a health professional interviewing the patient collects the information from the patient. However, health professionals do not always collect all the relevant information from the patient, besides the task of documenting the patient history is time consuming and patients may even do a better job by filling out a standardized and validated questionnaire [2].

Ask the patient – Patient Reported Outcomes

Across health systems, a wide range of activities have been launched for using Patient Reported Outcomes (PROs). PROs are a general designation for patients' responses to questions about their own state of health. According to the Food and Drug Administration (FDA), PRO is defined as: *"any report of the status of a patient's health condition that comes directly from the patient without interpretation of the patient's response by a clinician or anyone else"* [3]. PROs take the form of carefully designed and validated questionnaires that can be used to capture and quantify the patients' experience, health, and treatment impact. The patients' responses to a questionnaire are denominated as PRO-data. By systematically and actively using PRO-data in the dialogue with the patient, the planning and treatment of the care provided to the patient can be personalized to meet individual needs and concurrently fulfill clinical guidelines. Further PRO-data may also support value-based health management and can be used to perform screening for side effects and reduce the number of unnecessary consultations. At the same time, PRO-data create sound new data for research and quality development. Used correctly, PRO-data are just as essential to the quality of care as clinical data from other more accustomed sources. PRO-data should therefore be an integral part of data useful to clinical practice in the future.

The Danish Health Data Authority has established a permanent PRO secretariat [4] that is responsible for development of standardized cross-sector questionnaires to be used in the healthcare sector nationwide. Standardized questionnaires, for cross sector use, are to be stored and accessed in a national questionnaire repository.

Focus is on using PRO-tools to support active patient participation and involvement. PRO-data are to be used in clinical encounters or as a substitution for outpatient contacts. The aim is to support and strengthen communication between patient and healthcare professional and concurrently ensure efficient processes. PRO-data reported by the patient can be used for clinical assessment before the clinical encounter, or as a dialogue support tool during the encounter; furthermore, PRO-data can be applied to support planning of treatment and as a tool for continuous health monitoring. PRO-data can be shared cross sectors, to all relevant healthcare providers including the patient, via the national infrastructure.

Development of cross-sector questionnaire specifications require involvement of all affected stakeholders including patient representation. It is also crucial that the questionnaires are tested and validated in pilot projects before they are used in daily operations at a national level.

Sharing data via a national infrastructure

To support new flexible ways of cross sector cooperation that include patient involvement, requires concurrent development of IT-technologies as well as well-validated standardized and structured questionnaires. A prerequisite is a generic and standardized IT infrastructure that can support easy interconnection to the many different IT-systems that are used by the various care providers in healthcare.

Messaging has been the main technology applied in Denmark for exchanging information among various healthcare organizations for more than 20 years [5]. Messaging is easy to implement as the focus for the individual message (discharge letter, referral, lab result, etc.) is well-defined. The weakness

in messaging is that information is only shared between the sender and the receiver.

Today, there is a high demand among care providers and patients to request access to relevant clinical data at the point of care independent of location. A common national infrastructure for the healthcare sector has therefore been established in Denmark to make it possible to share relevant eHealth data across all healthcare organizations as well as patients at home. Furthermore, an agreement will be made in the 2020 finance act, which will oblige the parties to start connecting the local IT systems to the national infrastructure with the aim of exchanging PRO-data.

Use of PRO-data will be implemented across regions, municipalities and GPs to ensure sufficiently broad use in and across the healthcare sector based on the common infrastructure and the standardized questionnaires.

Methods

Development of standardized national questionnaires

A standardized method for development of national questionnaires has been developed and evaluated [6]. An overview of the development methodology is illustrated in Figure 1.

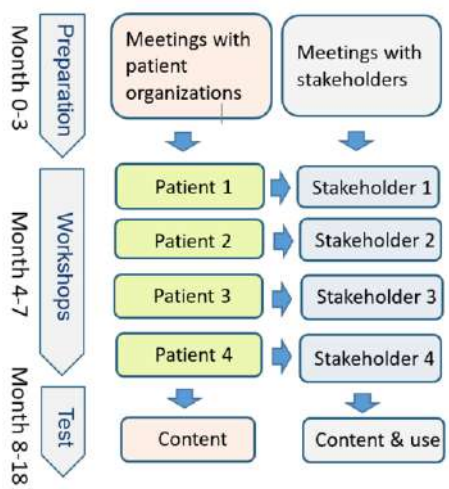

Figure 1 – The Development Methodology for Concerted National Questionnaire Definitions

The design method builds on participatory design principles [7]. A number of meetings and workshops with patient organizations are held to support patient involvement and complement the questionnaire development meetings and workshops with the various stakeholders. The starting point in the development process is always a review of existing PRO material within the area – it is presented to the stakeholders and concurrently a discussion of the aim and practical application is carried out.

By March 2019, six national standardized questionnaires, as shown in Table 1, have been developed.

Table 1 – Fully Developed Areas for PRO in the Program

Area	Status
Apoplexy	Pilot testing
Arthrosis (knee and hip)	Pilot testing
Screening for depression in somatic patients	Pilot testing
Pregnancy and childbirth	Workshops completed
Heart rehabilitation	Workshops completed
Diabetes	Workshops completed

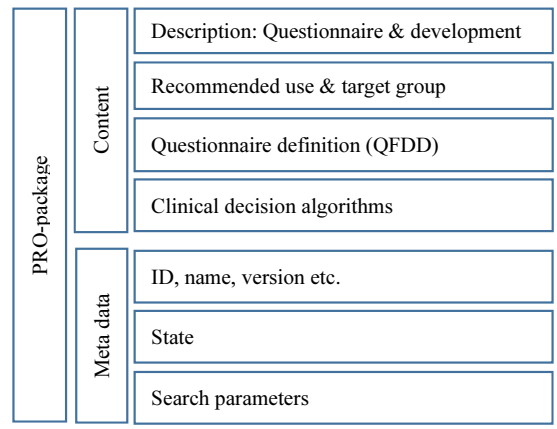

Figure 2 – A PRO-package Contains Content and Metadata

National questionnaire repository

A new national questionnaire repository contains PRO-packages that encompass questionnaires, clinical algorithms, and recommendations for use of PRO questionnaires and PRO-data. A PRO-package contains material as illustrated in Figure 2.

A PRO-package includes a description of the questionnaire and the intended use in several documents that support the technical implementation in the local IT-systems. Metadata are primarily data to be used to search for a specific PRO-package.

The PRO-packages are published via the national questionnaire repository and can be downloaded by healthcare organizations and software providers. However, if a user wants to download a PRO-package, the user must register in the questionnaire repository. As part of the registration, the user provide an e-mail address, that is used to notify the user when the PRO-package is updated.

Development of a national IT infrastructure

The national IT infrastructure builds on the Danish "Reference architecture for collecting health data from citizens" [8]. The reference architecture acts as the common reference for all business areas and IT solutions regarding collection of health data from citizens. The focus in the reference architecture is on data flow from individual citizens to healthcare systems. The data is collected from or provided by the citizen and is communicated to Cross-Enterprise Document Sharing (XDS) repositories in the national infrastructure. Healthcare professionals, that have a "care-relation" with a patient is cleared to look-up relevant data. The use of international standards for communication and content are considered important to ensure semantic interoperability. Furthermore, it

improves quality, as it is the same standardized data set that is applied by all involved care providers.

Further, an important aim of applying an infrastructure based on a standardized reference architecture is to accelerate dissemination and thus implementation in practice.

Sharing PRO-data via the national IT infrastructure focuses on both mono-sectorial and cross-sectorial use of data, thus supporting a smooth cooperation among the various care providers. The national infrastructure is built around a national service platform as shown in Figure 3. The platform among other things holds information on whether there is a 'care-relation' between any given care-provider and the patient.

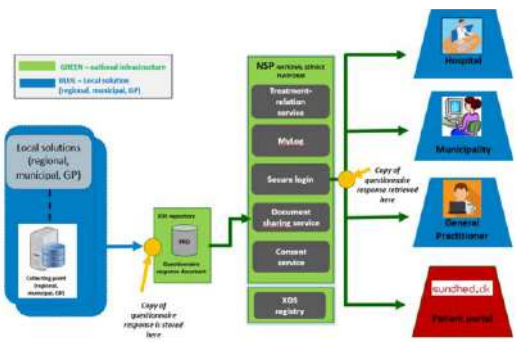

Figure 3 – National Service Platform and Services

Document Sharing Service

The Document Sharing Service (DSS) is a national service for sharing documents among healthcare organizations. Documents can hold any kind of data, but they have to be expressed in an agreed upon standardized format. The DSS is based on the international standard for maintaining and sharing documents among healthcare organizations – Cross-Enterprise Document Sharing (XDS). This is managed through federated document repositories and a document registry to create a longitudinal record of information about a patient within a given clinical affinity domain.

Consent service

According to the Danish healthcare laws, health professionals have by default the right to access the citizens' healthcare data, if it is relevant in relation to actual care situation and the patient has provided oral consent.

In order to restrict access to data a citizen can block:

- Access to all data for a specific period
- Acess to data from a specific healthcare organization
- Access to data for a specific person

The consulting service is linked to the DSS and will automatically filter out documents, if the citizen has blocked access to data.

Standards for questionnaires

Two HL7 CDA v2 standards are used for questionnaires. The Questionnaire Form Definition Document (QFDD) describes how the questionnaire is constructed and organized. The QFDD includes information about author, version, tittle, heading, text for sections and for each question; it is specified how the answer to any question can be given e.g. as free text, numeric values or multiple choice. It is also possible to add conditions where a specific response will open-up a new section with further questions. The QFDD is important to use, when receiving a populated questionnaire in order to understand and interpret the answer.

The Questionnaire Response Document (QRD) is the questionnaire filled by the patient (the PRO-data). The QRD has a link to the QFDD.

The QFDD and the QRD standards ensure that data can be integrated and reused (semantic interoperability) in the numerous existing IT systems, that are used every day in the hospitals, municipalities, and by the general practitioners.

Before the healthcare organizations can begin to share data via the national IT infrastructure, the correct implementation of the QFDD and QRD standards are tested and certified. The tests and certification are mandatory to all users of the IT infrastructure.

Testing and evaluation of the national standardized questionnaires

When a national questionnaire has been developed, a validation is carried out with approximately 20–30 patients, representing a broad diversity of potential responders, e.g. differing in age, sex as well as social and educational backgrounds. Questionnaire algorithms and usability are also tested in small-scale implementation and at several pilot sites. The pilot sites are cross-sectorial according to the relevant cross-sectorial workflows.

A research program has been set up to identify categories of eligible patients, benefits and disadvantages of using PRO-data and the effect application of a system for Patient Reported Information may have on clinical work. From previous experience, we know that the use of PRO-data will empower patients and improve efficiency and effectiveness of care processes in some patient groups [9, 10] and it may even improve outcomes [11].

Results

Dissemination

A new national IT infrastructure based on IHE XDS [14] and HL7 CDA standards has been established and tested. The use of international standards ensures that relevant data can be shared across hospitals, municipalities, and general practitioners independent of which IT-providers and systems are employed. The patients further have access to their own PRO-data as well as other health data via the Danish Public Healthcare Portal [12].

The IT infrastructure is in daily operation and is until now also used for sharing of patient appointments, patient master data, care plans and home monitoring as well as PRO-data.

Maturity the infrastructure

On the Technical Readiness Levels (TRL) scale developed by National Aeronautics and Space Administration (NASA) [13] as a methodology to access the maturity of critical technology solutions, the infrastructure is assessed to be on TRL 8 (in daily operation with real users) by March 2019.

As shown in 4, TRL is based on a scale from one to nine, where nine is the highest maturity level of the technology solution. The use of TRL also provides the basis of

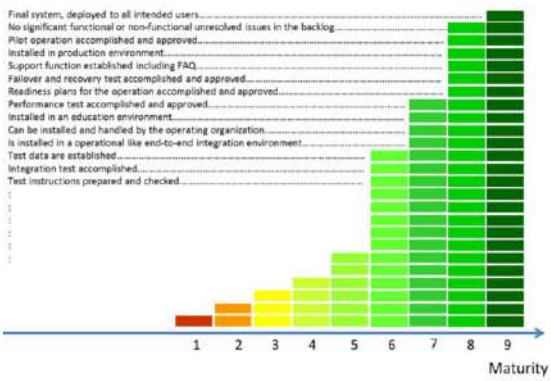

Figure 4 – TRL Scale to Access the Maturity

a consistent description of the maturity level of the national infrastructure.

Questionnaire development

The most important findings during the first rounds of development and evaluation of questionnaire are listed in Table 2.

Table 2 – The Most Important Findings During the Questionnaire Development Process

Area
1. Many issues need to be clarified by the patients before and between stakeholder workshops
2. Most patient pathways are cross sectorial, but cross sectorial workflows are complex and not well described
3. Most previous knowledge on patient reported information is derived from mono-sectorial use in hospitals, as digitalized Patient Reported Information has been only scarcely used in primary care
4. Use of Patient Reported information is a fundamental cultural transformation to health professionals
5. Legal clarification of who may have access to what kind of Patient Reported Information is important
6. Electronic questionnaire systems including algorithms are medical devices and thus must be CE marked in the EU

Discussion

Currently there is a lot of ongoing work in Denmark to develop new IT-solutions that can involve and empower the patient and make the care provision more personalized and efficient. There are several strategies to address this challenge, one is to ensure efficient access to relevant patient data for all care providers in all the various health organizations involved in the care process of a single individual.

Messaging

For many years, messaging has been the preferred approach for communication of health data. Messaging is based on the premise that the sender and the receiver have knowledge of each other; for example, a hospital is sending a discharge letter to the patient's general practitioner. This is a baton workflow, where the diagnosis and treatment are done stepwise by handing over the patient and what is judged as relevant information from one care provider to another care provider. In the baton workflow process, there is a risk of not sending the relevant information or for loss of information, as the patient's data are only communicated as singular messages between the sender and the receiver.

Collaboration via a national infrastructure

Today's tecnology allows the establishment of a national infrastructure where data are shared among many actors. Relevant data can be collected, shared, and applied where and when it is relevant (the services in the National Service Platform ensure that there is legitimate right to access the data).

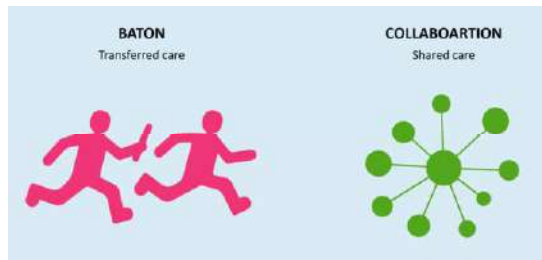

Figure 5 – From Baton to Collaboration

Going from Baton to Collaboration provides a profound shift in the information exchange paradigm as well as in the possible ways to cooperate. Further introducing questionnaires filled by the patients and accessible whenever relevant provide a completely new set of possible ways to cooperate in the healthcare sector.

The national infrastructure is designed as a common generic infrastructure, which can be applied by all care providers, though we have found that it is a challenge that many small healthcare organizations do not have internal IT knowledge and capabilities to establish a smooth integration to the national IT infrastructure. Further legal issues have to be addressed and handled in the way questionnaires are designed and distributed as well as in the design of the infrastructure. It is, however, a benefit that the security issues are taken care of in the design of the IT infrastructure

It is essential that all stakeholders are represented in the process of the development of questionnaires and that all stakeholders actively participate in the dialogue and teamwork. Furthermore, as one of the central aspects in participatory design points out, it is essential that stakeholders collaborate on equal terms [7]. We have managed to support this aspect by conducting dedicated workshops for patients and for clinicians from the primary care sector as we found that they needed more support in the process. Clinicians from the hospitals have an advantage of their prior experience in development and use of questionnaires with patient reported information.

Conclusions

Based on our findings, we are convinced that the increased use of patient reported information involving patients and clinicians in the development, evaluation, and implementation processes will be of great benefit to both the individual patients as well as the entire healthcare system [11]. However, it requires a thorough and exhaustive development program including tracks for technical infrastructure, questionnaire development, evaluation, and application as well as a research program.

Sharing data versus messaging is a major paradigm shift concerning technology, use of eHealth standards, clinical workflow, security, legal aspects, and privacy.

Acknowledgements

The Danish program on Patient Reported Information is a cooperation between state, regions, municipalities, and patient organizations in Denmark.

Acceptability of Telemedicine to Help African American Women Manage Anxiety and Depression

Terika McCall[a], Todd Schwartz[b,c], Saif Khairat[a,b]

[a] *Carolina Health Informatics Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA*
[b] *School of Nursing, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA*
[c] *Department of Biostatistics, Gillings School of Global Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Abstract

African American women experience rates of mental illness comparable to the general population, however they significantly underutilize mental health services. Past studies have shown that telemedicine is effective, and can be used to increase access to services. To assess the acceptability of using mobile video calls, a web-based survey was launched to solicit response from African American women. The results of this exploratory study (N=102) showed high acceptance of the use of video calls to communicate with a professional to receive help to manage anxiety and depression (> 70% endorsed). Statistically significant associations were found between age and agreement with the use of video calls, with younger women (< 50 years) more likely to indicate acceptance (p's < .05). The findings of this study demonstrated the need for additional research into the use of telemedicine to provide African American women with more accessible and convenient options for mental health care.

Keywords:

Telemedicine, women, mental health

Introduction

In 2017, an estimated 5.1 million African American adults experienced mental illness in the last year [1]. Women comprised approximately 54% of this population [1]. The prevalence of mental illness among African American women (18.6%) was comparable to the general population (18.9%) [1]. However, there is significant racial disparity in the use of mental health services among African American women compared to their white counterparts [1]. Telemedicine can be used to increase access to mental health care in this population, and reduce disparities.

Anxiety and mood disorders are among the most common mental illnesses in the U.S. [2]. Women are nearly twice as likely as men to experience an anxiety (e.g. generalized anxiety disorder) or mood disorder (e.g. major depressive disorder) in their lifetime [2]. Results from the 2008 *National Health Interview Survey* found that 15.7% of non-Hispanic black women reported having generalized anxiety in their lifetime [3]. Furthermore, 27.4% of non-Hispanic black women reported experiencing depression in their lifetime [3]. Mental illness is underreported in the African American community; therefore, the prevalence estimates may actually be substantially lower than the true burden.

Although there is significant burden of mental illness among African American women, mental health services are underutilized. Results of the 2017 *National Survey on Drug Use and Health* revealed that African American women use mental health services at less than half the rate of their white counterparts (10.6% compared to 23.4%) [1]. Among the African American women that reported experiencing mental illness in the last year, 64.2% did not receive any mental health treatment during that time [1]. There are many reasons why African American women may not seek mental health services when needed. Barriers such as stigmatization of mental illness [4,5], less access to treatment, no or inadequate health insurance, mistrust of providers, and low health literacy prevent traditionally marginalized populations from seeking care [5].

Actual and perceived racism and sexism may cause undue stress and lead to increased anxiety or depression in African American women. A study published by Ward & Heidrich [6] found that African American women's preferred coping strategies included praying and seeking medical and mental health care. Taking this into consideration, how do we make mental health services more accessible to this population? The ideal solution would incorporate technology they already have access to, and require minimal education on its use. Telemedicine may be a viable solution. Specifically, the use of mobile video calls to communicate with a professional to receive help for managing anxiety or depression.

Eighty percent of African American women own smartphones [7]. Most smartphones are equipped with the capability to complete video calls. To our knowledge, there have been no studies that have examined the use of mobile video call use to manage anxiety or depression in African American women. However, evidence from past studies showed that videoconferencing has been effective in helping participants reduce anxiety or depressive symptoms [8–10].

Due to the paucity of published peer-reviewed literature on the use of video calls for therapy, which also include a significant representation of African American women in the study sample, more investigation into the use of this technology with African American women is needed. Given that current mental health services are underutilized by this population, the population should be surveyed to determine the acceptability of this approach to treatment. The aim of this exploratory study is to gauge the acceptability of telemedicine, using mobile video calls, to deliver mental health services to help African American women manage anxiety and depression.

Methods

Study Design and Recruitment

The self-administered web-based survey was launched in June and closed August 2018. Eligible participants were African American women (≥ 18 years of age) that reside in the U.S.A. Participants were recruited through convenience sampling.

Recruitment methods included sending an invitation to take the survey via a direct email from the first author, or email distributed through listservs whose membership is primarily African American women. Participants were also recruited via social media (e.g. Facebook) posts and direct messages. A link to the research information sheet about the study was provided in the email text and social media posts. Following a snowball sampling technique, respondents were encouraged to share the link to the survey with their networks (e.g. family, friends, professional organizations, etc.). No remuneration was offered for participation. The study received notification from the institutional review board (IRB) of exemption from further review.

Measures

Due to the sensitive nature of the questions and for convenience, the computer-assisted web interviewing (CAWI) data collection technique was used to administer the survey instead of in-person interviewing. Respondents were provided an anonymous link to the online questionnaire. No personally identifiable information (PII) was collected in the survey. The survey consisted of 53 questions, and was administered using Qualtrics software. Survey domains included sociodemographic characteristics, attitudes toward seeking professional psychological help, mobile phone use, and acceptability of using a mobile phone to receive mental health care.

Sociodemographic data such as the respondent's race, ethnicity, age, gender, and highest level of education attained were captured at the beginning of the survey. The race, age, and gender questions were also used as screener questions to determine eligibility to complete the survey. If the respondent did not self-identify as a Black/African American (or biracial, Black/African American and another race) female age 18 years or older, they were routed to the end of the survey.

Attitudes Toward Seeking Professional Psychological Help

In the survey, the term "professional" referred to individuals who have been trained to deal with mental health problems (e.g., psychologists, psychiatrists, social workers, and family physicians). Respondents attitudes toward seeking professional psychological help was measured using questions from an adapted version of the validated *Inventory of Attitudes Toward Seeking Mental Health Services (IASMHS)* [11]. The IASMHS consists of 24 questions and the following factors: psychological openness, help-seeking propensity, and indifference to stigma. Response options to the survey items were on a 5-point Likert-type scale from disagree (0) to agree (4).

In order to collect data specifically about attitudes toward seeking professional help for anxiety and depression, six questions in the inventory were revised. The words 'psychological problems' and 'mental disorder' were substituted with 'anxiety' and 'depression'. For example, Item #3 in the IASMHS reads, "I would not want my significant other (spouse, partner, etc.) to know if I were suffering from psychological problems." The revised survey question states, "I would not want my significant other (spouse, partner, etc.) to know if I were suffering from **anxiety**." To prevent asking double-barreled questions, respondents were asked about anxiety and depression independently for the six questions. This increased the total number of questions in the inventory to 30.

Mobile Phone Use

Mobile phone use was ascertained with the following items: (1) current mobile phone ownership (yes/no); (2) frequency of sending text messages (never, less than 1 time per week, 1-6 times per week, 1-3 times per day, 4 or more times per day); (3) ability to complete video calls on mobile phone (yes/no); and (4) frequency of using mobile phone to complete video calls (never, less than 1 time per week, 1-6 times per week, 1-3 times per day, 4 or more times per day).

Acceptability of Mobile Phone Use for Mental Health Care

Acceptability of using a mobile phone to receive mental health care to manage anxiety or depression was measured by the following items: (1) comfortability communicating with a professional through text messaging to receive help for managing anxiety/depression; (2) comfortability communicating with a profession through video call to receive help for managing anxiety/depression; (3) whether having the option to use a video call to complete an appointment with a professional would increase access to mental health services; (4) convenience of using video call to complete an appointment (e.g. less travel time); (5) convenience of using video call to complete an appointment compared to an in-person visit; and (6) perceived helpfulness of having the option to use text messaging to communicate with a professional if feeling anxious/depressed. Response options to the survey items were on a 5-point Likert-type scale from disagree (0) to agree (4).

Before completing the survey, respondents were asked two questions, "Do you have any concerns about using a video call to complete an appointment with a professional?" and "Do you have any concerns about using text messaging to communicate with a professional?" If they answered 'yes' to either question they were presented with an open-ended question asking them to note their concerns in the multi-line text field provided.

Data Analysis

Statistical analyses were conducted using SPSS version 25 software. Descriptive statistics were calculated for sample characteristics and responses to video call questions as mean, standard deviation, and range for continuous variables, and as frequencies and percentages for categorical variables. Age was segmented into two groups (under 50 years and 50+), education was collapsed into three levels (< Bachelor's, Bachelor's degree, Graduate degree), and response options were collapsed into three categories (Agree/Somewhat agree, Undecided, and Disagree/Somewhat disagree). Fisher's exact test was used to determine whether an association exists between the response to each video call question with age group and highest education level, respectively. Statistical significance was determined at the two-sided $p < .05$ level.

Results

Of the 113 respondents that started, 102 (90%) completed the survey. The characteristics of the completers are presented in Table 1. Participants ranged in age from 19 to 80 years, and all identified as either Black/African American or biracial (i.e. Black/African American and another race) and female. Most respondents (98%) identified as non-Hispanic.

Approximately 15% had less than a bachelor's degree, 23% obtained a bachelor's degree, and 62% had a graduate degree. Most participants (96%) reported having video call capability on their mobile phone, and 39% reported completing a video call at least once per week.

Acceptability of Video Call Use

Communicating with a Professional

The majority of respondents (> 70%) indicated agreement (i.e. selected the 'Agree' or 'Somewhat agree' response options) with feeling comfortable using video call to communicate with a professional. Figure 1 shows 70.6% agreement (43.1% agree,

27.5% somewhat agree) with the statement, "I would feel comfortable communicating with a professional through a video call to receive help for managing **anxiety.**" Similarly, 71.6% (40.2% agree, 31.4% somewhat agree) of respondents showed agreement with the statement, "I would feel comfortable communicating with a professional through a video call to receive help for managing **depression.**" See Figure 2.

Access and Convenience

The survey results revealed high levels of agreement with the access and convenience statements. Figure 3 shows 83.3% agreement (69.6% agree, 13.7% somewhat agree) with the statement, "Having the option to use a video call to complete an appointment with a professional increases my access to mental health services." Likewise, 88.2% (72.5% agree, 15.7% somewhat agree) of respondents indicated agreement with the statement, "Using a video call to complete an appointment would save me time traveling to a professional's office." See Figure 4. Furthermore, Figure 5 shows 71.6% (47.1% agree, 24.5% somewhat agree) of respondents indicated agreement with the statement, "Using a video call to complete an appointment with a professional would be more convenient for me than an in-person appointment."

Table 1– Characteristics of Study Participants

Participant characteristics		(N=102)
Age in years, mean (SD)		38.8 (13.1)
Age group in years, n (%)		
	Under 50	81 (79.4)
	50 and older	21 (20.6)
Race, n (%)		
	Black or African American	100 (98.0)
	Biracial[a]	2 (2.0)
Ethnicity, n (%)		
	Hispanic	2 (2.0)
	Non-Hispanic	100 (98.0)
Education, n (%)		
	< Bachelor's degree	15 (14.7)
	Bachelor's degree	24 (23.5)
	Graduate degree	63 (61.8)
Mobile phone video call capability, n (%)		
	Yes	98 (96.1)
	No	4 (3.9)
Frequency of video call use[b], n (%)		
	Never	12 (11.8)
	Less than 1 time per week	46 (45.1)
	1-6 times per week	29 (28.4)
	1-3 times per day	9 (8.8)
	4 or more times per day	2 (2.0)

[a]Biracial defined as identifying as Black or African American and another race.
[b]Participants that indicated that their phone did not have video call capability (n=4) were not presented for the frequency of use question.

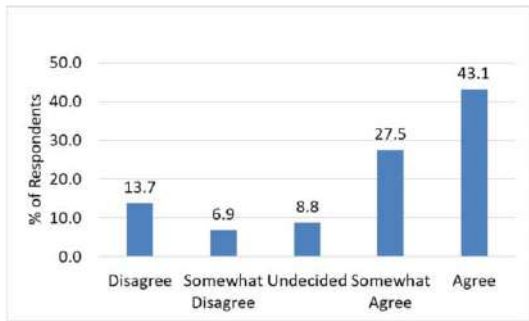

Figure 1–Sample percentages for response to the statement, "I would feel comfortable communicating with a professional through a video call to receive help for managing anxiety"

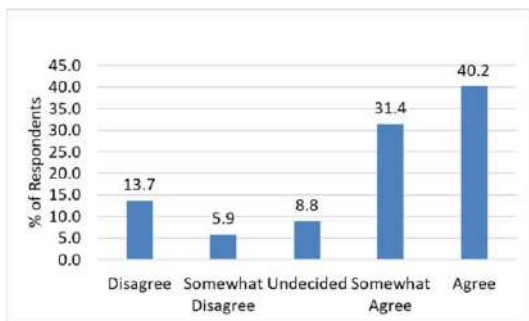

Figure 2–Sample percentages for response to the statement, "I would feel comfortable communicating with a professional through a video call to receive help for managing depression"

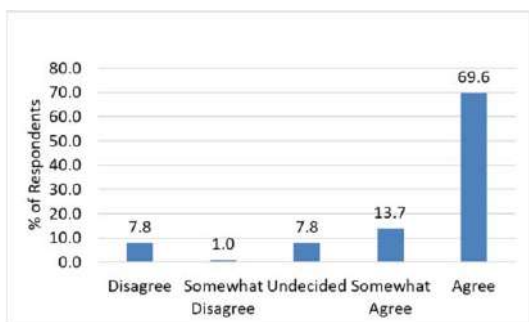

Figure 3–Sample percentages for response to the statement, "Having the option to use a video call to complete an appointment with a professional increases my access to mental health services"

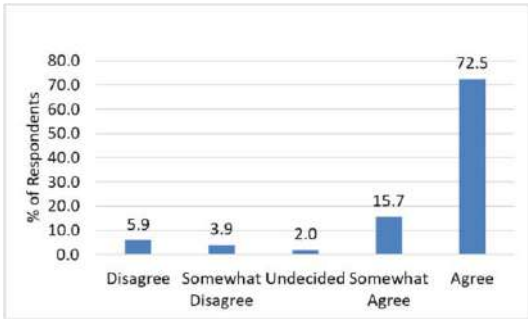

Figure 4–Sample percentages for response to the statement, "Using a video call to complete an appointment would save me time traveling to a professional's office"

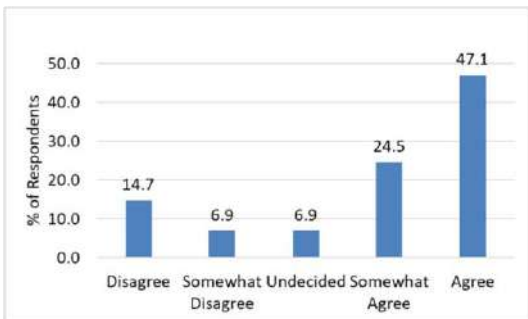

Figure 5–Sample percentages for response to the statement, "Using a video call to complete an appointment with a professional would be more convenient for me than an in-person appointment"

Concerns about Video Call Use

Although overall response to using video calls was positive, approximately 43% of respondents indicated having concerns about using a video call to complete an appointment with a professional. Most of the concerns centered around privacy, confidentiality, and maintaining the video call connection. Regarding privacy, one respondent stated, "I would also be concerned about how private the call is, like is the professional alone, how would I know?" Another respondent voiced connectivity concerns stating, "…the call could get disconnected. That breaks the rhythm of the conversation."

Acceptability of Video Call Use by Age and Education

Statistically significant associations were found between age and level of agreement with the following video call statements: "I would feel comfortable communicating with a professional through a video call to receive help for managing **anxiety**" (highly significant negative association, $p = .002$); "I would feel comfortable communicating with a professional through a video call to receive help for managing **depression**" (highly significant negative association, $p = .003$); "Using a video call to complete an appointment would save me time traveling to a professional's office" (highly significant negative association, $p = .001$); and "Do you have any concerns about using a video call to complete an appointment with a professional?" (positive association, $p = .025$). No statistically significant associations were observed between level of agreement and education (all $p > .05$).

Discussion

To our knowledge, this preliminary study was the first to measure the acceptability of telemedicine, using mobile video call, to deliver mental health services to African American women. The results of this study showed high acceptance. A majority of the women responded that they agree/somewhat agree with the statements regarding feeling comfortable using a video call to communicate with a professional to receive help to manage anxiety and depression (> 70%). Most respondents also believed that the use of video calls will increase their access to mental health services (> 80%), and that it is a convenient option for care (> 70%). Younger women (< 50 years) were more likely to indicate acceptance. While older women (≥ 50 years) were more likely to have concerns about using a video call.

These findings are consistent with literature on the use of telehealth modalities. Although a positive overall reaction was observed in adults, in general, there is greater acceptance among younger adults for the use of technology [12]. Previous studies have also found that older adults generally have many concerns about the use of technology [13].

The concerns of privacy, confidentiality, and connectivity must be addressed when considering use of video calls. Transparency is key to reducing medical mistrust and adoption of video calls as a sustainable mode to deliver care to this population. Clients should also be advised to connect to Wi-Fi or ensure they have a strong cellular signal and sufficient mobile data for high quality video transmission and to prevent disconnection.

Given the stigma of mental illness in the African American community, the option to complete an appointment with a professional in a setting of their choosing may appeal to African American women. Completing a therapy session in a familiar location (e.g. home) may provide a relaxing environment that is viewed as more discrete, and promotes open communication. Furthermore, increasing the accessibility and convenience of therapy helps to overcome some of the barriers to utilizing mental health services.

The main limitations of this preliminary study were recruitment method and sample size. Participants were recruited through convenience sampling, and encouraged to share the survey email or social media posts with their networks. Although no PII was collected in the survey and respondents accessed the survey through an anonymous link, social desirability bias could have resulted if the respondent personally knew the first author. The sample size of 102 respondents is small for this cross-sectional survey, and consisted of mostly younger (under 50 years) and highly educated women (over 85% had at least a bachelor's degree).

This limits our ability to broadly generalize the findings to all African American women. Although stigma may continue to be a barrier for highly educated African American women, access to mental health services, insurance coverage, and health literacy may be less of an issue for this group. However, due to the shortage of African American psychologists (< 5% of active psychologists), access to a professional that meets the ethnicity and gender preferences of the patient may remain an issue [14]. While some patients may have no preference, African Americans who indicate higher levels of mistrust of whites are more likely to discontinue therapy before treatment goals are reached if they are seen by a white counselor [15].

Future work will include relaunching this survey to a larger and more diverse sample of African American women. Questions from the Patient Health Questionnaire (PHQ-9) and Generalized Anxiety Disorder (GAD-7) screeners will be added to capture data on the presence and severity of depression and

anxiety, respectively. In addition, we will explore the acceptability of using text messages to communicate with a professional to receive help for managing anxiety and depression.

Conclusions

The use of telemedicine is a viable solution to help African American women manage anxiety and depression. The study showed high acceptance among this population. Furthermore, over 95% of respondents had the capability to complete video calls on their mobile phone. The use of video calls is an underutilized technology that has the potential to help reduce the disparity in mental health service utilization and improve health outcomes for this population.

Abstract

Clinical Decision Support System (CDSS) has been implemented to support physicians about the medical prescription of genetic testing. CDSS is based on open source software. A CDSS for prescribing these genetic tests in BRCA1 and BRCA2 and preventing gynecological cancer risks has been designed and performed in the 'Virgen del Rocio' University Hospital. Clinical evidence demonstrates that BRCA1 and BRCA2 mutations can develop gynecological cancer, but genetic testing has a high cost to the healthcare system.

The developed technological architecture integrates open source tools like Mirth Connect and OpenClinica. The system allows general practitioners and gynecologists to classify patients as low risk (they do not require a specific treatment) or high risk (they should be attended by the Genetic Council), According to their genetic risk, recommending the prescription of genetic tests. The aim main of this paper is the evaluation of the developed CDSS, getting positive outcomes.

Keywords:

Clinical Decision Support Systems, Breast Neoplasms, Ovarian Neoplasms.

Introduction

Breast Cancer (BC) is the most common type of cancer in women in the western world. Besides, Ovarian Cancer (OC) ranks fifth in cancer death in women. However, difficulties in their diagnosis and therapeutic treatment imply high mortality, greater than 50% at five years from diagnosis. The International Agency for Research on Cancer estimated a worldwide incidence of 1.67 million new BC cases per year and over 0.23 million of OC [1].

The appearance of tumors of BC and OC is usually sporadic, but around 10-15% of diagnosed cases are heritable. BRCA1 and BRCA2 genes describe germinal mutations. They are inherent dominantly and with high penetrance in 7% of BC and around 11-15% of OC [2]. Therefore, BRCA1 and BRCA2 mutations increase the risk of BC and OC. Concretely, people with BRCA1 mutations have a 57% risk of developing BC and around 40% of OC. People with BRCA2 mutations have a 49% risk of developing BC and approximately 18% of OC [3-5].

Hereditary gynecologic cancer usually starts in younger people while this trend is not usual for sporadic cancer. Also, it has a more invasive histopathological pattern. However, its diagnosis is important because the result could be positive with determined treatments [6].

In this sense, to know the risk of having a hereditary cancer is essential for people with family history. Moreover, patients' anxiety and concern may be provoked if the risk stays unknown. The treatments for individual patients are different, depending on the BRCA1 and BRCA2 gene mutation. If the mutation is positive, patients will receive monitoring or preventative measures. Otherwise, patients can be relieved of anxiety. In this sense, there are some studies which demonstrated that patients are benefited by the genetic testing results [7-9]. These studies found out a significant decrease in patient concern and anxiety about developing cancer.

In clinical practice, general practitioners and gynecologists are the first in the attendance of the patient. However, the genetic tests to analyze BRCA1 and BRCA2 gene mutation have a high cost to the healthcare system. Previous studies also indicate that performing these genetic tests to the population is not cost-efficient [10]. In this sense, criteria were defined to identify patients with high risk for developing those mutations. They were agreed between the scientific society and the official organization [11]. Genetic testing is only recommended for patients with previous family and personal history. The CDSS was developed for this purpose and it will optimize the prescription and the care process avoids unnecessary patient referrals.

Besides, a recent study has assessed data privacy, security protection and health-promoting role modeling in the technology acceptance model. After controlling for several covariates, perceptions of usefulness, data privacy and security protection, and health-promoting role were all statistically significant factors that influenced the use of electronic personal health records. Those findings suggest that electronic health records users feel more protected and less concerned about privacy and security when their providers use electronic health records [12].

In this paper, this CDSS is functionally and clinically evaluated with preliminary results. Concretely, static rules defined by the Spanish Society of Clinical Oncology (SEOM) will be validated. The dimensions to be assessed are: Perceived Usefulness, Perceived Ease of Use, Social Norms, Facilitating Conditions and Intention to Use.

Methods

Specific questionnaires based on Technology Acceptance Model (TAM) were designed to measure clinical staffs' acceptance of the technology. The model was developed by David (Davis, 1989) and David et al. (David et al., 1989) and it's effective and proven in predicting the use of information and communication technologies. Besides, it has been demonstrated the leading information and communication technology (ICT) application areas for the TAM in health services: telemedicine, electronic health records, and mobile applications. The original TAM has been extended to fit dynamic health service environments by integration of components such as the theory of planned behavior and unified theory of acceptance and use of technology. Those variables frequently reflect the concepts of subjective norm and self-efficacy, but also compatibility, experience, training, anxiety, habit, and facilitators are considered [13].

In another study [14], it was found that the original TAM constructs had a significant impact on the staffs' behavioral intention to adopt HIS in paraclinical departments. The user behavior factors are essential for successful usage of the system and should be considered. It provides valuable information for hospital system providers and policy makers in understanding the adoption challenges as well as practical guidance for the successful implementation of information systems in paraclinical departments.

The TAM model is used to predict the use of technologies, based on two main characteristics: Perceived Usefulness and Perceived Ease of Use. Perceived Usefulness refers to the degree to which a person believes that using a system will improve the performance of a given job. The Perceived Ease of Use aims to assess to what degree a person believes, using a particular system, makes less effort to perform their tasks. The TAM aims to explain the causes of the acceptance of technologies by users. In that sense, it is considered that a person's perceptions of the Perceived Usefulness and Perceived Ease of Use of a system are conclusive in determining their Intention to Use it. According to this model, there are external variables that have a direct influence on the Perceived Usefulness and Perceived Ease of Use. In our study, different variants of TAM are included to evaluate different dimensions.

In order to evaluate the Clinical Decision Support System for the prescription of the BRCA1, BRA2 genetic tests in the prevention of hereditary breast and ovarian cancer, a personalized questionnaire was designed for evaluation by Gynecology based on TAM. The dimensions to be assessed in this questionnaire were: Perceived Usefulness, Perceived Ease of Use, Social Norms, Facilitating Conditions and Intention to Use.

Specifically, the items of the questionnaires assessed for ech dimension are as follows:

Perceived Usefulness

1.1. I believe that the developed system will facilitate coordination with primary care professionals in the integrated assessment of the risk of Hereditary Breast and Ovarian Cancer.

1.2. I believe that the system developed will facilitate coordination with genetics professionals in the integrated assessment of the risk of Hereditary Breast and Ovarian Cancer.

1.3. I believe that the system developed will provide professionals with a useful Clinical Decision Support System for prescribing genetic tests, unifying the criteria for information and referral, where appropriate, to genetic counseling units.

1.4. I believe that the system developed will allow people who express to their family doctor/gynecologist their concern about suffering/being able to suffer in the future from hereditary family breast/ovarian cancer because of their personal or family history, resolve doubts, diminish their worries and their level of anxiety.

Perceived Ease of Use

2.1. I think it would be easy for me to learn how to use the developed system.

2.2. I think it would be easy to acquire the necessary skills to use the developed system.

2.3. Overall, I think the developed system will be easy to use.

Social Norms

3.1. My specialty colleagues would like me to use the developed system.

3.2. My superiors would like me to use the developed system.

3.3. Genetic colleagues would like me to use the developed system.

3.4. Primary care colleagues would like me to use the developed system.

Facilitating Conditions

4.1. I think I will have the technical assistance available to solve problems associated with the developed system.

4.2. I think I will have the necessary resources to use the developed system.

Intention to Use

5.1. I intend to use the system developed for the Integrated Risk Assessment of Hereditary Breast and Ovarian Cancer.

5.2. I intend to use the system developed to manage and visualize primary care patients who are referred to as Genetic Counseling.

5.3. I intend to use the developed system to be able to visualize and know the results of the genetic tests of the patients registered in the developed system on which they decide to perform the BRCA1 BRCA2 genetic tests.

The questionnaire was designed by exchanging questions of different dimensions. Next, the correct use of the application in the departments of Gynecology and Mammary Pathology and Oncology of the HUVR was verified. Individually, in the consultations of Breast Pathology, Gynecological Oncology and in the Department of Maternal-Fetal Medicine, Genetics and Reproduction of the HUVR and the consultations of Gynecology of the Specialties Centre. Dr. Fleming from Seville.

The correct use of the application in the different computers had been checked. A training session was held with the 16

gynecologists. User manuals of the application were also provided based on the professions of the users: primary care physicians, gynecologists and geneticists. After the training, the system was validated with the defined TAM questionnaire and the results are shown in the next section.

Results

16 users completed the questionnaires. Each item is rated from 1 to 5, where 1 represents the most negative, and 5 the most positive. and NK/NA in the case of not knowing or not answering. The results are shown below:

Table 1 – Results of questionnaires

Dimensions	Item	Mean	Typical Deviation
	1.1	4,19	1,33
	1.2	4,20	1,15
Perceived	1.3	4,53	1,06
Usefulness	1.4	4,37	0,88
	Mean	4,32	0,98
	2.1	3,87	1,26
Perceived	2.2	3,85	1,21
Ease of Use	2.3	3,62	1,36
	Mean	3,71	1,23
	3.1	4,06	1,34
Social Norms	3.2	4,87	0,34
	3.3	4,25	1,36
	3.4	4,21	1,25
	Mean	4,34	0,78
Facilitating	4.1	3,47	1,50
Conditions	4.2	3,47	1,50
	Mean	3,47	1,44
	5.1	4,27	1,33
Intention to	5.2	4,60	0,91
Use	5.3	4,62	0,80
	Mean	**4,48**	0,81

The table shows the average score of each item, grouped by dimensions. It is observed that the highest score, and therefore the one that obtained the best rating from health professionals, was the Intention to Use.

On the other hand, the dimension where the professionals detected the most inconveniences was in the Facilitating Conditions. This assessment can be attributed to the learning curve of the application, given that the questionnaire was administered after training. The clinicians carried out specific questionnaires to measure acceptance, using the TAM Model, at the end of the training sessions. The results of these questionnaires are described below.

Within the Perceived Usefulness dimension, it stands out as the most valued item "*I believe that the system developed will provide professionals with a useful Clinical Decision Support System for prescribing genetic tests, unifying the criteria for information and referral, where appropriate, to genetic counseling units*" with an average score of 4,53 while the least valued was "*I believe that the developed system will facilitate coordination with primary care professionals in the integrated assessment of the risk of Hereditary Breast and Ovarian Cancer*" with an average score of 4,19. However, this item was also rated positively, taking into account that the maximum value of the scale is 5.

Within the Perceived Ease of Use dimension, it stands out as the most valued item "*I think it would be easy for me to learn how to use the developed system*" with an average score of 3,87 while the least valued was "*Overall, I think the developed system will be easy to use*" with an average score of 3,62.

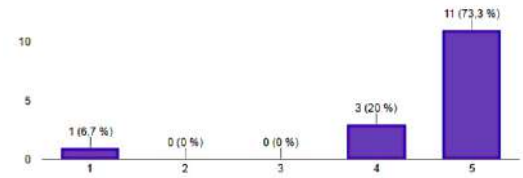

Figure 1 – "I believe that the system developed will provide professionals with a useful Clinical Decision Support System for prescribing genetic tests, unifying the criteria for information and referral, where appropriate, to genetic counseling units" (NK/NA: 1 user)

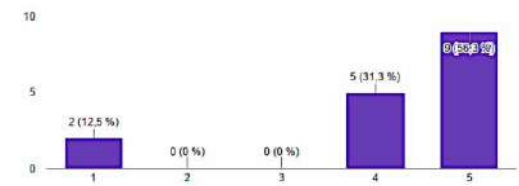

Figure 2 – "I believe that the developed system will facilitate coordination with primary care professionals in the integrated assessment of the risk of Hereditary Breast and Ovarian Cancer"

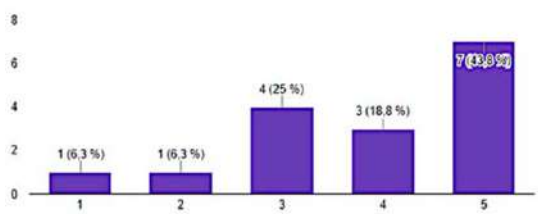

Figure 3 – "I think it would be easy for me to learn how to use the developed system"

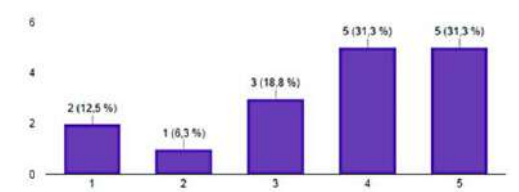

Figure 4 –" Overall, I think the developed system will be easy to use"

Within the Social Norms dimension, it stands out as the most valued item "*My superiors would like me to use the developed system*" with an average score of 4,87, while the least valued item was "*My specialty colleagues would like me to use the developed system*" with an average score of 4,06. However, this item was also rated positively, taking into account that the maximum value of the scale is 5.

Within the Facilitating Conditions dimension, the two items scored an average score of 3,47.

Finally, within the Intention to Use dimension, the most valued item is "*I intend to use the developed system to be able to visualize and know the results of the genetic tests of the patients registered in the developed system on which they decide to perform the BRCA1 BRCA2 genetic tests*" with an average score of 4.62 while the least valued was "I intend to use the system developed for the Integrated Risk Assessment of Hereditary Breast and Ovarian Cancer" with an average score of 4.27. However, this item was also rated positively, taking into account that the maximum value of the scale is 5.

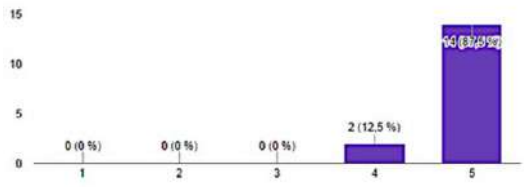

Figure 5– "My superiors would like me to use the developed system"

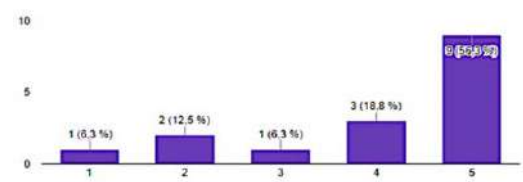

Figure 6 – "My specialty colleagues would like me to use the developed system"

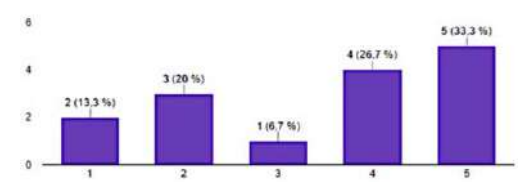

Figure 7 –" I think I will have the technical assistance available to solve problems associated with the developed system" (NK/NA: 1 user)

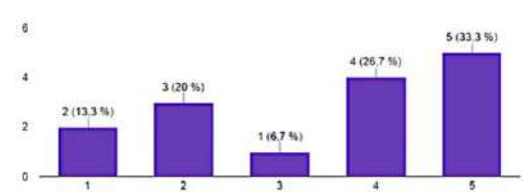

Figure 8 –" I think I will have the necessary resources to use the developed system" (NK/NA: 1 user.)

Discussion

The dimension of the questionnaires that obtained the best rating from health professionals was the Intention to Use. Therefore, this score is relevant for predicting the future use of the developed tool in this project. Within the Intention to Use dimension, the most valued item was "*I intend to use the developed system to be able to visualize and know the results of the genetic tests of the patients registered in the developed system on which they decide to perform the BRCA1 BRCA2 genetic tests*" with an average score of 4.62, meaning other items of this dimension also rated positively.

Besides, the dimension where the professionals detected the most inconveniences was in the Facilitating Conditions, due to the learning curve of the application, given that the questionnaire was administered after training. The two items scored an average score of 3,47, and these scores could be improved. For instance, guaranteeing and providing the required technical assistance and the necessary resources to use the developed system.

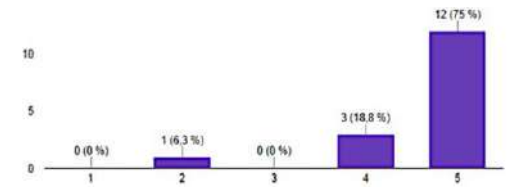

Figure 9–"I intend to use the developed system to be able to visualize and know the results of the genetic tests of the patients registered in the developed system on which they decide to perform the BRCA1 BRCA2 genetic tests"

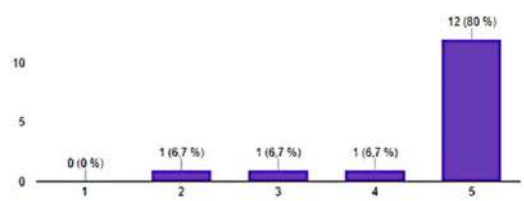

Figure 10 – "I intend to use the system developed for the Integrated Risk Assessment of Hereditary Breast and Ovarian Cancer" (NK/NA: 1 user)

Finally, other dimension with a low score is Perceived Ease of Use, where stands out as the most valued item "*I think it would be easy for me to learn how to use the developed system*" with an average score of 3,87 while the least valued was "*Overall, I think the developed system will be easy to use*" with an average score of 3,62. So it is essential to promote the realization of training sessions and the use of user manuals. Besides, these items rated positively, taking into account that the maximum value of the scale is 5.

In general, the results of the questionnaires show favorable and positive feedbacks. Therefore the use of the developed system is recommended to clinicians for supporting the prescription of genetic tests in the gynecological cancer risk.

According to analysis of the feedbacks, the developed CDSS will be useful for clinical practice. As a result, a tool adapted to the needs and preferences of clinicians, who have also formed part of the project's research team for the definition of requirements, the design of the tool and the implementation of clinical knowledge in the CDSS, has been achieved.

We are working on the development of Artificial Intelligence and Data Mining algorithms. So that through these predictive algorithms can potentially improve the recommendations following the guidelines of the SEOM for the prescripting genetic tests, since currently there are a high percentage of patients, who were prescribed the test and the result turned out

negative. In this way, the system will evolve into a learning healthcare system.

Predictive models are using information collected in electronic medical records, in addition to that referred to in clinical guidelines, to develop more efficient algorithms, with greater precision in prescribing the genetic tests. In this way, we are analyzing the set of variables relevant to this prescription, as well as their association with the target variable.

Conclusions

In this study, a CDSS for prescribing the genetic tests in BRCA1 and BRCA2 and preventing gynecological cancer risks was designed and evaluated in the Virgen del Rocío University Hospital. The developed technological architecture allows general practitioners and gynecologists to classify patients as low risk (who are not required a specific treatment) or high risk (who should be attended by the Genetic Council). Also, it provides recommending related to prescription of genetic tests and their genetic risk of suffering gynecological cancer.

An evaluation of the developed CDSS, for usefulness perceived by clinicians, the perceived ease of use and the intention to use, was also carried out and the results showed positive feedbacks.

Abstract

Health information exchange (HIE) is seen as an essential technology for improving health care quality and efficiency by allowing exchange of patient-centered data over time and across organizations. The objective of this study was to evaluate the usage and the perceived usefulness of a nationwide HIE in a centralized model that was implemented in 2013 in the province of Quebec, Canada. A mixed-method study was conducted with a longitudinal descriptive analysis of usage data combined with in-depth comparative case study in four selected primary care organizations and two emergency departments. Perceived benefits were reported by users across all dimensions of care performance, including accessibility, efficiency, quality and safety, and patient experience; however, the experience of users was very heterogeneous and strongly associated with the commercial electronic record system available in their work place and the implementation strategy.

Keywords:

Health Information Exchange; Electronic Health Records; Quality of Health Care

Introduction

Allowing for information exchange along the care continuum is seen as an essential component of a high quality and efficient health care system.[1,2] Around the world, many jurisdictions have implemented standards or systems to allow for this electronic exchange to be possible.[3] In short, two types of models are emerging: on one hand, the centralized model, with national or regional shared records that are available to authorized providers and/or patients in various fashions, such as in Finland and Sweden, and on the other hand, the federated model, where individual organizations share information based on exchange protocols, as is done in the United States.[4] The information available for exchange is highly variable from one jurisdiction to another and ranges from imaging information to hospital discharge summaries.[5] In primary care, where care is by definition anchored in the patient's life, information continuity is particularly challenging, and the promised benefits of HIE are especially important. For example, a study conducted in the state of New York demonstrated that when a general practitioner accessed the regional HIE in the 30 days following the hospitalization of one of his or her patients, the risk of readmission for the same problem as the original hospitalization dropped by 57%.[6]

In Canada, Quebec was the first province to implement a province-wide HIE in a centralized model, starting with medication, laboratory, and clinical imaging information. The objective of this study was to evaluate the usage and the usefulness perceived by users in primary care with this system, 2 years after its full implementation.

Design of the System and Available Features

The Ministry of Health manages the HIE in Quebec by for the entire healthcare system. It was built as a pull model, with central data warehouses, where every authorized provider is allowed to access and retrieve data depending on local certifications. All residents of the province (estimated population 8.2 million) are identified using their unique health insurance numbers. A secure connection between retail pharmacies, medical clinics, laboratories and diagnostic imaging centers allows for information to be transmitted to central warehouses.(for a detailed description of the medication domain, see a previous study [7]) A number of options are available to clinicians to access this information depending on the tools available at their work sites. Clinicians can use their electronic medical record (EMR) application if it was certified by the Ministry for interoperability. Ten different EMRs were certified in 2018, nine for primary care providers (outpatient EMR, O-EMR) and one for hospital-based providers. Alternatively, a web-based Viewer application can be used that was developed by the Ministry of Health and enables data access without EMR application. To access an individual patient's information through the Viewer, users need a certificate of security that was provided by the Ministry of Health on a USB device, combined with a password. As of Jan 2018, devices were distributed to 53,000 individuals in the province.

Users who access data through their EMRs are able to both view the patient's information, and import it, in a more or less structured format depending on the type of information and the commercial EMR they are using; however, users accessing data through the web-based Viewer only have the ability to view and print the patient's information.

Methods

Study Design and Data Collection

A mixed-method concurrent study was conducted, from January 2016 until December 2017. First, a descriptive analysis of usage was performed, using audit trails on accesses to the HIE obtained from the Ministry of Health. Information available for each access to the HIE included user ID, date, user role (e.g. physician, nurse, pharmacist), and which tool was accessed the HIE (e.g. Viewer, EMR1, EMR2). Second, an in-depth comparative case study was conducted, where a case was defined as a medical clinic or an emergencey department, where

clinicians declared using the HIE regularly. Purposeful selection of cases was performed in an exploratory phase, where the criteria for selection was clinicians' regular system usage that was assessed using usage data combined with exploratory interviews with stakeholders in the province. In each targeted organization, the manager was invited to participate and to invite clinicians to an interview and an observation session. All clinicians (nurse, physician and pharmacist) were invited per site. Table 1 describes the cases selected, as well as the participants in each case. After consent was obtained, semi-structured interviews were conducted with users (24 general practitioners, eight nurses, nine pharmacists) following an interview guide with open questions about their usage of the HIE, their satisfaction, and their perception of the usefulness of the system in relation to their daily activities. Observation sessions were also organized at each site to complete interviews and describe usage practices.

Data Analysis

Adoption was estimated using the number of actual users compared to the potential number of users, per role. A user was defined as an individual who accessed the HIE at least once in October 2017 (this month was selected as a typical month of usage because individual users could not be followed during the whole study period due to replacement of user IDs without mapping between old and new IDs). Descriptive statistics on the proportion of potentially authorized users who actually accessed the HIE was calculated, according to the users' roles. The proportion of users accessing the HIE by tool was also calculated in Oct 2017 to describe usage. Finally, to describe the level of use for each data domain, the number of accesses to each domain was calculated by user for each week in 2017.

All audio files were transcribed verbatim, and thematic content analysis was performed using the framework proposed by Lau and colleagues (quality of the information and the system, usage patterns, perceived usefulness) [8]. Emerging codes were also allowed until saturation of the findings. Preliminary reports were shared with the participants at each site, and their comments were included in the final analysis. Adoption and level of use were combined with case study results to analyse the users' experience. The ethics committee of the Centre Hospitalier de l'Université (CHU) de Québec and McGill University approved this project.

Table 1 – Organizations Selected and Participants at Each Site (GP=General Practitioner; phm = Pharmacist; nurse = Clinical Nurse or Nurse Practitioner, ED = Emergency Department)

Site	Tool available for HIE usage	Participants
Family health team 1 - Urban region A	O-EMR 1 + Viewer	9 GPs, 1 nurse, 1 phms
Family health team 2 - Rural region	O-EMR2 + Viewer	3 GPs, 2 nurses, 1 phms
Family health team 3 - Urban region B	O-EMR3 + Viewer	3 GPs, 1 nurse, 1 phms
Family Health Team 4 - Urban region A	O-EMR4 + Viewer	3 GPs, 3 nurses, 1 phms
ED Academic Health Center 1 Urban region A	Viewer	2 GPs, 3 phms
ED Academic health center 2 Urban region A	Viewer	4 GPs, 2 phms, 1 nurse

Results

Usage of the HIE

Adoption

Table 2 presents the number of users compared to the potentially authorized users per role. Overall, adoption was higher in primary care, where the vast majority of pharmacists (78%), general practitioners (74%) and nurse practitioners (72%) in the province accessed the HIE in October 2017. Interestingly, only 26% of specialists accessed the tool. The Viewer was used by 89% of users in October 2017, while only 17% of users accessed the HIE using an interoperable EMR (Table 3). While more than 90% of GPs in the province have access to an interoperable EMR in their workplace, only 50% of GP users accessed the HIE using their O-EMR, while 74% of GP users accessed the HIE using the Viewer, indicating that a rudimentary adoption of the HIE is high, while the adoption of more advanced features linked to HIE integration still needs to be improved. Finally, only 12 % of specialist users accessed the HIE using an integrated EMR.

Table 2 – Number of Users by Role in Oct 2017

Role	N potential users[1]	N Actual users (%[2])
Physicians (total)	**20,052**	**9,612 (48%)**
General practitioners	9,503	6,992 (74%)
Specialists	10,239	2,620 (26%)
Pharmacists	**9,212**	**7,162 (78%)**
Nurses (total)	**74,469**	**8,762 (12%)**
Nurse practitioners	413	297 (72%)
All roles	NA	**31,915**

[1]Data obtained from the annual reports of the respective professional associations; [2]actual users / potential users

Table 3 – Number of Users by Tool, Selected Roles in Oct 2017

Role	N users[1] (%[2])	
	EMR	Viewer
General practitioners	3,496 (50%)	5,187 (74%)
Specialists	309 (12%)	2,428 (92%)
Pharmacists	102 (1%)	6,790 (94%)
Nurse practitioners	146 (49%)	232 (78%)
All roles	**5,571 (17%)**	**28,395 (89%)**

[1]Users may have accessed with more than one tool (sum >100%) Access with a pharmacy management system is not presented; [2]=N users with this tool / N actual users with this role (table 2)

Level of Use

The medication domain was the one with the highest number of weekly accesses by physician users, in comparison to the lab and imaging domains, with an average of the mean number of weekly accesses per user of 21 for meds, six for labs and seven for images. Figure 1 presents detailed weekly accesses by tools, per domain. For the medication domain (Fig 1A), the number of weekly accesses using an outpatient EMR (O-EMR) was higher when compared to the Viewer and an EMR in the acute care setting (mean ± SD : 35 ± 4 vs 17 ±1 vs 10 ±1 respectively). This was aligned with the available feature of the O-EMR confirmed with the case study, where only these tools in outpatient settings had the availability of the most advanced feature for importing granular medication data from the HIE, to be reused for clinical activities, such as generating a new electronic prescription. In the lab domain (Fig 1B), the level of use was similar for O-EMR and Viewer, and lower for EMRs in the acute care setting. For images (Fig 1C), the level of use

was higher using the Viewer application. This might be related to the fact that the image was only accessible using the Viewer application, while O-EMR and EMR only provided access to the report.

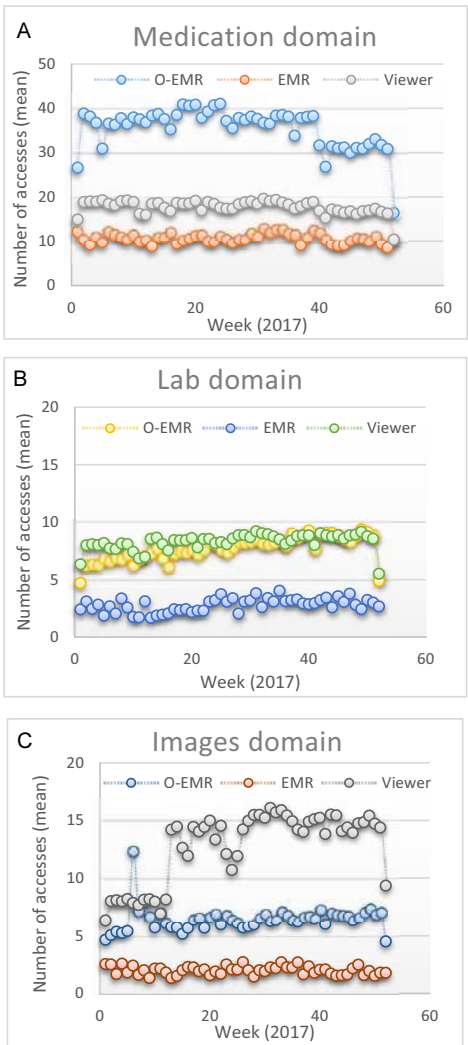

Figure 1. Level of Use of Each Data Domain of the HIE by Physician Users in 2017, by Tool Used to Access the HIE (O-EMR = Outpatient Electronic Medical Record; EMR = Electronic Medical Record) (Scale for Graph A is Different)

Perceived Benefits in Primary Care

Benefits associated with HIE usage were identified across all cases, by a comparative analysis, highlighting differences and similarities among and between cases. Interestingly, perceived benefits were similar across cases, and rapidly saturated in terms of how using the HIE impacted care quality, productivity, and the experience of patients. The diversity of perceived benefits was great and aligned with what is already documented with such clinical information sharing in other settings.[9–11] They were also aligned with the expectations associated with the implementation of the HIE.

Overall, the added value seemed greater for medication information, while this was the only source of information in all cases visited. On the other hand, in the lab and imaging domains, the added value depended on the regional organization and available tools in the workplace. Indeed, other systems in place in some regions for electronically sharing this information were making a difference.

To be precise, perceived benefits were reported across all dimensions of care performance : productivity, quality and safety, accessiblity, and experience of patients (Table 4). According to users, these benefits are actualized, because the information accessible through the HIE is of greater quality: more complete, more reliable, more valid and available when needed. For productivity, clinicians perceived that using the HIE reduces delays related to clinical information management (e.g. receive active medication list, lab results or imaging reports by fax), thus reducing delays for patients, reducing duplication of exams, and dedicated (avoidable) resources. Then, the users perceived that the quality and safety of care was improved, thanks to a better informed clinician, who is more confident about the clinical judgement based on a more accurate portrait of the patient, thus reducing errors and improving continuity. Similarly, the participants perceived that access to care was improved, in particular for general practitioners, who mentioned that they were less reluctant to register complex or vulnerable patients who became less difficult to follow with this kind of tool facilitating care coordination through clinical information sharing. Finally, some clinicians reported that the experience of their patients was improved, particularly in relation to timely access to information and reduced unnecessary visits.

Table 4. Perceived Benefits Associated with HIE Usage

Productivity
↓ Delay in getting information
↓ Delay in receiving results
↓ Duration of visits
↓ Duration of care episodes
↓ Duplicate exam
↓ Avoidable visit
Quality and security
↑ Confidence in decision making
↓ Errors
↑ Appropriateness of care
↑ Continuity and coordination of care between the team members and different heathcare organizations
Accessibility
↑ Volume of patients
↓ Waiting time
↑ Management of vulnerable and complex patients who consume healthcare services
Patient experience
↑ Relationship with clinicians and teams
↑ Comprehension and involvement
↓ Unnecessary visits and wait times
↑ Satisfaction

Legend : ↑ = Improve or Increase; ↓ = Decrease

A Very Heterogeneous Journey

However, the experience of users, a mediating factor in the actual level of use and persistence over time, was highly heteronegeous and closely associated with the commercial tool available on the work site, as well as the implementation strategy. While in some organizations (family health team 1 (FHT1) and FHT2), using the HIE was reported as easy and was highly integrated in the daily activities, in some other organizations (FHT3, FHT4, ED1, ED2), using the HIE was

only motivated by certain specific situations, where the added value was high enough to compensate for the efforts and irritants reported by users to access and integrate the clinical information from the HIE in routine clinical activities. The main barriers were related to the completeness of the information, the usability of the applications, the performance of the system (e.g. some long periods of shut downs), and the process for access (a pull system requiring a USB device on a physical desktop) not well aligned with the fluid nature of care.

When is Using HIE Worthwhile?

In the ED, the added value was clear and very high, for almost every patient but especially when the patient was unconscious, unable to communicate for various reasons, or when the clinician had a doubt about the veracity of the story from the patient; however, both EDs had access to the HIE only through the Viewer application, with limited integration into their work flow and basic features of viewing information. In medical clinics (family health teams), the added value was particularly high for patients with chronic conditions, navigating through the health care system with a long trajectory requiring clinical information sharing or for walk-in clinics when patients were not known.

Discussion

To our knowledge, this is the first study conducted with HIE users in Canada. While evidence of HIE positive outcomes are growing [12,13], it is important to deepen our understanding of the different systems, and associated users' experience across different jurisdictions. The actual experience of users, and thus the potential outcomes, are highly related to the availability of given features, and their levels of use by many health care professionals, in a given setting.[14] Our results highlight the fact that one dimension needs to be deepened when studying HIE, namely the integration within the main tool used by healthcare professionals, i.e. the commercial electronic record available in their work place. While a recent systematic review conducted by Menachemi and colleagues [13] highlighted the fact that most studies with positive outcomes were associated with American community HIEs, one should consider what it means in terms of newly available information, and the actual features available for a given clinician, in a particular setting. As already described by Opoku and colleagues in the US, this is strongly associated with the health care system organization, and underlying systems [15]. Nonetheless, what this means in other jurisdictions is poorly described. This is where this study makes a contribution by deepening the description of an HIE in Canada.

First, adoption was higher in primary care, with almost three quarters of general practitioners, pharmacists and nurse practioners in the province accessing the HIE. Moreover, perceived usefulness by clinicians in family health teams and emergency departments was important, with a diversity of benefits identified by users. The added value seemed significant for clinicians in these cases, even if some barriers were mentioned as to the quality of information and of the system. This relates to previous studies in Finland [9], New York state [6,8–10], and Midwestern states [16], highlighting the benefits of HIE especially for primary care providers, and emergency department physicians.

On the other hand, a lower adoption rate by specialists was observed, which may be related to many factors. First, most of these physicians work in hospitals, where the availability of an integrated EMR with an HIE is scarce, and most clinicians only have access to the Viewer application to access the HIE. In fact, most hospital centers in the province do not have an advanced EMR available, and paper charts are still the norm as the basis for the integration of clinical information. Moreover, the added value of the HIE is lower in acute care centers, because what you can do with the Viewer application is very basic : view and print clinical information. While very useful in the emergency department, to complete the medication list, and review lab results and imaging reports from other organizations, as a way to get a quick overview of a patient and his or her recent care episode, it does not seem to be enough for specialists to access the system in their usual patient care. Furthermore, the performance of the system for viewing images is not satisfactory for diagnostic purposes, and the PACS (picture and archiving communication system) already available on a regional basis in the province reduced the added value of the HIE.

Interestingly, the HIE in the province of Quebec was the first clinical information system integrating information between primary care and acute care settings, and integrating information between private and public organizations. In Quebec, most hospitals are publicly owned, and clinicians practicing within these organizations have access to some form of an integrated system while all pharmacies are privately owned, and about 30% of lab centers and imaging centers are private organizations.

Overall, it is important to note that HIE is a generic term to describe clinical information sharing, but what is shared, and how it is integrated into clinical and cognitive workflows, are crucial to benefit actualization. This study is one step ahead on this road in that it highlights the fact that the **added value** associated with HIE needs to be considered **in comparison** to other available systems in a given setting. In other words, two main questions need to be considered around such systems: 1) what it adds to what is already known about a given patient (quality of the information); 2) how easy and quick it is to use the clinical information from the HIE versus the other available systems (quality of the system).

This study has a few limitations. First, only a few cases were selected in three regions of the Province (out of 18), thus limiting the external validity of the findings. While triangulation of data sources and types allowed us to present interesting findings, further research is needed to deepen our understanding of the actual practices in a more diverse sample of work sites. Moreover, this study was conducted in the early phases of the implementation of the integrated EMR/HIE features. Some users were not very familiar with these features when we visited their work site, and further research should investigate routine practices when users are more experienced with their interfaces.

Conclusions

This study was able to describe the level of use of the HIE at the scale of the whole system in the province of Quebec, and characterize the perceived usefulness for clinicians using the system. Interestingly, the adoption is higher in primary care and at the emergency department, where the added value of the system is higher. Further research is needed to deepen our understanding of the heterogeneity of usage practices of the HIE, particularly with different commercial EMR and their specific integration features, as well as the various factors associated with perceived usefulness and outcomes actualization.

Abstract

Electronic prescribing, defined as the electronic generation and transmission of a medication order for community-dwelling patients, is presented as an essential technology to improve medication use. The objective of this study was to evaluate a nationwide e-prescribing system in Quebec, Canada. A mixed-method study was conducted from July 2017 until June 2018. A descriptive analysis of e-prescription usage was performed using aggregated usage data, combined with an exploratory descriptive analysis of the e-prescribing system from the perspective of users of two electronic health records (EHR) and pharmacy management systems (PMS) (n=9 prescribers; 8 pharmacy technicians and 11 pharmacists). Overall, the adoption of the system was low, with only 2% of prescriptions being electronically transmitted and retrieved during the study period. Alignment problems were identified on the prescriber's and receiver's side, generating safety issues, and hindering the potential for benefits realization.

Electronic Prescribing, Medication Adherence, Health Information Technology

Introduction

Improving safety and quality of medication use in primary care is a priority, both for clinical and economical reasons. For more than two decades, electronic prescribing (e-prescribing) has been presented as an essential technology to support clinicians and patients towards this goal[1]. While the technology may differ by jurisdictions, the terms e-prescribing usually refers to any computerized system used to generate and communicate information related to medication prescriptions for community-dwelling patients[2]. The opioid epidemic, off-label use, polypharmacy and potentially inappropriate medications are examples of clinical issues that are promised to be resolved, or reduced, with e-prescribing[3.4]. Many jurisdictions around the world have implemented nationwide e-prescribing systems, including the generation of a prescription using a computer system (with or without a clinical decision support system), and the electronic transmission of the prescription to the dispensing pharmacy. European countries are leading the way, with Finland, Denmark and Sweden at almost 100% of the outpatient prescriptions being transmitted electronically[5–7].

While it is already known that e-prescribing can support the decision making processes of clinicians, and reduce legibility and transcription problems, it is also known that it can create new problems and errors at all steps of the medication management process[8–10]. Precisely, issues with the design of the e-prescribing feature have already been described, leading to e-prescriptions of highly variable quality[11], while the transmission and reception models are heterogeneous in different jurisdictions, and pose various issues for the pharmacy work processes[12,13].

In Quebec, a nationwide e-prescribing system was implemented in 2013, in a central pull model, connecting all primary care electronic record systems with pharmacy management systems for electronic transmission of the prescriptions. The objective of this study was to evaluate the system after its full implementation, focusing on the adoption of the system in the province, and its quality for improving the prescribing and dispensing processes in primary care.

Methods

Description of the e-Prescribing System

The e-prescribing system is managed by the Ministry of Health, and is constituted of a central repository of e-prescriptions that are generated from certified electronic health record (EHR) systems, and then accessible to certified pharmacy management systems (PMS) in the province for importation and execution in pharmacies. All prescribers (e.g. general physicians, nurse practitioner) using a certified EHR system can use their local e-prescribing feature to generate an e-prescription, that is then validated when transmitted to the central e-prescription repository. Pharmacists and their team can then log-in to the central repository for a given patient, and import e-prescriptions in their local PMS to dispense the medication. The system uses a national index registry for patient identification, and Drug Identification Numbers (DIN) as the index for medication identification. DINs are managed by Health Canada and issued for every medication that receives approval to be marketed in Canada. They uniquely identify the product name, the active ingredient, the manufacturer, the strength, the pharmaceutical form, and the route of administration. At the time of the study, only EHR and PMS in the outpatient setting were certified for connection with the e-prescription repository. No feature was designed for the patients. Details on the system have been described elsewhere[14].

Data Collection and Analysis

A mixed-method study was conducted in parallel, from July 2017 until June 2018. First, a descriptive analysis of usage of the e-prescribing system was performed, using aggregated usage data provided by the Ministry of Health. Information available included the number of prescriptions dispensed by all retail pharmacies in the province, to all citizens with a health insurance number (mandatory), the number of electronic prescriptions (eRx) sent by prescribers using a certified EHR system, and the number of eRx retrieved by pharmacists, by region and in the whole province (population approximately 8 million inhabitants). Adoption was estimated by calculating the proportion of eRx compared to the total number of prescriptions dispensed, per month. To triangulate these observations, one pharmacy was visited to manually gather all prescriptions

executed within a typical week, and classify them per type (manuscript vs electronic). The proportion of prescriptions of each type was calculated per day.

Second, an exploratory descriptive study was conducted by interviewing and observing users of the e-prescribing system, both on the prescribing and receiving sides. Purposeful selection of high users was performed based on the declared regular usage of the system, specifically in regions targeted for their high adoption of e-prescribing (based on usage data). Two commercial EHR systems and 5 PMS were analyzed (details on participants are presented in Table 1).

On the prescriber side, frequent e-prescribing users were invited to participate to an interview and an observation session using think aloud protocols around defined prescribing scenarios. Semi-structured interview guide was elaborated to describe their usage of the system, their work process, and their experience with using the system on a daily basis. Moreover, typical scenarios were designed from previous studies[15], to identify problems related to the e-prescribing feature, including all steps of the process (medication review and reconciliation, medication selection, validation and transmission of the e-prescription[16]. Users were encouraged to "think aloud" and verbalize their thoughts as they were completing the scenarios. Their screen and voice were then recorded. Seven physicians and 2 nurses participated (See Table 1).

On the pharmacy side, all users (pharmacists and pharmacy technicians) of the PMS in a given pharmacy were invited to participate. A convenient sample of prescriptions was executed while the screen and the voice of the user were recorded. Semi-structured interviews were also conducted with users, including open questions about their usage of eRx, their work process, and their experience with using the system on a daily basis. Overall, 11 pharmacists and 8 pharmacy technicians participated (see Table 1).

Audio files were transcribed. Verbatim and thematic content analysis was performed to describe the flow of each step of the process, and identify alignment problems per step of the process. Videos were used to confirm the problem identified as described previously[17]. Emerging codes were allowed, until saturation of the findings. This project was approved by the ethics committee of the Université de Montréal, and all participants consented before their participation.

Table 1 – Data Gathered

Systems	Participants
PMS A	1 pharmacist 4 technical assistants
PMS B	4 pharmacists 4 technical assistants
PMS C	3 pharmacists
PMS D + E	3 pharmacists
EHR A	4 physicians
EHR B	3 physicians 1 nurse practitioner 1 nurse

Legend: PMS = Pharmacy management system; EHR = Electronic Health Record

Results

Adoption

The number of eRx sent and retrieved by all prescribers and pharmacies in the province are presented in Figure 1, and compared to the total number of prescriptions dispensed in retail pharmacy during the study period (target for eligible prescriptions). The total number of eRx sent represented on average 13% of all prescriptions dispensed during the study period (10% in July 2017, and 14% in March 2018). Hence, the adoption was low on the prescriber side, with a total number of individual clinicians sending eRx varying from 2,397 clinicians in July 2017, to 3,946 clinicians in March 2018 (while the potential is more than 10,000 clinicians, including general practitioners and nurse practitioners).

In terms of pharmacy, this observation is reflected in the fact that the vast majority of prescriptions that were received were not electronically transmitted (Table 2). When analyzing the characteristics of all prescriptions dispensed in a typical pharmacy, we observed that while 55% of all new prescriptions were created through an EHR, only 35% were actually transmitted electronically. This means that 20% of prescriptions were generated by using an e-prescribing system, but were printed instead of electronically transmitted. Interestingly, almost one fourth of all prescriptions (23%) were still manuscript in this pharmacy located in the region with the highest rate of adoption of eRx in the Province. This suggests that even if the adoption of EHR in primary care in Quebec has increased, the adoption of the e-prescribing feature is lagging.

Moreover, the level of use is low in pharmacy, where only 2% of prescriptions were actually received electronically on average during the study period. When compared to the eRx that were sent, only 16% were retrieved by pharmacists, leading to the vast majority of eRx "sleeping" in the central e-prescribing repository (which will be deleted after two years).

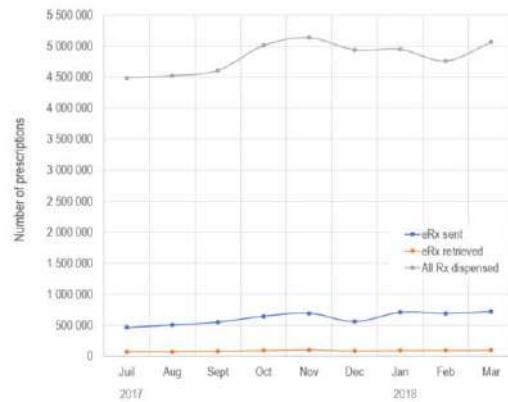

Figure 1 – Level of Use of e-Prescribing in Quebec

Problems on the Prescribers' Side

The main problems that were identified on the prescriber's side were related to the following features: a) design of the medication order; b) the absence of clinical decision support including information about the dose and the characteristics of patients (except allergies); c) the absence of a feature for electronic prescription requests; d) the systematic printing of a paper copy of the prescription.

Table 2 – Proportion of Prescriptions Executed in a Typical Pharmacy During Five Consecutive Weekdays, per type (in June, 2018)

Type of prescriptions	Total	Mean (SD) per day	%
Manuscript	99	20 (7)	23%
Printed form	27	5 (3)	6%
Fax	63	13 (4)	15%
EHR-printed	84	17 (5)	20%
EHR-electronically	149	30 (14)	35%
Verbal	8	2 (1)	2%
Total	430	86	100%

a) First, the design of the medication order were all based on a product-based design using DINs (Fig 2A). Here, the product refers to what you can take in your hand as a patient (e.g. tablet of 500 mg of acetaminophen made by Apotex). The product includes information about the brand, the pharmaceutical form (e.g. tablet, liquid, inhaler), the molecule that is aimed to be administered (e.g. acetaminophen) and the amount of the molecule within this product (or the strength, e.g. 500 mg). This type of design requires the user to select the product (e.g. Apo-acetaminophen comp. 500 mg), and the instructions are built using the number of "unit" the patient has to take, based on the formulation of the product (e.g. 2 tabs). In contrast, the molecule-based medication ordering (Fig. 2B) would require the prescriber to select a molecule and its route, following by the dose and the frequency. The problems we identified with the product-based design were the error-prone selection of the medication, because the list of products was long, and was not up to date. For example, all clinicians were wrongly able to validate the order of a product that is not on the market anymore in Canada (Lasix™) (Fig 3A1).

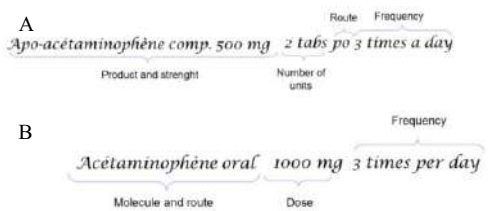

Figure 2 – Product-Based Design of the Medication Order (A) Observed, Compared to the Molecule-Based Design (B)

b) Second, no system had clinical decision support integrating information related to the dose, or the characteristics of the patients (such as age or diagnostic). Consequently, all clinicians were wrongly able to validate a prescription at a lethal dose, for example if they thought it was for an adult and it was actually for a child. The absence of structured and standard information required for intelligent alerts was limiting the utility of the decision support feature from the point of view of prescribers (Fig 3A2).

c) Third, the feature for requesting prescription repeats, from pharmacists or from patients, was not available. Patients would need to call their prescribers, and pharmacists would need to send paper requests by fax to get repeats of an ongoing prescription. This was seen as a major irritant by most prescribers and pharmacists interviewed, given the volume of transactions it generated per day. Moreover, a safety issue was associated with this situation, because most prescribers would not add this paper prescription to their electronic record, and would simply manually sign the request, and send it back to the pharmacy. The electronic record of patients would then become incomplete (Fig 3A3).

d) Finally, the last problem was due to systematic printing of a paper copy of the prescription when the electronic transmission was validated. Consequently, it was not infrequent that prescribers would manually modify the paper copy or a writable PDF form that was created before printing, while the electronic copy would remain unchanged (Fig 3A4). This creates a major safety issue because two copies of the same prescription would then exist. An unclear legal status for the electronic prescription seemed to have led to this situation, where vendors and prescribers were being told that they had to print a paper copy, and pharmacists, that they have to wait for the paper prescription to be allowed to retrieve the eRx.

Problems on the Receivers' Side

The main problem in pharmacy was related to the fact that the execution of a prescription always began with a paper copy of the prescription (Fig 3B1). Pharmacy staff were not informed when an electronic prescription was available for one of their patients, given the design of the system that was developed without a feature for allowing a push or an alert to an assigned pharmacy. The only way for pharmacists to know that an electronic prescription was available was a sign (a logo or a number depending on the EHR) on the paper copy of the prescription. Moreover, in three (out of 5) pharmacy systems, viewing eRx for a given patient would require the staff to execute a request, while in two other pharmacy systems, eRxs for a given patient would be visible from the summary page of the patient record without a specific action. Moreover, because most prescriptions were not electronic, pharmacy staff struggled to adapt their process to a relatively "rare" event.

At the second step of the process, when the eRx repository was accessed, the first problem was associated with the absence of visual aid or code to target medications associated with the same order (Fig 3B2.1). For pharmacy staff, this would mean that they had to be carefully reviewing the list of medications in the repository (that can be long given the low adoption on the pharmacy side) to select precisely the ones that they would need to import. Because orders are chronologically ordered in the repository, this created confusion for some participants. Even though batch importation of many medications was possible with some systems, it was not the case in all of them, constraining the execution process at the pharmacy (Fig 3B2.2).

Once all medications would have been imported in the local pharmacy system, the auto-population of the different fields of the prescriptions was problematic (Fig. 3B3). For all prescriptions, at least one field had to be manually modified, namely the instructions, that were free text (even if initially structured in the prescriber's EHR system). A manual copy-paste of the instructions, from the eRx to the pharmacy system, was possible in some PMS, but not all. For other fields, such as medication ID, prescriber ID, quantity, refills, and duration, manual modifications were also frequent, indicating a lack of standardization. Moreover, it seemed that manual modifications were more frequent with some pharmaceutical forms or some type of prescribers: while capsules and tablets were usually correctly auto-populated in the PMS, other pharmaceutical forms (inhalers, injectables, drops, creams) seemed to create problems more frequently. Similarly, while physicians as a prescriber were generally correctly auto-populated in the PMS, residents, nurse practitioner and nurses seemed to generate more manual modifications in the local pharmacy system for the prescriber ID field.

Finally, the last problem identified for the validation in the PMS was the absence of a visual representation of the original eRx, that is required by pharmacist in the final step of the validation process (Fig 3B4). More problematic, one PMS had no

inalterable version of the eRx available, leading to an impossibility for the pharmacist to know if the staff had manually changed any field during their execution process, a shortfall creating an important risk of error.

Overall, the execution of a prescription using the paper copy was generally perceived as quicker and easier for pharmacy staff, while they recognized that a printed (electronic) prescription was easier to read than a manuscript prescription.

Discussion

To our knowledge, this is the first study to evaluate an e-prescribing system fully implemented in Canada, both from the prescriber and the receiver's sides. While the potential for positive outcomes associated with computerized provider order entry (CPOE) for medications have been demonstrated in some settings, many safety issues have been documented[16,18,19]. Our study adds to this literature by highlighting some specific challenges hindering adoption and increasing the risk of technology-induced errors in the medication management process.

First, our results suggest that the misalignment between the system and the prescribing and dispensing processes were numerous, with no simple workarounds for users. Second, the implementation of the transmission feature was still not completed, hindering the potential for benefits at various steps. Third, the quality of e-prescription needs to be improved, and safety issues were identified both by prescribers and pharmacists using the system with their respective EHR or PMS. Consequently, the level of use of the system was low, with only 2% of prescriptions being electronically transmitted and retrieved in pharmacy. Overall, the low adoption of e-prescribing that was observed in this study is probably essentially related to the poor quality of the system from the user's point of view, both on the prescriber's and the receiver's side.

On the Incomplete Implementation of the System

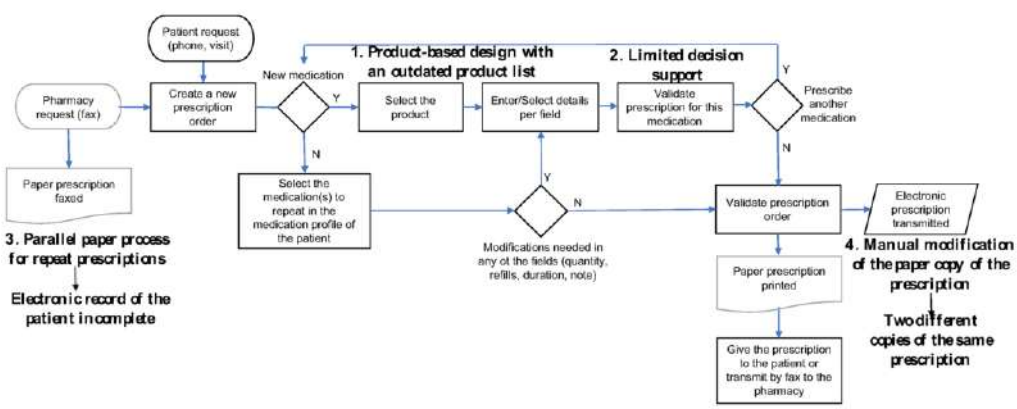
E-prescribing consists of different features that all needs to be coherently implemented for benefits to be actualized, from the request, to the creation & validation of the order, and finally its transmission. While the adoption of EHR with an e-prescribing feature for creation of orders has increased drastically in the past decade in Quebec, our results suggest that the implementation is still incomplete. First, only 2% of prescriptions were electronically transmitted and retrieved during the study period. While many prescribers, such as clinicians in acute care centers, do not have access to a certified EHR including the e-prescribing feature in Quebec, our results also suggest that many prescribers have access to an EHR to create their medication orders, but then only print it (or they may electronically fax it to the pharmacy). It is thus important that further research on e-prescribing considers this distinction between the creation of the order and its transmission, where one step of the process can be electronic, and not the other.

Moreover, even when prescribers were using the transmission feature, we have observed a systematic printing of the paper copy of the prescription, sometimes associated with manual modifications of the paper copy as a work-around for the design of the feature. This creates a major safety issue, with an increased risk of error because two different copies of the same prescriptions are created. While e-prescribing is being presented as a technology designed specifically to decrease the risk of falsification, by ensuring the integrity of prescriptions, this situation undermines the credibility of the system, and reduces its potential for benefits at this step.

On the Quality of e-Prescription

Our results suggest that the quality of e-prescription transmitted through the system could be improved. Specifically, two elements were problematic: 1) the limited decision support, with no alert including dose or patient-related characteristics; 2) the product-based design of the e-prescription, not well aligned with the cognitive process of prescribing medications, because it includes information about the packaging and the format that was not useful for clinicians. A recent study by Quist and colleagues have already described the high variability in the display of medication names in different CPOE systems in US (both inpatient and outpatient)[20]. Our study suggests that the structure of the prescription order, and specifically the logic behind the selection of the medication (product-based or dose-based) might be more important than the name of the medication itself. Precisely, caution attention needs to be dedicated to the fields, their format and content, and their reference terminology (if any). This is not yet standardized in an electronic format in the Canadian setting, as observed in this study. Consequently, on the pharmacy side, the auto-generation of the various fields was associated with problems, where manual manipulations were required, decreasing the potential for benefits realization here again. While this lack of standardization was already described during the pilot phase of the technology, no changes to the system were made in the past 5 years[14]. This first study since the full implementation of the system highlights the need for further research on the usability of this e-prescribing system, including a more diverse sample of commercial systems and users.

A



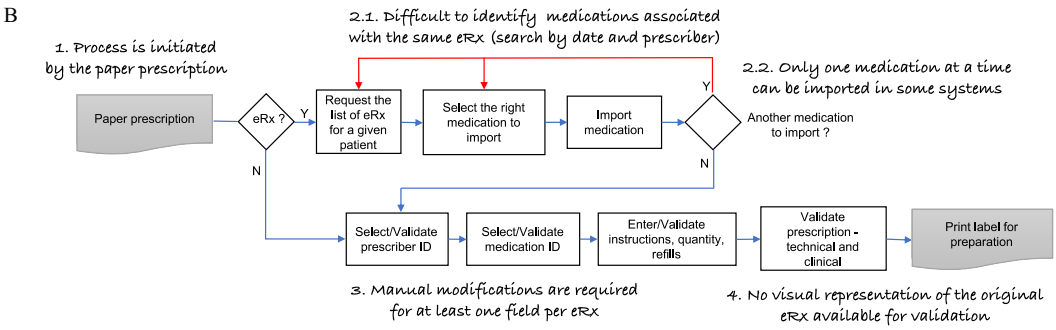


Figure 3 – Problems Identified on the Prescriber's Side (A) and Pharmacy's Side (B)

Conclusions

The adoption of a nationwide e-prescribing system was impeded by the low quality of the system, and its incomplete implementation, where the dispensing processes were based on the paper copy of the electronic prescription. Overall, this study highlights the need for improved certification mechanisms of EMR and PMS related to e-prescribing feature at the level of the province, as well as a proactive implementation strategy addressing the identified issues. Further research should also analyze the design of the prescription order, and adopt a standardized way to describe different types of design for medication prescription to improve our ability to compare systems and their effectiveness to improve the medication management processes.

Citizen Perspectives on Cross-Border eHealth Data Exchange: A European Survey

Pantelis Natsiavas[a], Christine Kakalou[a], Kostas Votis[b], Dimitrios Tzovaras[b], Vassilis Koutkias[a]

Abstract

Efficient and secure cross-border eHealth data exchange has been recently identified by the European Commission as one of the top-three priorities for the digital transformation of health and care in the European Union. To this end, various organizational, legal, ethical, and technical challenges, related to citizens' privacy and health data security arise. This paper discusses an online survey that was conducted with the participation of European citizens, aiming to identify how they feel about exchanging their health data with healthcare professionals or eHealth service providers and to what extent they are aware of the privacy, legal, security, and technology acceptance issues (e.g. use of biometrics, mobile apps, etc.). The survey rationale, structure, and results are presented, while potential barriers and facilitators regarding cross-border health data exchange and the adoption of eHealth solutions at large are discussed.

Health Information Exchange, Privacy, Computer Security, Surveys and Questionnaires

Introduction

Recent advances in digital health technologies outline a paradigm shift for healthcare delivery [1, 2]. While technologies such as the Internet of Things (IoT), big data analytics, Artificial Intelligence (AI), robotics, the Future Internet offer new opportunities for more effective and personalised healthcare delivery, they also introduce significant challenges that have to be addressed [3]. In particular, due to the increased connectivity and the underlying technical complexity of these novel technological artifacts, complex cybersecurity risks have to be tackled. To this end, cybersecurity threats could prove a significant barrier for their adoption in the healthcare sector. These concerns are further reinforced by various alarming reports purporting approximately 90% of healthcare institutions as victims of security breaches and cyberattacks [4]. Since 2010, cyberattacks have increased up to 125% and have been the main culprit of health data security breaches. As a result, patients/citizens, healthcare providers (HCPs) as well as policy makers tend to be reluctant about digital health services [5]. Investors also express scepticism to fund such activities, thus significantly affecting the acceptance of these new technologies as a part of the provided healthcare services.

As the number of travellers for work, education, and tourism constantly increases in the European Union (EU), cross-border health data exchange becomes a natural need to support proper healthcare services and continuity of care. However, people, especially those suffering from chronic diseases, are facing obstacles in travelling outside their country of residence, due to the lack of an established framework for health data exchange among healthcare organizations across the EU. To this end, one of the top three priorities of the European Commission regarding the digital transformation of health and care in the Digital Single Market constitutes citizens' secure access to their health data, including across borders of the EU [6].

To-date, the core effort in the EU for enabling cross-border health data exchange has been focusing on interoperability aspects, with projects such as epSOS (European Partners – Smart Open Services) [7], OpenNCP (Open-source and reference version of the NCP software [8] - the software implementation of epSOS), and lately the Trillium project, which focuses on EU-US cooperation and particularly on exchanging patient summary data. However, limited focus has been given to the cybersecurity aspects that are entailed in cross-border health data exchange.

Aiming to address this challenge, the EU-funded H2020 KONFIDO (Secure and Trusted Paradigm for Interoperable eHealth Services) project [9] that develops a toolset to facilitate secure cross-border exchange, storage, and overall handling of health data [10]. The toolset leverages various novel technologies, such as homomorphic encryption [11], photonic Physical Unclonable Functions (p-PUF) [12], a Security Information and Event Management (SIEM) system, [13] and blockchain-based auditing [14]. In addition, it builds upon existing frameworks, mainly OpenNCP and eIDAS (electronic IDentification, Authentication, and trust Services) [15]. OpenNCP offers a set of interoperability services to enable national and regional eHealth platforms to conduct cross-border health data exchange, while eIDAS implements the EU regulation regarding electronic identification and trust services for electronic transactions in the internal market, which includes eHealth applications among others.

As part of the KONFIDO user requirements engineering phase [16], we conducted an online survey to gain useful insights for the technical development of the envisaged toolset. The main goal of the survey was to identify how patients/citizens feel about exchanging their health data with healthcare professionals or eHealth service providers, as well as to what extent patients/citizens are aware of the entailed privacy and security issues. The survey also aimed to investigate technology acceptance issues, like the use of mobile health apps and the potential use of biometrics based on input collected from citizens across Europe.

In this paper, we present the overall survey methodology and the results, and conclude by consolidating these outcomes in terms of key barriers and facilitators regarding the acceptance and ultimately the adoption of digital health technologies focusing on cybersecurity and interoperability issues.

Methods

The survey was designed and implemented upon key principles of human psychology [17]. The main steps involved in this methodology are:

1. Deciding what information should be collected
2. Deciding how to conduct the survey
3. Constructing a draft of the respective questionnaire
4. Revising the draft questionnaire
5. Pre-testing the questionnaire
6. Revising the questionnaire and its use procedures

Several online sources were investigated prior to the questionnaire design. These included relevant surveys conducted by other organizations, reports, and scientific papers. In addition, the survey was designed and deployed, incorporating sophisticated features, such as:

- conditional workflow of questions based on the answers submitted on earlier questions, so that only questions relevant to the responder appear;
- input validation to avoid erroneous data entries;
- use of control questions (or "trap questions") to verify response quality; and
- export of the collected responses in a format that facilitates further data analysis

The respective questionnaire was built in an iterative fashion to validate its alignment with the survey scope and comprehension. The final version of the questionnaire was published in seven European languages, namely, Danish, Dutch, English, French, Greek, Italian, and Spanish.

The questions (35 in total) were organized in six sections:

7. *Awareness regarding Information Technology (IT) risks*: Focused on identifying the responder's awareness level regarding the risks entailed (both explicitly and implicitly) in using digital health tools
8. *Legislation*: Aimed at identifying the responder's familiarity with relevant legislation artifacts
9. *Cross-border medical treatment*: Aimed to provide insights on whether the responder was medically treated or hospitalized abroad, detailing the circumstances under this event
10. *Cross-border health data exchange*: Concerned with the responder's opinion regarding the need of cross-border health data exchange
11. *Barriers and facilitators*: Aimed at identifying key issues that facilitate or discourage cross-border health data exchange from a patient's/citizen's viewpoint
12. *Demographics*: Aimed to identify some key information about the responder, in order to facilitate the statistical analysis of the obtained data

The online survey was disseminated publicly via relevant forums,, mailing lists, and social media (i.e. KONFIDO project Twitter and Facebook accounts), targeting citizen groups that could be related with the subject of cross-border health data exchange (for example, chronic patient associations, immigrant groups, medical tourism groups) and also the general public. No exclusion criteria were applied aiming to increase participation of people who were not necessarily aware of the recent advances in the eHealth domain and its security aspects..

Before conducting the survey, it was approved by the Bioethics Committee of the Centre of Research and Technology Hellas (CERTH), as CERTH was responsible for the data collection and control of the study. The survey did not require the disclosure of the responder's identity.

Results

The survey was available online for three weeks and collected a total of 437 responses, out of which about 30% of responders contributed to the online questionnaire but did not complete it (124 incomplete responses out of 437 in total). This is a typical behavior in online surveys, as the responder might quit the process for any reason, therefore, the incompletely taken surveys were still taken into account. More specifically, regarding the demographics of the responders, their average age was 43.96 years, their gender distribution was 38.54% females and 57.96% males, and they were distributed in 14 European countries (most of the responders declared that they were from Greece, Germany, or Denmark). Since the survey distribution was conducted via public Internet communication channels, we cannot confirm the number of people reached through the online invitation campaign and, therefore, the response ratio cannot be calculated. We summarize the main findings in the following section.

Awareness regarding IT risks

The key results from this questionnaire section can be summarized as follows:

a) 11.96% did not thought about possible health data risks.

b) Only 36.41% felt informed about these risks.

c) 66.21% of the responders did not read the respective applications' "Terms and Conditions", with more than 30% declaring that they did not feel it is worthy, given the time required to read them and 19.79% declaring indifference towards them (Figure 1).

Figure 1 - Answers to Question "Why haven't you read the terms and conditions?" (Only Responders Who Answered the Previous Question that They Did Not Read the "Terms and Conditions" Were Asked)

Furthermore, the responders expressed confusion and lack of confidence on the subject. Only 26.09% of the responders felt confident regarding their electronic health data privacy, 38.04% felt concerned but helpless about, and 16.3% stated that they avoid using eHealth services due to the lack of confidence regarding their data handling.

An interesting remark is that the responders clearly preferred to entrust their health data to national and state organizations than to private ones, despite the rather high-rate (35.33%) declared in using applications exploiting personal health data.

These applications are typically provided and operated by private companies, mostly belonging to the category of lifestyle/wellbeing monitoring.

It should also be noted that only 20% of the responders felt that their privacy was fully covered in the "Term and Conditions" of the applications. The findings regarding the reasons that led responders to not read the "Terms and Conditions" were directly linked to legislation complexity, legislation misalignment between countries and the need for usability – most of the responders felt that too much time is required to read them, and 12.50% declared that they do not understand them.

Legislation

The need for raising awareness was also evident from the findings of this section (Figure 2 and Figure 3). While almost 80% of the responders declared being familiar with the EU General Data Protection Regulation (GDPR) [18], more than 50% declared that they were familiar with legislation items that do not really exist (as captured by a control question). In particular, about 27.37% declared being aware of data concepts/initiatives that do not really exist. The need for raising awareness was also supported by the fact that 24.93% of the responders expressed no opinion on whether the current legislation effectively protects them.

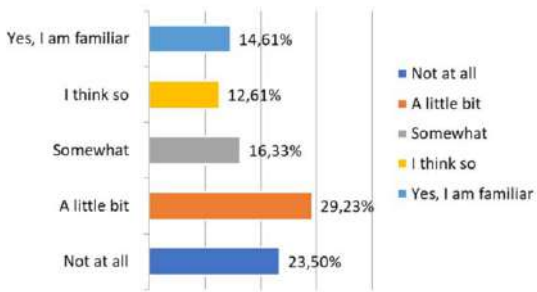

Figure 2 – Answers to the Question "Are you familiar with legislation that concerns the use of health data?"

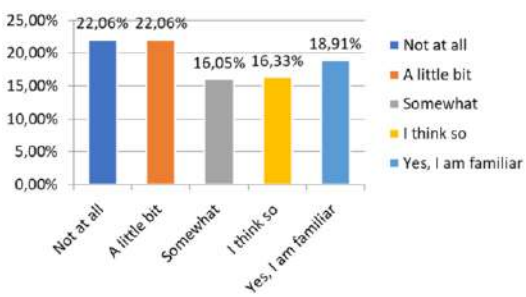

Figure 3 – Answers to the Question "Are you familiar with the data ownership concept?"

Regarding the effectiveness of the current legislation, only 27.79% of the responders felt protected, while 37.54% felt either defenceless, or insufficiently protected (Figure 4). As shown in Figure 5, citizens argued that legislation alignment among EU countries is a necessity. Furthermore, dissemination regarding legal issues and the level of legal protection provided were also identified as important items.

Cross-border Medical Treatment

28.16% of the responders were medically treated abroad. The reasons for their hospitalization or medical treatment abroad

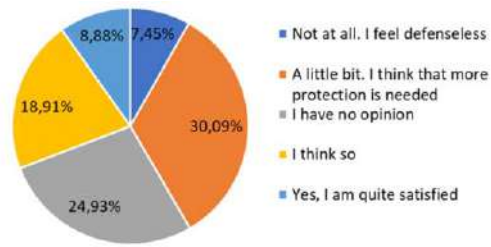

Figure 4 – Answers to question "Are you satisfied with the level of protection provided by current legislation?".

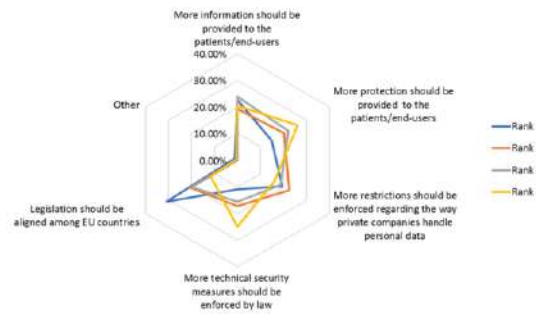

Figure 5 – Ranking of reasons for question "Regarding legislation, please rank the most important things to be improved regarding cross-border health data exchange".

were clearly depicted: 44.90% of the responders reported a sudden incident while travelling (e.g. a car accident), 37.76% were immigrants, and 16.33% referred to other reasons (e.g. studying abroad).

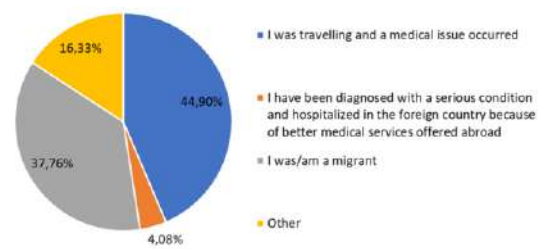

Figure 6 – Answers to the Question "In what circumstances have you used medical services abroad?"

These findings clearly highlighted that unscheduled access to healthcare services abroad, such as accidents/incidents while travelling, were critical for European citizens.

Cross-border Medical Data Exchange

The responders were highly in favor of cross-border data exchange, since only 9.28% expressed a negative opinion (Figure 7). Among the responders who viewed this issue as a critical one, the main concern involved technical issues and, particularly, information security aspects. Furthermore, a high percentage of responders (71.56%), would consent in sharing medical data with foreign medical personnel in case of an emergency, with the rest of them mostly worrying about the technical issues.

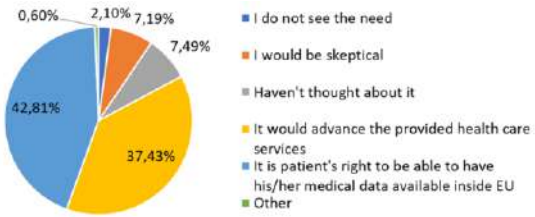

Figure 7 – Answers to the Question "How do you feel about medical data shared with foreign healthcare professionals /institutions to facilitate treatment while being abroad?"

It is also clear that the responders would prefer to use a European authentication card, rather than using biometric characteristics to authenticate themselves for cross-border eHealth data exchange. In addition, the need for a detailed description of the underlying context for using health data was evident, given that 53.29% of the responders wanted to be thoroughly informed before consenting to their health data usage.

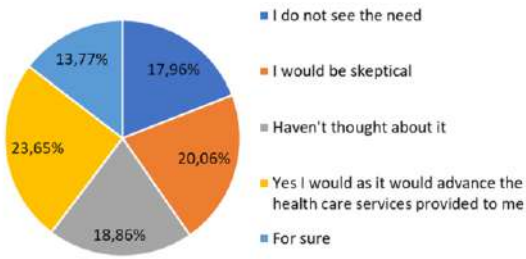

Figure 8 – Answers to the Question "Would you prefer using a biometric characteristic (e.g. fingerprints) instead of an ID card to facilitate cross-border medical data exchange?"

An interesting remark is that the vast majority of the responders (72.46%) declared that they were in favor of sharing personal data for research purposes, at least under the terms of anonymization. Finally, it should be noted that the responders who were sceptical towards cross-border health data exchange did not focus on the cross-border data exchange, but rather on the security challenges that have to do with data sharing, regardless of whether this sharing had to do with foreigners or not.

Barriers and Facilitators

The responders identified the following key factors for the acceptance of cross-border health data exchange:

1. A common legislation among EU Member States
2. Better control of data management practices applied by companies
3. More information on the processing of citizen health data

These key points clearly support the application of new European regulation, GDPR. Providing consent is one key aspect of the overall data sharing process: it could, on one hand, facilitate the process and, on the other hand, act as a barrier. The results clearly indicate the need for a flexible consent process, as 73.44% of the responders supported that "*Patient consent should be actively enforced. However, in some special cases (e.g. when the patient is unconscious), it could be skipped in favour of the provided medical services*" (Figure 9).

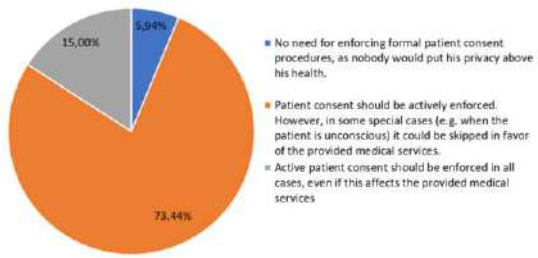

Figure 9 – Answers to the question "Please select in your opinion the level of required patient consent, in cases of cross-border data exchange"

Finally, the most important barriers regarding the acceptance of cross-border health data exchange are:

1 Lack of trust regarding the intentions of data collection

2. Lack of suitable legislation

3. The risks of interlinking these data with other personal information already available and traceable in the Internet (e.g. posts in social media platforms)

Consolidated Outcomes

The main outcomes of the survey focusing on how these could contribute to the development of cybersecurity solutions for health data exchange at large, and in cross-border scenarios in particular, are as follows:

- Raise awareness among patients/citizens and other stakeholders. More specifically, awareness should be raised regarding: (a) the risks of using IT for health data management (b) citizens' confidence with respect to their personal data handling (c) the need to simplify the "Terms and Conditions" for using eHealth services/applications (d) the need for a flexible and comprehensive consent process, and (e) the need for a clear and aligned legislation across EU Member States.
- Incidents during travel seem to be of high value. However, other use cases (such as immigrants living temporarily abroad) should be considered.
- The main control of cross-border health data exchange should be built upon national infrastructures (such as the national Electronic Health Record), as the patients/citizens tend to trust them more.
- Technical solutions should focus on using a Europe-wide authentication method such as one based on eIDAS and avoid the use of biometric characteristics.
- Provide a simple and comprehensible consent process, while being flexible in cases where the patient is unconscious (emergency scenarios).

Discussion and Conclusion

Citizens are a key stakeholder in eHealth data management, as cross-border health data exchange becomes a necessity across the EU. Recent regulation and legislation activities such as the GDPR set a framework for legal, ethical, and practical issues related to health data management and personal data protection. The KONFIDO project develops a technology toolset,

aiming to enhance information security for cross-border health data exchange, building upon emerging European frameworks such as OpenNCP and eIDAS.

To this end, the project relied on an intensive end-user engagement strategy [16], aiming to obtain feedback related to the current landscape and the practical issues that health data exchange entails through digital health solutions. Various activities were conducted, including a survey with health IT professionals, eHealth companies, and health policy makers [19], to identify digital health acceptance barriers and facilitators, using the survey presented in the current paper.

We presented the main results of the survey focusing on European citizens. A list of key issues was identified and a number of challenges were consolidated. These results could be used as a beacon for the development of new technical solutions in the context of health data exchange and health data management at large, including cross-border health data exchange. We thus argue that our findings provide useful insights for stakeholders of the European eHealth ecosystem, encouraging them to adapt their services and reinforce the acceptance and consequently the adoption of their solutions by the targeted end-users.

The main limitations of the current study relate to the risk of bias due to the following reasons: (a) the specific questions could be considered as "leading" responders to specific answers based on the reader's subjective judgement, and (b) the non-uniform distribution of the responders across European countries. The lack of detailed responders' demographic information is because of the fact that all the questions were optional and as the demographics section was put last, only a small portion of the responders answered them. As part of the presented methodological approach, all project partners revised the questionnaire to avoid responder "guidance" and also tried to disseminate the survey as widely as possible. Despite these limitations, we consider the results valuable and be able to provide useful insights. In order to reduce the effect of bias and further explore the collected data, the collected responses will be analyzed in combination and in comparison with the relevant studies and surveys conducted by other organizations such as the Healthcare Information and Management Systems Society (HIMMS).

Acknowledgements

The research leading to these results has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 727528 (KONFIDO - Secure and Trusted Paradigm for Interoperable eHealth Services). This paper reflects only the authors' views and the Commission is not liable for any use that may be made of the information contained therein.

The authors would like to thank the KONFIDO partners for their help on the survey dissemination and the questionnaire translation to the supported European languages.

Abstract

Potential drug-drug interactions (PDDI) rules are currently represented without any common standard making them difficult to update, maintain, and exchange. The PDDI minimum information model developed by the Semantic Web in the Healthcare and Life Sciences Community Group describes PDDI knowledge in an actionable format. In this paper, we report implementation and evaluation of CDS Services which represent PDDI knowledge with Clinical Quality Language (CQL). The suggested solution is based on emerging standards including CDS Hooks, FHIR, and CQL. Two use cases are selected, implemented with CQL rules and tested at the Connectathon held at the 32nd Annual Plenary & Working Group Meeting of HL7.

Keywords:

Potential Drug-Drug Interaction, Clinical decision support systems, Electronic health records.

Introduction

Drug-drug interactions (DDI) are biological processes that result in a clinically meaningful change to the response of at least one co-administrated drug [1]. Identifying potential DDIs during the care process is important to ensure patient safety and health care quality. DDIs can often be predicted and mitigated at the point of care. However, a large number of drugs, lack of knowledge of DDIs [2] hinders the ability of physicians to preemptively identify all potential DDIs [3]. Therefore it is important to guide care providers with well design computerized alerting systems during the medication prescribe process [4].

In the last two decades, numerous clinical decision support (CDS) systems have been developed to support physician by presenting alerts in real time to the clinician about the current medication's potential impact to patients [5]. Ideally, CDS should provide clinicians with the relevant reference information such as knowledge or suggestions, intelligently filtered and presented at appropriate times [6]. Currently, there are many CDS systems that provide drug interaction alerts [4]. Most of the systems curate their own knowledge base since there is no complete source of potential DDI (PDDI) knowledge [7]. Also, there are currently no broadly accepted standards to guide implementers in the organization and presentation of PDDI information [8]. Most EHR vendors either develop their own internal rule engines based on their custom standards, or contract with a third party. Since these rules are written in a way just for those systems, it is difficult to exchange, review and rewrite the rules. Lack of agreement on standards hinders the reuse of the rules by third parties, creating additional burden to rewrite rules at each side.

The minimum information models help to describe the PDDI information in a detailed, actionable and contextualizable format. Standardized PDDI information can be exchanged via broadly applicable formats. In this research, we will demonstrate the use of the PDDI minimum information model developed by Semantic Web in Healthcare and Life Sciences Community Group [9], by implementing them with CQL language and extend CQF Ruler[1] to provide decision support.

The aim of this work is to present an example implementation of representing PDDI logic in CQL and execution of them by using the FHIR Clinical Reasoning module. We selected Digoxin-Cyclosporine and Warfarin-NSAIDs as use cases because they are non-trivial PDDIs for which alerts can be contextualized to specific patient cases. The developed prototype detects a PDDI and provides alerts using Clinical Decision Support Hooks to Electronic Health Record systems that subscribe to the CDS services.

The following sections provide an overview of our methods, prototype architecture, implementation of PDDI with CQL, and evaluation.

Methods

PDDI: The PDDI Minimum Information Model [9] [10] is a standard proposed by the W3C Semantic Web in Healthcare and Life Sciences Community Group. It is aimed to help the clinicians to keep up with the PDDI evidence base, document and share PDDI information by summarizing PDDI evidence from primary sources using the information elements from the PDDI minimal information model.

The information model contains 10 core information items that should be used to describe every PDDI CDS knowledge artifact as follows: (i) Clinical consequences; (ii) Contextual information/modifying factors; (iii) Drugs involved, (iv) Evidence; (v) Frequency of exposure to the interacting drug pair; (vi) Frequency of harm for persons who have been exposed to the interacting drug pair; (vii) Mechanism of the interaction, (viii) Recommended actions; (ix) Seriousness rating; and (x) Operational classification of the interaction.

CQL: Clinical Quality Language (CQL)[2] is a Health Level Seven International (HL7) authoring language standard that can

[1] https://github.com/DBCG/cqf-ruler

[2] http://cql.hl7.org

be used with both CDS and electronic Clinical Quality Measures to represent the PDDI information. The CQL syntax provides a clinical focused, author-friendly and human-readable language to clinical domain experts, since it allows for rich, modular and flexible expression of the logic, and supports different data models including FHIR. CQL is a query language built up by combining rules, namely statements, to describe the available data in terms of a data model. For decision support, the rules will be evaluated in the context of a specific patient to produce a response at some specific point in a workflow.

CDS Services: CDS Service [11] is a role which provides real-time clinical decision support as a remote service. It enables a consumer to ask for clinical decision support based on his current context. The consumer gives relevant contextual information as part of the request and receives clinically relevant suggestion describing potential actions to be taken. The service implementation must comply with CDS Hooks specification.

CDS-Hooks[3] is an emerging standard gained considerable interest from EHR vendors. It is a "hook" based pattern designed to provide a simple way to initiate requests for CDS, from any point in a clinical workflow. It specified the basic actions of registering for CDS services, calling those services, and then receiving the CDS service response in form of simple cards providing appropriate information within the context of the EHR.

Concept

Architecture: As shown in the Figure 1, the PDDI CDS Implementation was designed as a self-contained service, with three main components including HAPI FHIR server[4], CDS Services, and CQL engine[5]. The first component is the HAPI FHIR server which is an option to store the definition of services, called PlanDefinition, supported by the system and knowledge base of CQL rules, called Library. The second component is the CDS services, which serve as a core logic to map the incoming request to the corresponding service defined by PlanDefinition, execute the CQL logic of the service defined in Library following the instruction from the PlanDefinition, and generate response cards. By this way, the new service can be introduced into the system without changing the core CDS services and the configuration. The third component is the CQL engine which provides CQL rule execution for the core CDS services.

As described in detail in the current draft of the PDDI Implementation Guideline (IG) [12], the CDS Discovery service is hosted at a stable endpoint, i.e. {baseUrl}/cds-services, and allows EHRs to discover the list of available supported CDS Service, e.g. {baseUrl}/cds-services/warfarin-nsaids-cds. The list of CDS Services contains information such as a description of the CDS Service, when it should be invoked, and any data that is requested to be prefetched.

PDDI CDS Implementation Workflow: The PDDI IG envisions two hooks which are medication-prescribe at order authorization, and medication-select at the time of selecting a medication and prior to the order authorization. For this paper, we focus only on medication-prescribe in the Level 1 Implementation.

Firstly, the EHR invokes the "medication-prescribe" hook and PDDI CDS service is called by sending an HTTP POST request, namely CDS Hooks Request, containing JSON to the service endpoint (e.g. {baseUrl}/cds-services/warfarin-nsaids-cds).

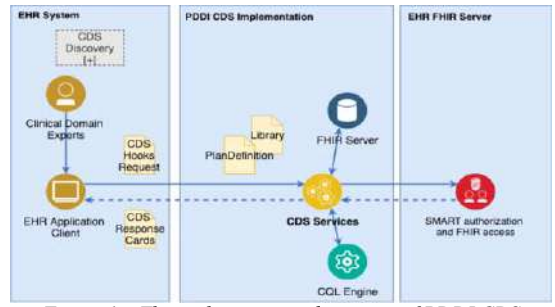

Figure 1 – The architecture and process of PDDI CDS Implementation

The CDS Hooks request contains specific information for the hook that was triggered including hook name FHIR server url, context data that the service will need, and prefetch data that is pre-queried data based on the CDS discovery. If the PDDI CDS service does not receive prefetch data in the request, it will query the EHR FHIR Server via network call with the authentication given by the EHR Application Client.

When CDS Service processes the request, the corresponding PlanDefinition and Library resources are loaded from FHIR server. Once the resources are loaded, the CQL logic in Library resource is decoded and evaluated by CQL engine with the data received either in the prefetch or from EHR FHIR server. The CQL engine evaluates the CQL logic following the guidance specified in the PlanDefinition resource.

After the evaluation is done, CDS Response cards are generated and returned to the client. Each Card has specified attributes including summary, detail, indicator, and list of suggestions providing actionable information. The specified attributes map to the core elements of the minimum information model (e.g. summary = Drugs Involved, detail = Clinical consequences, Seriousness, Mechanism of Interaction, and Evidence). The Card indicator element dictates how the EHR presents the alert (e.g. indicator = "hard-stop" could be a modal alert).

CDS Services Workflow: When the PlanDefinition is loaded by PDDI CDS services for the corresponding request, the services will load the CQL library defined in the PlanDefinition and decode it based on base64format.

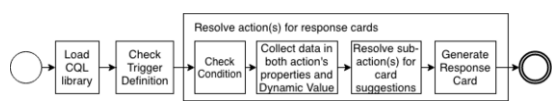

Figure 2 – The flow of processing Plan Definition

After the CQL library is loaded, the services check the hook event specified in the incoming request with the trigger definition defined in the PlanDefinition. If the hook event meets the trigger definition, the services begin to resolve the actions by evaluating the condition defined in CQL library to see whether or not the definition specified in the Action is to be applied. Then, the services collect the data in the action's properties and evaluate the dynamic value specified in the CQL library for the customizable properties. For the suggestions, the services resolve the sub-actions as the same approach as resolving actions.

[3] https://cds-hooks.org
[4] http://hapifhir.io
[5] https://github.com/DBCG/cql_engine

When the data is ready, the corresponding response card is generated and the services continue to resolve the next action until no actions left. Once finished, the services return the response cards as a result to the client.

Results

The implementation focuses on two PDDI CDS use cases which are Digoxin + Cyclosporine and Warfarin + NSAIDs. This section only discusses the Digoxin + Cyclosporine use case. Please refer to our repository (http://doi.org/10.5281/zenodo.1481220) for the full implementation and the PDDI IG [12] for the detail including PDDI model of the two use cases.

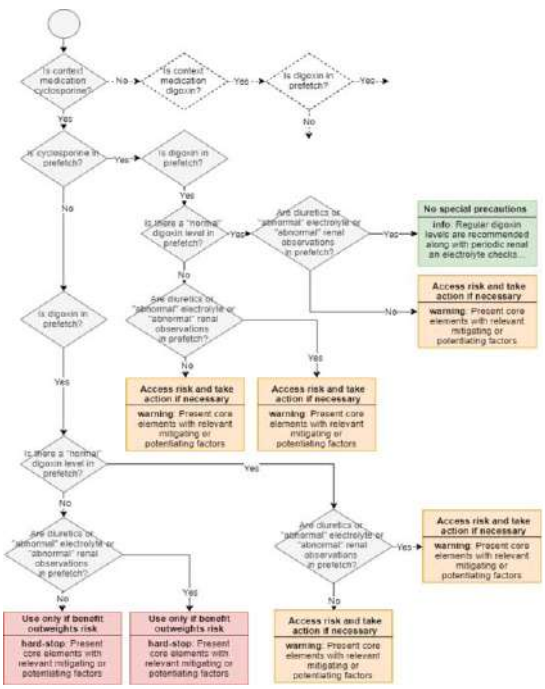

Figure 3 – The partial of decision tree for Digoxin Cyclosporine use case [12]

Use Case

The Digoxin + Cyclosporine exemplar artifact has two main decision blocks. Whether the patient is taking digoxin and/or cyclosporine at the time of the current order for digoxin or cyclosporine, and whether the patient has risk factors that may potentiate the risk of digitalis toxicity.

As shown in the Figure 2, each decision block has a certain suggestion in rectangle shape which presents core elements of PDDI model, necessary actions and level of indicator (i.e. "info" – green, "hard-stop" – red, and "warning" – orange).

Implementation of Plan Definition: PlanDefinition is a definition of the service served as a guide for the incoming request. PlanDefinition contains a set of definition including Library, Trigger Definition, Condition, Action, and Dynamic Value (Figure 3).

The Library element defines the reference to the logic used by the PlanDefinition. An example of digoxin-cyclosporine-cds PlanDefinition is the reference to Library/digoxin-cyclosporine-cds Library. This Library contains the CQL logic library encoded in base64 format as a string used by the PlanDefinition.

The Trigger Definition uses the Name Event, which allows triggering of an event opposed to a scheduled or fixed event. As an example, by specifying medication-prescribe as an event, the service only serves for the incoming request sent from medication-prescribe hook.

The condition element is used to determine whether or not the CDS logic specified in the Library is to be applied. By specifying "Inclusion Criteria" as a CQL statement for the condition, an action(s) is initiated once the condition is satisfied (i.e., true or false).

The Action element defines a list of response card needed to be generated. The subaction element indicates a list of suggestion which recommends a set of changes in the context of the current activity.

The Dynamic Value enables customization of the response card's properties by collecting the dynamic data defined in CQL statements. For the action, we define three dynamic values, such as "Get Summary" statement for the card title, "Get Detail" for the card description and "Get Indicators" for the card level. Since each decision block for PDDIs has one or more individualized information components, integrating patient-specific and product-specific data into Card elements is facilitated by the Dynamic Value element.

Implementation of CQL: All artifact logics of CQL for the Digoxin Cyclosporine use case are wrapped in the Digoxin_Cyclosporine_CDS library. A set of declarations, including data model, included libraries, valuesets, parameters, and context, provide information about the library.

The PDDI CDS uses FHIR model, version 3.0.0 as the primary data model to support for the FHIR resources.

A common library, namely PDDICDSCommon, contains all supported statements. The PDDI IG provides a number of valueset used in this library. Each valueset describes RxNorm codes drawn from one or more code systems for certain drugs. For example, the "Digoxin" valueset has this number of codes which is 197604 for Digoxin 0.125 MG Oral Tablet, 245273 for Digoxin 0.0625 MG Oral Tablet and other RxNorm codes. CQL evaluate the rules using all these RxNorm codes.

A ContextPrescription parameter refers to the list of Medication Request prescribed by the clinician specified in the incoming request. The Patient context restricts the information within a scope of single patient.

As specified in the condition element of the PlanDefinition, the "Inclusion Criteria" statement is used to check whether the patient of the incoming request is taking digoxin and/or cyclosporine at the time of the current order for digoxin or cyclosporine.

```
define "Inclusion Criteria":
  ( "Is Context medication cyclosporine"
      and "Is digoxin in prefetch"
  ) or (
    "Is Context medication digoxin"
      and "Is cyclosporine in prefetch"
  )
```

To express "Is Context medication cyclosporine" criterion, we need to check the existence of the list of Medication Request containing Cyclosporine specified in the ContextPrescription. The "Cyclosporine Prescription" statement requires that all codes from medication of the ContextPrescription parameter belong to the valueset identified by "Cyclosporine".

```
define "Is Context medication cyclosporine":
  exists ("Cyclosporine Prescription")
```

```
define "Cyclosporine Prescription":
  ContextPrescriptions P
    where Common.ToCode(P.medication.coding[0]) in
"Cyclosporine"
```

Next, the second criterion is "Is digoxin in prefetch". This criteria requires that the code of MedicationRequest is the code in the valueset identified by "Digoxin". Since we are in the Patient context, this query retrieves all Medication Request for only current Patient in the context. To filter the results which authored within the 100-day look-back period, we had to construct an interval from the 100-day look-back to infinitive.

```
define "Is digoxin in prefetch":
  exists ("Digoxin Rx")

define "Digoxin Rx":
  [MedicationRequest: "Digoxin"] MR
    where MR.authoredOn.value in Interval[Today()-100 days,null]
```

We use the same approach for the remaining criteria.

As defined in the dynamicValue element of the PlanDefinition for the "summary" property of the response card, the "Get Base Summary" statement provides the short description of the drugs involved in this interaction.

```
define "Get Base Summary":
  'Potential Drug-Drug Interaction between digoxin ('
    + (if "Is Context medication digoxin"
        then Common.GetDrugNames("Digoxin Prescription")
      else Common.GetDrugNames("Digoxin Rx")
    )
    + ') and cyclosporine ('
    + (if "Is Context medication cyclosporine"
        then Common.GetDrugNames("Cyclosporine Prescription")
      else Common.GetDrugNames("Cyclosporine Rx")
    )
    + ')'
```

For the "detail" property of the response card, the "Get Base Detail" statement provides detail of PDDI minimum information.

```
define "Get Base Detail":
  'Increased risk of digoxin toxicity...'
```

For the "indicator" property of the response card, the "Get Base Indicator" statement specifies the importance of what this card conveys.

```
define "Get Base Indicator":
  if "Is Context medication cyclosporine" then
    if "Is cyclosporine in prefetch" then
      if "Is there a normal digoxin level in prefetch" then
        if "Are diuretics or abnormal electrolyte or abnormal
renal observations in prefetch"
          then 'info'
        else 'warning'
      else 'warning'
    else
      if "Is there a normal digoxin level in prefetch" then
        then 'warning'
      else 'hard-stop'
  else
    if "Is digoxin in prefetch" then
      if "Is there a normal digoxin level in prefetch" then
        if "Are diuretics or abnormal electrolyte or abnormal
renal observations in prefetch"
          then 'info'
        else 'warning'
      else 'warning'
    else 'warning'
```

The first criterion of the "Get Base Indicator" statement is "Is there a normal digoxin level in prefetch". This criterion requires that all codes of Observation are in the valueset identified by "Digoxin LOINC". The normal digoxin observation is identified by measure the number of quantity less than 0.9ng/mL. To filter the results which take effects within the 30-day look-back period, we had to construct an interval from the 30-day look-back and infinitive. Because the most recent of Observation is important for the check, we select the latest result after ordered by the effective date.

```
define "Is there a normal digoxin level in prefetch":
  exists ("Normal Digoxin Observation")

define "Normal Digoxin Observation":
  Last (
    [Observation: "Digoxin LOINC"] O
      where O.effective.value in Interval[Today()-30 days, null]
        and Common.ToQuantity(O.value) < 0.9 'ng/mL'
      sort by effective.value
  )
```
